Study on Spark Counters of the Rosenblum Type for Counting α Particles and Neutrons

By Suekichi KAWATA

Department of Physics, Kōnan University, Kōbe

(Received March 23, 1960)

Characteristics of the Rosenblum type spark counters were studied experimentally. In the case of a single-wire counter, number of count was investigated when the α-particle source was moved parallel to the cathode plate, and in relation to voltage applied to the anode wire and also when the source was moved perpendicularly to the cathode plate. Especially effects of temperature, pressure and humidity of the surrounding air on counts were investigated, and the efficiency of counting of α particles was estimated. Experiments were also carried out for a multiple-wire counter. A counter with 14 anode wires was constructed, and it was found that uniformity of counting through the whole acting region might be greatly improved by inserting a high resistance in series with each wire. A neutron detector was constructed by putting a boron-coated glass plate above the multiple wires and surrounding the counter with paraffin.

§ 1. Introduction

The Chang-Rosenblum type spark counter[1] for α-particle detection has several attracting features: (1) it is insensitive to low specific ionization radiation; (2) it has a rapid rise-time of pulse; (3) it operates in the open air; (4) it is of very simple construction; (5) it does not need special amplifiers; and (6) it can get easily a wide plateau for applied voltage. Many workers have offered various reports[1)–16)] about its characteristics and applications, but their experimental results are not always consistent among themselves. Sometimes the experimental conditions are not made clear. The present writer has investigated the counter to make its characteristics clearer and also to make contributions from the point of practical uses.

§ 2. Single-wire Counter

A counter was constructed with a tungsten wire 0.1 mm thick and 40 mm long (anode) and a flat plate of stainless steel of 60×60 mm (cathode), the wire having been stretched on a frame made of acryl-resin and placed at a distance of about 1.2 mm above the plate separated by two narrow spacers of glass. The cathode plate was put on an ebonite plate placed on a horizontal stage of a travelling-microscope. Two modes of irradiation by α particles from Po^{210} were used. Firstly, an old deposit of Po on a silver foil prepared 2–3 years ago was used, and secondly a newly prepared deposit was used after the most part of the experiment had been performed with the first source. The α particles were passed through a circular hole of 2 mm in diameter and 5.5 mm in length in the first case, and through a hole of 0.8 mm in diameter and 11 mm in length in the second case. The second source was found to be much more homogeneous with respect to the energy when it was examined by a scintillation spectrometer with a CsI(Tl) crystal of 1/16″ thick, and was far stronger than the first source. The sources with the slits were attached to the microscope holder projected horizontally from the vertical support. Generally the whole apparatus was placed in a thermostat of 40×40 ×60 cm which communicated slightly with outer air. The counter was operated by a circuit as shown in Fig. 1.

The voltage pulses of sparks caused by the passage of α particles are of nearly uniform shape and magnitude, when examined with an oscilloscope and a synchroscope. The rise time and the recovery time were estimated to be of the order of 10^{-7} sec and a few hundred μsec respectively.

(1) After preliminary experiments the old Po source was placed at about 28.0 mm above the cathode plate, and the counter was ope-

63/ 0 neu

rated by applying 3.70 kV to the anode wire. Throughout the experiment the irradiation was always end-on. Curve (A) in Fig. 2 shows variation of count of the spark when the first source was moved perpendicularly to the anode wire. The situation of the source giving the maximum count at about 28.0 mm from the plate was taken as the normal position for the measurement. Curve (B) is the corresponding one with the new Po-α source.

(2) Fig. 3 illustrates curves of count *versus* applied voltage of the anode wire, not the potential difference between the anode and the cathode, the Po source being at the normal position, under three different conditions of the air. Corona current is given in the curve II′ corresponding to the curve II. The voltage characteristics depend naturally on resistances inserted in the circuit. In the present example it has a very wide plateau.

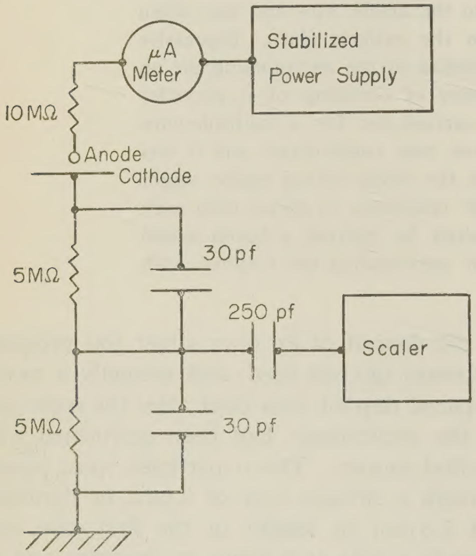

Fig. 1. Operating circuit of the spark counter.

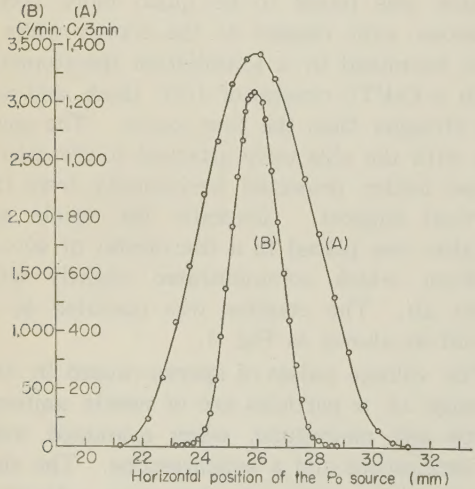

Fig. 2. Relation between count and displacement of the Po source perpendicular to the anode wire, (A) when α particles from the old source were passed through a hole of 2×5.5 mm, and (B) when α particles from the new source were passed through a hole of 0.8×11 mm.

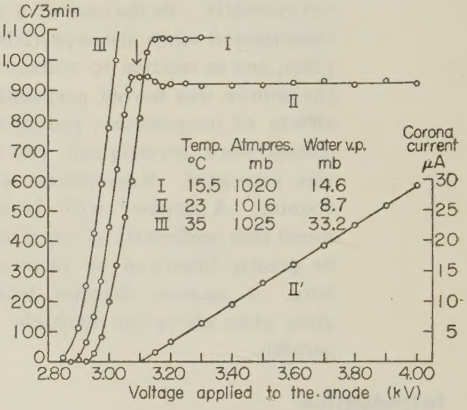

Fig. 3. Relation between count of spark and voltage applied to the anode wire, under three different conditions of air (curves I, II and III). The curve II′ showing corona current *versus* applied voltage corresponds to the curve II. (The old source was used.)

Various workers have shown that such humps as marked by a vertical arrow to the curve II were observed generally, and sometimes very markedly in such characteristic curves, but others have not observed them, and an opinion was presented by the latters to attribute their appearance to the different collimation of α particles. In the present experiment, however, such humps appeared rather markedly in some cases, but not in other cases notwithstanding that the geometry of irradiation was the same. Again, the appearance was not much more marked with the well-collimated beam of α particles from the second source. Also it is not clear that whether conditions of temperature or humidity may affect their appearance or not.

(3) Fig. 4 shows a diagram obtained when the old Po source was moved vertically, i.e. perpendicularly to the cathode plate, from the normal position indicated by a vertical arrow. Since the ordinate indicates count of spark, this diagram is different from the ordinary Bragg curve obtained for the ionization cur-

rent in a shallow chamber. In the present case it may be remarked that the count will depend upon the number of incident particles and also upon specific ionization, angular spread of particles and directional sensitivity of the counter. In this figure, (a) indicates the position of the source about 7 mm from the cathode plate. Then there is a region of rapid increase of count as indicated by (b), arriving at a maximum (c), and next there comes a somewhat gradual decrease (d) followed by a plateau (e) of about 10 mm, and lastly a steep fall (f) appears which is familiar in the Bragg curve near the end of the range.

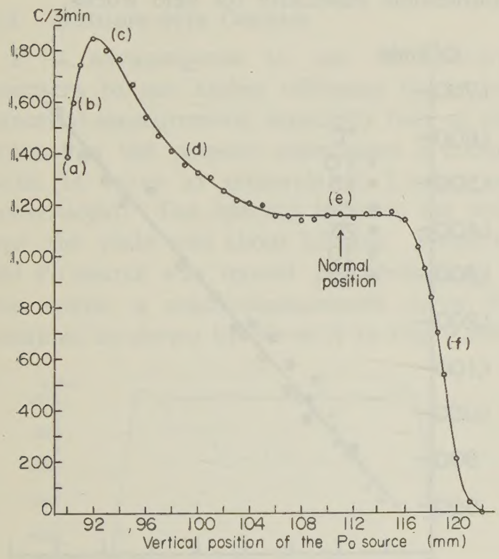

Fig. 4. Variation of count when the Po source was moved vertically to the cathode plate. (The old source was used.)

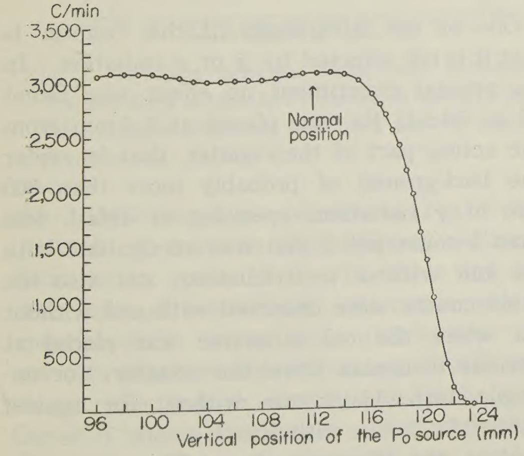

Fig. 5. Variation of count when the new Po source was moved vertically to the cathode plate.

Fig. 5 shows the similar curve obtained with the second source. In this curve the regions corresponding to (c) and (d) in Fig. 4 are not observed.

(4) Effects of temperature and humidity. As to the effect of temperature Saha and Nath[11] indicated a shift of the count *versus* source-distance curve at 20°C and 49°C (humidity having not been indicated), and as to the effect of humidity Andreschev and Isaev[9] showed a nearly linear increase of count with vapour pressure in 5–28 mb, and very recently Daddi and Franceschi[14] gave results obtained for water vapour of 27 and 112 mm Hg in broadside irradiation and remarked that the counting efficiency depended upon the air condition and particularly upon humidity, and in the case of completely dry air the efficiency was practically zero for broadside irradiation.

In order to obtain various conditions of temperature and humidity we used saturated solutions of various salts in the thermostat at different temperatures, and stirred the air violently with a fan. Both the temperature and the humidity were measured by use of a small resistance-type hygrometer devised by K. Shiba.

As illustrated in Fig. 3 the count *versus* applied voltage curve alters with different conditions of the air. Fig. 6 shows curves similar

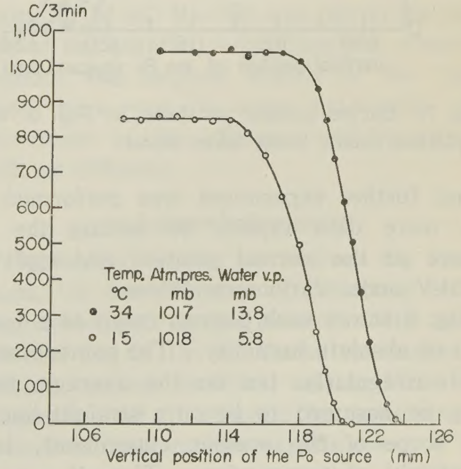

Fig. 6. Two curves similar to the curve in Fig. 4 near the end of the range of α particles under different conditions of temperature, atmospheric pressure and water vapour pressure.

to the curve in Fig. 4, which was obtained by applying 3.70 kV to the anode and moving the old Po source vertically under two different conditions of temperature and humidity. It was found that the curves move not only horizontally as shown by Saha and Nath[11)], but also vertically. In order to clarify the matter, curves were drawn again with two additional ones by taking the plateau counts to be equal. The results are shown in Fig. 7. It will be seen that the normalized curves undergo displacement approximately due to the density variation of the air in the path of α particles from the source to the counter, and that the displacement along the horizontal axis will not be intrinsic to the counter, whereas the displacement along the vertical axis seems to be due al most to humidity.

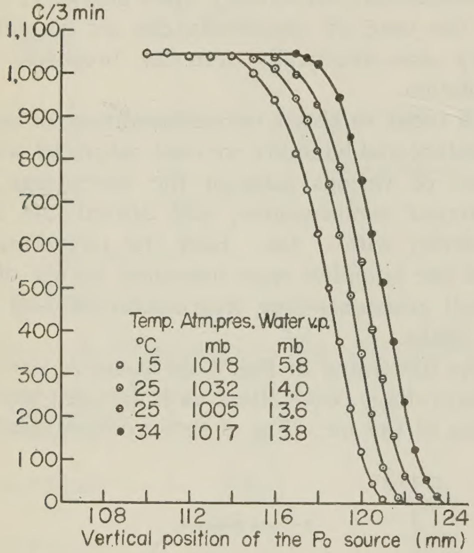

Fig. 7. Curves similar to those in Fig. 6, the plateau counts being taken equal.

Thus, further experiment was performed to get more data rapidly by setting the Po source at the normal position and applying 3.70 kV under various conditions.

Fig. 8 shows such plateau count as a function of absolute humidity. The points scatter fairly irregularly, but on the average, they may be assumed to lie on a straight line in the scope of the present experiment, irrespectively of temperature. Thus it may be concluded that temperature has only minute effect upon the counting efficiency, but humidity influences remarkably. Dependence of the applied voltage-count curve upon temperature and humidity will be seen again in Fig. 3. It seems that the curves undergo displacement towards lower voltage side with the rise of temperature and towards higher voltage side with increase of absolute humidity, and count increases with absolute humidity. The effect of humidity seems to be an interesting problem for the understanding of the mechanism of the counter, yet in order to avoid this effect the counter will have to be put in an enclosed vessel or corrections will have to be made by preliminary experiment, and from the point of practical use, the effect will be troublesome especially for field works.

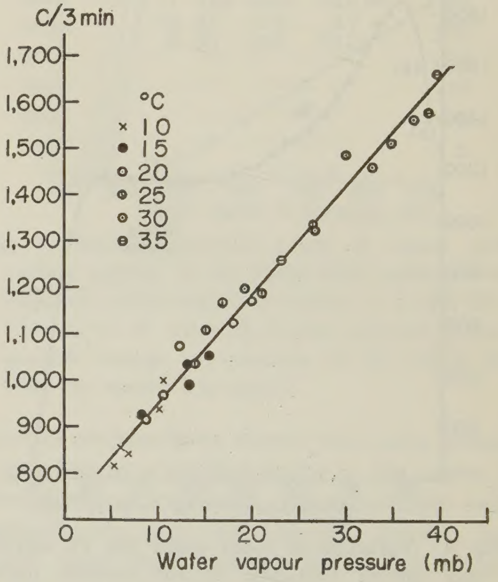

Fig. 8. Relation between plateau count and absolute humidity.

One of the advantages of this counter is that it is not affected by β or γ radiation. In the present experiment no effect was found when 50 mC Ra was placed at 5–6 mm from the acting part of the counter, that is, under the background of probably more than 600 r/hr of γ radiation, speaking in detail, less than 1 count per 5 min was recognized with Ra and without α irradiation, and also the same counts were observed with and without Ra when the old α source was placed at various distances from the counter, for example 1476±15 c/3 min without Ra against 1491±15 c/3 min with Ra.

Next, the efficiency of counting α particles with the counter was studied. For this purpose, count was taken, in one hand, with the counter by placing the new source at about 28.0 mm directly above the anode wire, and passing α rays through the narrow slit, and in the other hand, with the scintillation counter by placing the source with the same slit at as possibly equal distance as 28.0 mm above the CsI(Tl) crystal. The count ratio was ~3090 c/min for 23°C and 18.8 mb water vapour and ~3610 c/min for 25.4°C and 28.8 mb water vapour against ~7720 c/min, that is, ~40% and ~47% respectively, by assuming the CsI(Tl) scintillation count as 100%, under the indicated conditions of geometry.

§ 3. Multiple-wire Counter

It is advantageous to use multiple-wire counters to get higher efficiency for various practical measurement, especially that of neutrons. In the present experiment a counter with 14 wires at intervals of 2.5 mm was constructed. The spacing between the wires and the plate was about 1.3 mm. When the old Po source was moved perpendicularly to the wires, a count-displacement curve was obtained as shown by curve A in Fig. 9 when the 10 MΩ resistance shown in Fig. 1 was omitted. It may be that different nature of each acting space of the 14 wires and also their mutual interactions will cause such an unsatisfactory non-uniform distribution. In order to eliminate the interaction 10 MΩ resistance was put in series with each wire. Curve B shows the result. The uniformity of counting shown in curve B was not obtained without adding such a high resistance to each wire, for example with a resistance of 1 MΩ to each wire or with one resistance of 10 MΩ in series with a parallel connection of the 14 wires. Fig. 10 shows a voltage-count curve obtained by putting the α source at about 27 mm above the central part of the wires. It shows also a very wide plateau.

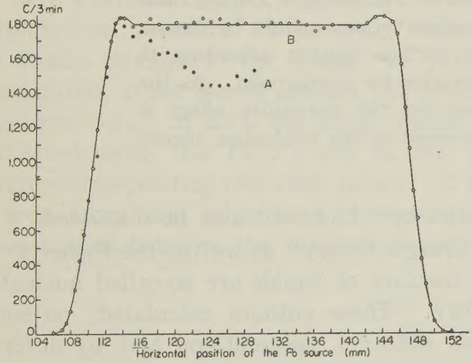

Fig. 9. Relation between count and horizontal displacement of the old Po source in the multiple-wire counter similar to the curve for the single-wire counter in Fig. 2.

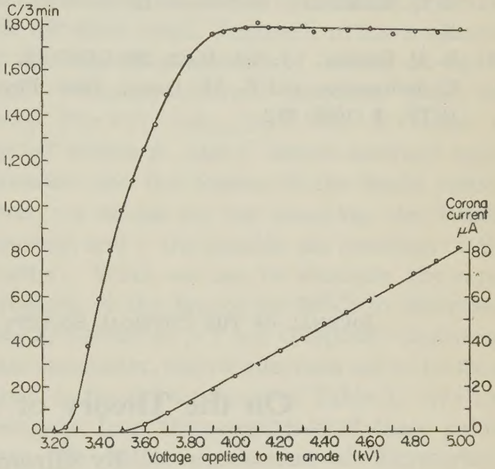

Fig. 10. Relation between count and applied voltage to the anode wires in the multiple-wire counter, similar to the curve for the single-wire counter as shown in Fig. 3.

Next, an apparatus for measuring neutrons was constructed by making use of the 14-wires counter. A glass plate coated with natural boron powder mixed with styrol over the area of 3×3 cm was put above 1.5 mm from the wires and the assembly was covered with paraffin 4 cm thick. When a neutron source of 50 mC Ra+Be was put on the upper side of the paraffin, ~70 c/min was observed. Without the neutron source or the boron plate there was no count practically. Improvement of the efficiency will be achieved without difficulty.

Acknowledgements

The writer wishes to express his cordial thanks to the Ministry of Education for the financial support to this research. His thanks are also due to Dr. K. Yuasa for kindly affording various facilities, and to Messrs. T. Watanabe and T. Aragaki for their kind assistance throughout the experiment.

On the Theory of the Fracture of Liquids

By Hiromu WAKESHIMA

The Kobe University of Mercantile Marine

(Received April 25, 1960)

The theories of fracture of liquids, those of Temperley's, Döring's and Fisher's are criticized in comparison with observations mainly by Lyman J. Briggs. The effect of bubble size on surface tension according to Tolman's theory is also taken into consideration for comparison. As the result is not satisfactory, a new hypothesis for the curvature effect is proposed, which brings about a better agreement of the nucleation theory with Briggs' data.

§ 1. Introduction

As is well known, there are different theories of the fracture of liquids at present. Temperley[1] put forward an idea that the pressure at the minimum on van der Waals' isothermals corresponds to the tensile strength of the liquid. The temperature at which the minimum of the pressure is practically zero, i.e. the limit of superheating of the liquid according to this theory, is, as is shown by Temperley, in general accord with the observed limits given by Kenrick, Gilbert and Wismer[2]. But, as far as the author is aware, there seems to be no published comparison of his theoretical results with the recent experimental data obtained by Lyman J. Briggs[3], applying centrifugal forces to liquids in a rotating tube. Moreover, there are other ways than that given by Temperley, of computing the pressure corresponding to the minimum on van der Waals' isothermals, the results by which will also be discussed.

Döring's theory[4] as well as the Fisher's[5], of the fracture of liquids are so-called nucleation theory. These authors calculated, on somewhat different assumptions and by different technique of derivation, the rate of formation by thermal fluctuation, of critical nuclear bubbles for the rupture in homogeneous liquids under tensile stress. The ultimate strengths of liquids according to these two theories show considerable discrepancies; the limiting negative pressures from Döring's theory come out to be larger than those from the Fisher's. It will be shown that this is mainly due to an unrealistic assumption upon which Döring's theory is based. The tensile strength of liquids, when calculated by Döring's method, but modified so as to give more reasonable foundation, is essentially the same as that by Fisher's formula, as it is the case for the limit of superheat. Both of these theories give tensile strengths of right order of magnitude in many cases, but agreement with the experiment is still unsatisfactory. It will be shown that the agreement is much deteriorated when we take into consideration the effect of curvature on surface tension, which is to be expected from Tolman's theory[6]. To improve the accordance the author has made a new approach to the problem of the effect of curvature on surface tension, the result of which seems to be promising.

§ 2. Temperley's Theory and Its Implications

A simple treatment of the problem of tensile strength of liquids by Temperley[1], in a slightly modified form, is as follows: The limit of stable region of the state of liquid corresponds to the minimum on van der Waals' isothermal. Therefore, eliminating V numerically from the equation

$$(\boldsymbol{P}+3/V^2)(V-1/3)=8/3\cdot \boldsymbol{T}, \tag{1}$$

expressed with corresponding variables, and the relation

$$(\partial \boldsymbol{P}/\partial V)_T=0, \quad \text{or} \quad \boldsymbol{P}-3/V^2+2/V^3=0 \tag{2}$$

we have a relation $\boldsymbol{P}_m(\boldsymbol{T})$, from which we can compute the pressure $\boldsymbol{P}_m\cdot p_c=p_{\min}$, meaning the tensile strength of the liquid. In Table I is tabulated, in the second column, the limiting pressures $-p_{\min}$ at 20°C for some liquids, as calculated using this $\boldsymbol{P}_m(\boldsymbol{T})$, and in the last column corresponding observed values. It will be seen from this table that in most cases discrepancies between the theoretical and the observed tensile strengths are not so large. But this does not necessarily mean the correctness of Temperley's stand point, because it would obviously be an over-simplification to use van der Waals' relation of the form Eq.(1) as the equation of state throughout the liquid state and to correlate the limiting tensile strength with $\boldsymbol{P}_m$ times the critical pressure. On the other hand, Tolman[8], in his treatment of the superficial density of matter at liquid-vapor boundary, derived formulas which express $p_v/\gamma'rT$, $-p_{\min}/\gamma'rT$ etc. in terms of $a\gamma'/rT$ where p_v, and γ' denote ordinary vapor pressure and the density of the liquid respectively; a stands for the usual van der Waals' constant and r the specific gas constant of the matter. When we use, for example, the vapor pressure of the liquids (at 20°C) to determine the parameter $a\gamma'/rT$ and compute $-p_{\min}$ using this parameter, the results turn out to be those given in the third column of Table I. We can recognize from the comparison of these values that the better agreement of Temperley's results with the observation is rather a fortunate coincidence.

Formally we can determine in other ways the parameter $a\gamma'/rT$, e.g. from a relation including the bulk modulus κ of the liquid as follows: As the van der Waals' equation using density, instead of volume, is

$$p=\gamma rT/(1-\gamma/\gamma_\infty)-a\gamma^2 \tag{3}$$

(here $1/\gamma_\infty$ stands for the usual van der Waals' constant b), for the compressibility

$$\kappa=\gamma(\partial p/\partial\gamma)_T \tag{4}$$

Table I. Limitting Pressures
(at 20°C, in Atm. P.)

Liquid	from Crit. Const.	from Vap. Pres.	from Compr.	Döring	Döring Mod.	Fisher	Tolman	Curve III		
								from Vap. Pres.	from Comp.	Obs.

* Those marked with asterisk are data given by J. Meyer[7].

we have

$$\kappa/\gamma rT=(a\gamma/rT+p/\gamma rT)^2-2a\gamma/rT \qquad (5)$$

If we denote $\kappa=\kappa_0$ for $p=0$, then

$$a\gamma'/rT=1+\sqrt{1+\kappa_0/\gamma' rT} \qquad (6)$$

Now the parameter $a\gamma'/rT$ from κ_0 give the tensile strengths given in the fourth column of Table I. These values come closer to the observation than those in the third column do, but it is doubtful whether we have come to the reality more closely. A direct estimation of the limiting negative pressures from extrapolation of the observed pressure-compressibility relations give results which do not agree with these values, though they do not differ in the order of magnitude.

§ 3. Döring's Theory in Comparison with the Fisher's

Döring imagines that, by thermal fluctuation, there appears in meta-stable liquids a series of embryonic bubbles, in mechanical equilibrium with the surrounding liquids; the vapor in the bubbles is assumed to obey the perfect gas law:

$$p_\nu'=p+2\sigma/r_\nu;\ p_\nu'\cdot 4/3\cdot\pi r_\nu^3=\nu kT \qquad (7)$$

Here p_ν' denotes the vapor pressure in a bubble with ν molecules, r_ν the radius of the bubble, p the ambient pressure σ, the surface tension of the liquid and k Boltzmann constant. Note that p_ν' is not the vapor pressure p_n of vapor in thermodynamical equilibrium with the liquid in question. Now from the equation of state above, it follows that, with p negative, ν as a function of r_ν, has a maximum at a radius $r_{\nu m}=4\sigma/(-3p)$, which is smaller than $2\sigma/(p_n-p)$ if $p<-2p_n$: A bubble which happens to grow larger than this critical size, will continue to develope spontaneously, resulting in a rupture of the liquid. Döring calculated, from a kinetic consideration, the number J, of such critical bubbles appearing in a stationary state, per unit volume of the liquid per unit time, the result being

$$J=B\cdot\exp(-A) \qquad (8)$$

where

$$A=\frac{64\,\pi\sigma^3}{27\,kT(-p)^2}\{1+2/3\cdot\log(-p/2p_n)\}$$

The factor before the exponential term in the above expression is taken by Döring to be roughly equal to the molecular collision frequency, times the number density of molecules, times the fraction of molecules having an energy larger or at least equal to that required to remove a molecule from the interior of the liquid, i.e. twice the heat of vaporization per molecule $2\varepsilon_0$, namely

$$B\doteq(1/\rho\cdot\sqrt{3kT/m})\cdot\gamma'/m\cdot(\sqrt{2\varepsilon_0/kT})$$
$$\exp(-2\varepsilon_0/kT) \qquad (9)$$

Here ρ and m denote the average distance between molecules and the mass of molecule respectively. As the value of p satisfying Eq.(8) does not vary much when J is multiplied by a factor of a few powers of ten, the tensile strength of liquids can be computed approximately by putting $J=1$* in Eq.(8) and solving for $(-p)$ which are tabulated in the fifth column of Table I.

Now there are some points in Döring's theory which have no physically plausible basis. First, Döring assumes the perfect gas law for the vapor in embryonic bubbles supposed in mechanical equilibrium with the ambient liquid (see Eq. (7)). Even at the critical bubble with a radius $4\sigma/(-3p)$, where the vapor pressure in the bubble is just half the magnitude of the tensile strength of the liquid, one will be convinced from Table I that he has assumed the perfect gas law quite improperly for the vapor in question. A more serious objection to Döring's theory can be raised against his basic idea that only embryonic bubbles in mechanical equilibrium (but not in thermodynamical equilibrium, as noted previously) with the ambient liquid, are needed for consideration in the nucleation problem of this kind. But before going into details of the discussion on this point, Fisher's theory[5] of the fracture of liquids will be reviewed briefly.

According to Fisher, the rate of formation of nuclei for the rupture of liquids can be approximated by a statistical population in equilibrium of the critical hole in meta-stable liquids, $n\cdot\exp(-\Delta\psi^*/kT)$, (here $n=\gamma'/m$), times a factor expressing the time rate at which a critical hole passes to a larger bubble capable of growing spontaneously. $\Delta\psi$ for the critical hole, $\Delta\psi^*$, corresponds to the maximum free energy of formation of a hole in the liquid; i.e. to $\partial\Delta\psi/\partial r=0$, where

$$\Delta\psi=4\,\pi r^2\sigma+4/3\cdot\pi r^3 p\ ,$$

therefore

---

* c.f., e.g. J.C. Fisher: J. Appl. Phys. 19 (1948) 1063.

$$\Delta\psi^* = 4\pi r^{*2}\sigma/3 \qquad (10)$$

Here r^* means the radius of the critical hole. The kinetic factor derived from the theory of absolute reaction rates by Turnbull and Fisher[9] is to the order of magnitude, $kT/h \cdot \exp(-\Delta f^*/kT)$, where h is Planck's constant and Δf^* the free energy of activation for the motion of a molecule, at the boundary of the critical hole, into or away from the hole. Therefore

$$J = nkT/h \cdot \exp\{-(\Delta\psi^* + \Delta f^*)/kT\} = B' \exp(-A')$$
$$A' = 16\pi\sigma^3/3kTp^2, \quad B' = nkT/h \cdot \exp(-\Delta f^*/kT) \qquad (11)$$

Fisher thinks Δf^* to be less than 10 Kcal/mol in most cases. If we assume with Fisher that $\Delta f^* = 0$, then the tensile strengths of liquids, as listed in the seventh column of Table I will be obtained. Evidently these values correspond to the lowest possible strengths from Fisher's theory and when, for example, the value of 10 Kcal/mol is assumed for Δf^*, some thirteen percent increase of these values results.

Discrepancies between the tensile strengths from Döring's theory and those according to Fisher's are primarily due to the exponential factors in Eq.(8) and in Eq.(11), specifically to the difference in magnitude of A and A'. Now A can be interpreted as the work, necessary to generate a Döring's critical bubble, divided by kT, just as $A'kT$ is the free energy of formation of a Fisher's critical hole. Let W_1 be the work necessary to expand a spherical surface against the surface tension σ from radius 0 to a radius $r_{\nu m} = 4\sigma/(-3p)$, with a constant inner pressure $(-p/2)$ and under an ambient pressure $(-p)$. We have

$$W_1 = \int_0^{r_{\nu m}} 4\pi r^2 \left\{ p + \frac{2\sigma}{r} - (-p/2) \right\} dr = \frac{64\pi\sigma^3}{27p^2} \qquad (12)$$

Further, let W_2 be the work of transformation of ν_m molecules satisfying

$$4/3 \cdot \pi r_{\nu m}^3 (-p/2) = \nu_m kT$$

from the liquid state to the vapor state of presure $(-p/2)$. We have

$$W_2 = \nu_m kT \log \frac{-p/2}{p_n} = \frac{2}{3} \times \frac{64\pi\sigma^3}{27p^2} \log \frac{-p}{2p_n} \qquad (13)$$

Therefore

$$(W_1 + W_2)/kT$$
$$= \frac{64\pi\sigma^3}{27p^2kT}\{1 + 2/3 \cdot \log(-p/2p_n)\} = A \qquad (14)$$

We now see that Döring's critical bubble is less likely formed by thermal fluctuation than Fisher's critical hole, as $A > A'$. Though the Döring's critical bubble is smaller in size than Fisher's, Döring obtains larger tensile strengths as Döring's embryos are of rarer occurrence than the Fisher's. Fisher's treatment, however, has weakness too. Because, here the population factor for the critical holes is that in thermodynamical equilibrium and so discrepancies therefrom is more or less to be expected in the stationary state of nucleation. Moreover, a rational evaluation of the quantity Δf^* would be difficult. Therefore it may be of interest to modify Döring's theory so as to consider embryonic bubbles of other category than those treated by him. When we assume the vapor in embryonic bubbles to have a constant pressure p_n, instead of the pressure given by Eq.(7), and follow the similar approach of the problem as made by Döring, it is easy to obtain the rate of nucleation J,

$$J = n \cdot \exp(-\Delta\psi_{\nu c}/kT) \cdot \sqrt{2\sigma/\pi m} \qquad (15)$$

Here $\Delta\psi_{\nu c}$ denotes the work to be done to form the critical embryonic bubble. The tensile strengths of liquids as computed using this formula, are listed in the sixth column of Table I. It will be seen that the values are essentially the same as obtained by Fisher's formula.

When these theoretical values are compared with the observed ones, we see that in many cases they are not different as far as the order of magnitude is concerned, but generally speaking the theoretical threshold pressures are larger than the observed and notably in cases of water and mercury. But before going into the discussion of a detailed comparison, we must first inquire into the factor assumed in the theory, which has possibly a large influence upon the values mentioned above, i.e. the problem of using macroscopic surface tensions in the above theory.

§ 4. Tolman's Theory of Surface Tension and the Fracture of Liquids

Even if we leave the question unanswered, whether the term surface tension has any meaning when applied to small clusters of molecules[10], there is a serious problem about the dependence of surface tension on the size of bubbles. Various authors has discussed a possible effect in question[11], but only Tolman could afford a general formula[6] readily comparable with experimental results, though his stand point has some theoretical weaknesses[11]. Tolman argued that droplet size has a considerable effect on surface tension when it is under, e.g. 10^{-6} cm in radius. Similar effect should exist for embryonic bubbles for the rupture of liquids, according to his theory, and not in a slight degree. A conspicuous influence is expected to appear on the rate of nucleation, as the latter is sensitive to the change in surface tension. Therefore a brief discussion of the possible influences will be made.

Tolman derived in a detailed thermodynamical treatment of surface tension a formula of the change in surface tension of a spherical boundary of radius r:

$$\frac{1}{\sigma}\frac{d\sigma}{dr}=\left(\frac{2}{r^2}\frac{\Gamma}{\gamma'-\gamma''}\right)\Big/\left(1+\frac{2}{r}\frac{\Gamma}{\gamma'-\gamma''}\right) \tag{16}$$

where γ', γ'' denote densities of the fluid on the concave side as well as on the convex side of the boundary respectively, and Γ Gibbs' superficial density with reference to his surface of tension. Further Tolman showed that between $\Gamma/(\gamma'-\gamma'')$ and a quantity δ, which means the distance from the surface of tension to the dividing surface with respect to which superficial density vanishes, the following relation holds:

$$\Gamma/(\gamma'-\gamma'')=\delta\{1+(\delta/r)+1/3\cdot(\delta^2/r^2)\} \tag{17}$$

For a nearly plane surface with the liquid on the concave side, i.e. for a large droplet, δ is approximately the superficial density Γ, divided by the difference in densities of homogeneous portion of fluids on both sides of the boundary, whereas for a large bubble the sign of δ must be reversed though the magnitude is unaltered, as will be seen from Eq.(17). Therefore, following Tolman's calculation we obtain a formula for the corrected surface tension σ of a bubble of radius r,

$$\begin{aligned}\sigma(r)&=\sigma_0\phi(z)\\&=\sigma_0\exp\int_0^z\{(1-z+z^2/3)/[1-2z(1-z+z^2/3)]\}dz\\&\qquad z=\delta/r\end{aligned} \tag{18}$$

An explicit expression can be obtained for the integral on the right side of this equation, but the result is so complicated that it cannot be used conveniently for further computation of, e.g. the critical radius or the rate of nucleation. The following results were all obtained by numerical calculations.

Fig. 1 gives the change in surface tension with the radius of bubble (Curve I). Corresponding change with the radius of droplet is shown for comparison (Curve II). We see from these graphs that the change is, not only reversed, but more conspicuous for embryonic bubbles than for droplets according to his theory, and that application to the limiting pressure for liquids would possibly throw much light upon the validity of Tolman's theory.

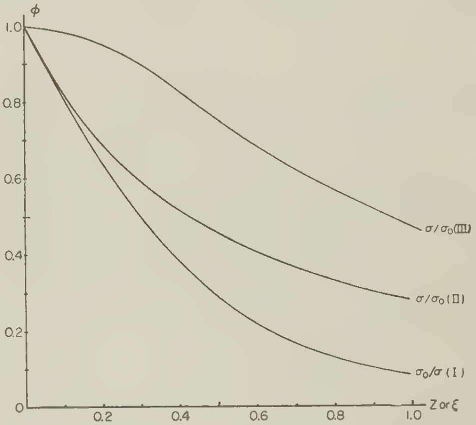

Fig. 1. Change of Surface Tension with the Size of Bubbles or Drops
$\phi(z)$ is given by Eq. (18); $z=\delta/r$
$\phi(\xi)$ is given by Eq. (32), Eq. (33); $\xi=c\lambda$

Now in the computation of the rate of nucleation when the surface tension changes with the size of embryonic bubbles, we are not allowed, simply to replace the ordinary surface tension σ in the factor A' in Eq.(11) or in the corresponding factor $\Delta\psi_{vc}/kT$ in Eq.(15), with the one given by Eq.(18). Because with the change in surface tension the radius of critical bubbles also changes. As an approximate evaluation of the corrected threshold pressures, we shall make use of the fact that the magnitude of the rate of nucleation is primarily determined by the factor A'/kT in Eq.(11) or $\Delta\psi_{vc}$ in Eq.(15), expressing the work of formation of a critical bubble in the meta-stable liquid, and proceeded as follows: The rate of nucleation is the same approximately for the corrected surface tension and at the corrected threshold pressures p_c, as the rate for the ordinary surface tension σ_0 and at the uncorrected threshold pressure p. Therefore, from Eq.(10) we have

$$4/3\cdot\pi r^{*2}\sigma_0=4/3\cdot\pi r_c{}^{*3}p_c+8\pi\int_0^{r_c^*}r\sigma(r)dr \tag{19}$$

where $r_c{}^*$ denotes the corrected critical radius, satisfying

$$-p_c=2\sigma(r_c{}^*)/r_c{}^* \tag{20}$$

Changing the variable from r to $z=\delta/r$, we get the relation,

$$1/2\cdot z^{*2}=-\phi(z_c{}^*)/z_c{}^{*2}+3\int_1^{z_c^*}\phi(z)/z^3\cdot dz \tag{21}$$

the lower limit for the integral above is set unity, meaning in effect that the work needed to form a cavity of the size δ is neglisible compared with the total work necessary for the formation of a critical bubble. The right hand side of Eq.(21) was numerically computed, from which we obtained the corrected critical radii $r_c{}^*=\delta/z_c{}^*$ or the corresponding threshold pressures p_c which satisfy

$$p_c/p=z_c{}^*\phi(z_c{}^*)/z^* \tag{22}$$

The results are summarized in the eighth column of Table I. We see from this table that accordance with the observed data is much deteriorated by taking into consideration the change of surface tension with radius of bubbles as derived from Tolman's theory.

Now, as is well known, Tolman's theory of the effect of droplet size on surface tension is based upon the relation6)

$$d\sigma=-\Gamma d\mu \tag{23}$$

where μ is the Gibbs' potential for the fluid in the homogeneous portions of either of vapor and liquid phases. In calculating Γ Tolman first introduces approximate expressions giving fluid pressure as a function of position within the transition layer on the boundary, (see the next paragraph) and determines a parameter giving the rate of change of pressure in the layer, by comparing the conclusion therefrom with the fact for a plane boundary. Then, making use of van der Waals' equation, he transforms his expressions for fluid pressure into expressions for fluid density within the transition layer, with which Γ is expressed. Finally this Γ is used for the computation of δ which is assumed to be approximately constant in the integration of Eq.(18). It cannot be justified, however, that van der Waals' equation even with the choice of parameters adopted by him, give a plausible representation of the succession of fluid states in the heterogeneous and minute layer in the transition region. The large discrepancy between the experimental fact and the theory mentioned above seems to show that his assumption is impermissible even in approximation.

§ 5. A New Approach to the Problem of Surface Tension of Embryonic Bubbles

To improve Tolman's theory, we shall try to avoid using Eq.(23) and van der Waals' equation in the way followed by Tolman, i.e. to connect fluid pressure and density in the transition layer: Instead, we shall use the relations

$$\sigma=\int_{-a}^{0}(p'-p)(1+cx)^2dx+\int_0^b(p''-p)(1+cx)^2dx \tag{24}$$

$$0=\int_{-a}^{0}(p'-p)(1+cx)xdx+\int_0^b(p''-p)(1+cx)xdx \tag{25}$$

first derived by Tolman12) thermodynamically and interpreted on a molecular theoretical bases by Buff10) afterward. Here x means the distance of a point in the transition layer, measured from the surface of tension along its normal, in the direction from concave side to convex side of the boundary with a curvature c. The first of these equations gives the surface tension σ in terms of distribution of liquid pressures p', and p'' in the homogeneous portion of the two phases and p in the transition layer respectively.* The second prescribes a specific location for the surface of tension within the transition layer. We shall further retain formally the parameter expressions for the stress factors in the transition layer ($p'-p$ or $p''-p$), adopted by Tolman in his theory;

$$p'-p=(p'-p_{\mathrm{max}})e^{y/\lambda_v} \tag{26}$$

$$p''-p=(p''-p_{\mathrm{min}})e^{-y/\lambda_l} \tag{27}$$

each holding over the range of vapor states from $y=-\infty$ to $y=0$, and over the range of liquid state from $y=0$ to $y=\infty$ respectively. Here a variable y designates distance along axis normal to the dividing surface between phases and has the value zero at the point of abrupt change in stress, increasing in the same direction as x increases, therefore $x=y-y_t$, where y_t denotes the distance of surface of tension from the point of abrupt change in stress. p_{max} and p_{min} are tentatively assumed to be equal in magnitude to the maxium and minimum possible pressures from van der Waals' equation. λ_v and λ_l are parameters expressing the rates with which stresses in the transition region on each side of the discontinuous dividing surface change. Now, combining Eqs. (24) and (25) we have the relation

---

* p means the stress tangential to the transition layer in the statistical-mechanical treatment10).

$$\sigma=\int_{-a}^{0}(p'-p)(1+cx)dx+\int_{0}^{b}(p''-p)(1+cx)dx \tag{28}$$

Therefore, making use of Eqs.(26) and (27) we get ($c\ll 1$)

$$\sigma=(p'-p_{\max})\lambda_v(1-cy_t-c\lambda_v)+(p'-p'')(y_t-1/2\cdot cy_t^2)+(p''-p_{\min})\lambda_l(1-cy_t+c\lambda_l) \tag{29}$$

The first term can be neglected compared with the rest on the right hand side of this equation, as it is expected that $p_{\max}\ll|p_{\min}|$ and $\lambda_v\approx\lambda_l$. Kelvin's relation is available when σ is defined with reference to the surface of tension, as proved by Tolman[8], therefore $p'-p''=2c\sigma$; further, $p'\ll|p''|$ for minute bubbles. Using these relations a formula for σ is obtained:

$$\sigma=\frac{-p_{\min}\lambda(1-cy_t+c\lambda)}{1-2cy_t(1-1/2\cdot cy_t)+2c\lambda(1-cy_t+c\lambda)} \tag{30}$$

Here we dropped the suffix of λ_l. On the other hand, eliminating p' by the use Eq.(25) a similar equation for σ can be easily derived:

$$\sigma=\frac{-p_{\min}\lambda\{(1-cy_t)cy_t-c\lambda(1-2cy_t)-2c^2\lambda^2\}}{-[c^2y_t^2(1-2/3\cdot cy_t)-2c\lambda\{(1-cy_t)cy_t-c\lambda(1-2cy_t)-2c^2\lambda^2\}]} \tag{31}$$

In order that σ remains finite, y_t must be equal to λ when $c=0$. Either of the above equations for σ give the same surface tension $\sigma_0=-p_{\min}\lambda$ for $c=0$, the result already obtained by Tolman. Now, in order that Eq.(30) and Eq.(31) are compatible with each other, $cy_t\equiv\eta$ must be a function of $c\lambda\equiv\xi$. This relation between η and ξ can be obtained by comparing the factors σ/σ_0 from Eq. (28) and that from Eq.(29). i.e.

$$\begin{aligned}\Phi_1&=\frac{1-\eta+\xi}{1-2\eta(1-1/2\cdot\eta)+2\xi(1-\eta+\xi)}\\ \Phi_2&=\frac{2\xi^2+\xi(1-2\eta)-\eta(1-\eta)}{\eta^2(1-2/3\cdot\eta)+2\xi\{2\xi^2+\xi(1-2\eta)-\eta(1-\eta)\}}\end{aligned} \tag{32}$$

In order that $\Phi_1=\Phi_2$, the following relation must hold,

$$(1-\eta)^2/(1-\eta+\xi)=\eta^2(1-2/3\cdot\eta)/\{2\xi^2+\xi(1-2\eta)-\eta(1-\eta)\}$$

From this equation, ξ can be expressed as a function of η

$$\xi=-F_1+\sqrt{F_1^2+F_2}$$

where

$$F_1=\{(1-2\eta)^2-4/3\cdot\eta^3\}/4(1-\eta)^2;\qquad F_2=\eta(1-\eta+1/3\cdot\eta^2)/2(1-\eta) \tag{33}$$

We can compute numerically an inverse expression, η as a function of ξ and thus compute $\Phi=\Phi_1=\Phi_2$ as a function of ξ. The curve III in Fig. 1 shows this in comparison with Tolman's surface tension, though the relation between radius of bubble and y_t or λ is not given yet. Now assumptions Eq.(26) and Eq.(27) imply that pressure and density distribution near the surface $y=0$ would be essentially the same down to very minute bubbles, so far as the material and the temperature remains unaltered. Then it seems natural to assume that parameter λ can be regarded as approximately independent of radius of bubbles, in view of the circumstance λ is presumably a function of molecular force and the local density distribution. If this is the case, we can see from the curve III how surface tension changes with the size of bubbles. It should be remarked that surface tension diminishes as radius of bubbles decreases, contrary to the result from Tolman's theory. Second, the change in surface tension with the size of bubble is not so conspicuous in magnitude, as compared with Tolman's case.

A similar treatment as described in the preceding paragraph derives the threshold pressures for the fracture of liquids, as listed in the ninth column of Table I. Here $-p_{\min}$, listed in the third column of the same table, are used for computation of $\lambda(=\sigma_0/-p_{\min})$. When the values of $-p_{\min}$ as given in the fourth column of Table I are used, the threshold pressures in the column the last but one of the table will be obtained. We notice from this table that agreement with experimental fact is somewhat improved, instead of getting worse as in the former case, when the surface tension for embryonic bubbles is given by the relation Eq. (18) shown previously.

§ 6. Concluding Remarks

Generally speaking, the discrepancy between the theoretical threshold pressures and the observed ones shown in the table are not so large as it is sometimes believed to be. Larger disagreement for water, alcohol, ether and mercury may primarily be due to different causes. In cases of alcohol and ether, observational errors which probably have accompanied Meyer's old experiment[7)] may be responsible for the discord, while in the case of mercury the discrepancy can essentially be explained by the assumption that observed rupture took place at the mercury-glass boundary, instead of occurring in the body of the liquid. When contact angle of, e.g. 140° is assumed as a condition at the boundary, it is expected from the theory of nucleation[5)] that the threshold pressure for the rupture at a plane boundary will be reduced almost to one quarter of those for the rupture in the body of mercury. Moreover, there is no reason to believe that only plane boundary is concerned, as minute portions of a boundary, almost of molecular dimensions are in question here. As discussed, for example by Fisher, we can expect small fraction of this threshold pressure, by assuming the existence of a suitable cavity at the boundary. Further, inapplicability, for the metalic mercury, of van der Waals' equation to compute $-p_{\min}$ may be responsible for the discord. Whether the discrepancy between the theoretical and the observed values of the threshold pressure for water is to be attributed to a similar situation due to heterogeneous nucleation, or to any other peculiarity of this common but special material, is not clear at present.

As for the constancy of parameter λ assumed in our theory of the size effect of surface tension, it has evidently to be confirmed by statistical-mechanical treatment of the problem, though it is recalled that Tolman had also to assume a similar relation, the constancy of parameter δ, in addition to the validity of van der Waals' equation to describe the fluid state in the transition region between phases. Actually, as will be seen from Table II, δ and λ or y_t for plane surfaces are most likely related quantities, presumably closely connected with intermolecular distances in the fluid. Further, it may be necessary to add that assumption of the constancy of y_t, instead of λ, leads to an improbable consequence that λ becomes unreasonably large as radius of bubbles diminishes.

Table II. Various Constants
(Unit 10^{-8} cm)

Liquid	r^*	δ	λ	λ/δ
Water	10.3	0.988	1.05	1.06
Ethyl Alcohol	18.1	1.35	1.47	1.09
Ethyl Ether	20.8	3.44	3.82	1.11
Chloroform	16.5	3.04	3.34	1.10
Benzene	16.0	3.15	3.43	1.09
Acetic Acid	16.5	1.31	1.42	1.08
Aniline	13.2**	1.68**		
Carbon Tetra-Chloride	16.6	3.37	3.69	1.09
Mercury	4.00	2.27	2.37	1.04

** The values for Aniline, marked with asterisks, are computed, using an extra-polation for the vapor pressure and are less reliable.

The preceding arguments are based upon the premise of correctness of the experimental fact. In this respect it seems that there remain much to be done to expand the scope of observation and to increase the reliability of the values of tensile strength of liquids.

In conclusion, the author wishes to express his gratitude to Professor Akira Harashima of the International Christian University, Professor Ituro Uhara of Kobe University and Professor Ichiro Shoji of Marine Technical College for their kind discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 1, JANUARY, 1961

On the Irreversible Behavior of Coupled Oscillators with Application to Time of Flight

By Youzou KOGURE

Department of Physics, Faculty of Science
Tokyo University of Education

(Received September 3, 1960)

The irreversible behavior of simple systems is studied. An example is a system composed of coupled many harmonic oscillators. It is shown that the amplitude of a specified oscillator under appropriate initial condition, and the response function vanish after a long time, as the number of oscillators tends to infinity. Another example is a system of gaseous particle which is subject to collisions due to fixed scattering centers. It is shown that if there is only one scatterer the occupation number for the initial state changes periodically, and if there are many scatterers the occupation number exhibits exponential decay.

§ 1. Introduction

One of the basic problems of statistical mechanics is to account for the irreversibility which takes place generally in physical phenomena.

Since the day of Maxwell and Boltzmann, this problem has been extensively studied. General approaches to irreversible statistical mechanics has been developed. A remarkable progress in this field is due to Van Hove[1], R. Kubo[2] has afforded the theory of linear response in which relation between physical quantities are derived in elegant forms.

In this paper, however, we shall pay special attention to irreversible behavior of simple systems which can be treated more or less rigorously. As the complete dynamics of a set of coupled harmonic oscillators can be treated in a simple mathematical way, it is convenient to calculate its physical quantities with reference to irreversible processes.

There are a number of irrestigations of this sort. Recently, taking an assembly of harmonic oscillators coupled in periodic array, P. Mazur and E. Montroll[3] have shown that the irreversibility is a consequence of the vanishing of the correlation coefficients as the recurrence time becomes infinite M. Toda[4] has treated the Brownian motion of a harmonic oscillator coupled with thermostat which is composed of a great number of harmonic oscillators, and has derived the damping equation and the Langevin equation.

On the other hand, we may cite other attempts dealing with special phenomena. V. E. Derr[5] has investigated the irreversibility of quantum mechanical systems perturbed by random forces using phenomenological equation derived from Schrödinger equation. M. Lax[6] has shown in his theory of mobility of electrons that the response function vanishes after a sufficiently long time if one takes into account the effect of the surrounding heat reservoir in a rather conventional way.

Moreover N. Saito[7] has pointed out that the transfer function, the Laplace transformation of the response function with respect to time, has poles on the imaginary axis. In the limit of infinitely large system, the distribution of these poles becomes continuous, which might be replaced by some poles on the left half of the complex plane, just like image charges in electrostatistics. If this is the case, the response function will really vanish after a long time.

In § 2, of this paper we shall study general dynamics of systems to harmonic oscillator with a specified one, with special reference to the subsequent development and especially to the relations of transformation coefficients or the direction cosines between the particle coordinates and the normal coordinates. Taking a special example in § 3, the amplitude of an excited oscillator is shown to diminish after a time under an appropriate condition. In § 4, we evaluate the response function classically, and quantum mechanically. It is shown that the response function really vanishes after sufficiently long time. In § 5, we shall be concerned with application of § 3 to the calculation of time of flight of a particle subject to fixed scattering counters. § 6 and § 7, are devoted to conjectures and discussions.

§ 2. General Theory

Let us consider a simple system which is composed of a great number of harmonic oscillators. The interaction energy between each pair of oscillators is assumed to be proportional to the product of the displacements from their equilibrium positions.

In unperturbed state, the set of equations which determine the frequencies Ω of the normal modes is given by

$$m_j(\omega_j^2-\Omega^2)x_j+\sum_{k=1}^{N}{}' \lambda_{jk}x_k=0\,, \qquad (j=1,2,\cdots,N). \tag{2.1}$$

where x_j is the displacement, m_j the mass and ω_j the frequency of the j-th oscillator, $\sum'$ represents the sum over oscillators excluding the specified oscillator and λ_{jk} is the coupling constant between the j-th and the k-th oscillator.

Denoting $y_s=\sqrt{m_s}\,x_s$, $y_j=\sqrt{m_j}\,x_j$ and $\Lambda_{jk}=\lambda_{jk}/\sqrt{m_jm_k}$, we rewrite Eq. (2.1) as

$$(\omega_j^2-\Omega^2)y_j+\sum_{k=1}^{N}{}' \Lambda_{jk}y_k=0\,. \tag{2.2}$$

It is convenient to write the coordinates $\{y_j\}$ in terms of the normal coordinates $\{Q_j\}$ by the orthogonal transformation

$$Q_n=\sum_{j=1}^{N}(c^{-1})_{nj}y_j\,, \qquad y_j=\sum_{n=1}^{N}c_{jn}Q_n\,. \tag{2.3}$$

From Eqs. (2.2) and (2.3) we see that the characteristic frequency Ω_n of the n-th mode is given by one of the characteristic roots of $N\times N$ matrix whose elements satisfy the relation

$$\sum_{k,l=1}^{N}(c^{-1})_{nk}(\omega^2+\Lambda)_{kl}c_{ln}$$
$$=\sum_{k=1}^{N}\omega_k^2|c_{kn}|^2+\sum_{k,l=1}^{N}\Lambda_{kl}c_{kn}^{*}c_{ln}=\Omega_n^2\,. \tag{2.4}$$

In virture of Eq. (2.4) we have $\sum\omega_k^2=\sum\Omega_n^2$, that is, trace is invariant. Differentiating both sides of Eq. (2.4) with respect to ω_j^2, we obtain

$$c_{kn}^2=\partial\Omega_n^2/\partial\omega_k^2\,. \tag{2.5}$$

On the other hand, Ω_n^2 is defined as the n-th eigenvalue of Ω^2 which approaches to ω_n^2 of the n-th oscillator when all the coupling constants Λ_{jk} tend to zero.

With the matrix $c=(c_{jk})$ satisfying

$$\sum_j c_{jk}c_{jl}=\delta_{kl}\,, \quad \sum_k c_{jk}c_{lk}=\delta_{jk}\,,$$
$$(c^{-1})_{kj}=c_{jk}\,. \tag{2.6}$$

We note that the transformation coefficient c_{jn} is the direction cosine between the coordinate y_j and the normal coordinate Q_n. As an example we shall assume first that the oscillator s is interacting with the surrounding oscillators, but the latter are not interacting among themselves. Then Eq. (2.2) can be rewritten as

$$(\omega_s^2-\Omega^2)y_s+\sum_{j=1}^{N}{}' \Lambda_{sj}y_j=0\,, \tag{2.7}$$

$$(\omega_j^2-\Omega^2)y_j+\Lambda_{sj}y_s=0\,. \tag{2.7$'$}$$

Eliminating y_s and y_j from Eqs. (2.7) and (2.7)′, we get the equation for Ω_n

$$\omega_s^2-\Omega_n^2=\sum_{j=1}^{N}\frac{\Lambda_{sj}\Lambda_{js}}{\omega_j^2-\Omega_n^2}\,. \tag{2.8}$$

Differentiation of Eq. (2.8) with respect to ω_s^2 and ω_j^2 leads to

$$\left.\begin{aligned} c_{sn}^2&=\frac{\partial\Omega_n^2}{\partial\omega_s^2}=\frac{1}{1+\sum_{k=1}^{N}{}'\{\Lambda_{sk}^2/(\omega_k^2-\Omega_n^2)^2\}}\,,\\ c_{jn}^2&=\frac{\partial\Omega_n^2}{\partial\omega_j^2}=-\frac{\Lambda_{sj}^2/(\omega_j^2-\Omega_n^2)^2}{1+\sum_{k=1}^{N}{}'\{\Lambda_{sk}^2/(\omega_k^2-\Omega_n^2)^2\}}\,.\end{aligned}\right\} \tag{2.9}$$

Thus we get the relation

$$c_{sn}^2+\sum_{j=1}^{N}{}'\,c_{jn}^2=1\,. \tag{2.10}$$

Differentiating both sides of $\sum\omega^2=\sum\Omega_n^2$ with respect to ω_j^2, and using (2.3), we obtain

$$\sum_{n=1}^{N}c_{jn}^2=1\,. \tag{2.11}$$

Another example for which Eq. (2.2) can be solved explicitly is the case when all the coupling constants are equal and is Λ, Eqs. (2.10) and (2.11) are easily verified with the same method as in the previous case. The set of equations which corresponds to Eq. (2.2) is given by

$$(\omega_j^2-\Omega^2)y_j+\Lambda\sum_{k=1}^{N}{}'\,y_k=0\,. \tag{2.12}$$

Eliminating the coordinates $\{y_j\}$ from Eq. (2.12), we obtain the equation for Ω_n,

$$\sum_{j=1}^{N}{}'\frac{\Lambda}{\omega_j^2-\Lambda-\Omega_n^2}=-1\,, \tag{2.13}$$

and the direction cosines

$$c_{jn}^2=\frac{1/(\omega_j^2-\Lambda-\Omega_n^2)^2}{\sum_{k=1}^{N}\{1/(\omega_k^2-\Lambda-\Omega_n^1)^2\}}\,. \tag{2.14}$$

§ 3. Special Example

In this section, we examine a system composed of N harmonic oscillators which have the special frequency spectrum given by

$$\omega_j^2=\omega_s^2+(j-s)\Delta^2\,,$$
$$j=s\pm1,\ s\pm2,\ \cdots,\ s\pm N/2\,. \tag{3.1}$$

As is well known, a condition that has proved vital in all works in statistical mechanics of irreversible processes is the largeness of the system. In this section, this manifests itself in the fact that the spectrum of frequencies ω_j becomes dense as $N\to\infty$.

We shall take the first model in the previous section, and assume that all coupling constants Λ_{sk} do not depend on the k-th oscillator, that is, $\Lambda_{sk}=\Lambda$.

We can easily calculate Eq. (2.8) in the limit of infinite N:

$$\omega_s^2-\Omega_n^2=\frac{\pi\Lambda^2}{\Delta^2}\cot\frac{\pi}{\Delta^2}(\omega_s^2-\Omega_n^2)-\frac{\Lambda^2}{\omega_s^2-\Omega_n^2}\,. \tag{3.2}$$

From Eq. (2.9) we obtain

$$\begin{aligned} c_{sn}^2&=\left\{1+\sum_{j=1}^{N}{}'\frac{\Lambda^2}{(\omega_j^2-\Omega_n^2)^2}\right\}^{-1}\\ &=\left\{1+\frac{\pi^2\Lambda^2}{\Delta^4}\operatorname{cosec}^2\frac{\pi(\omega_s^2-\Omega_n^2)}{\Delta^2}-\frac{\Lambda^4}{(\omega_s^2-\Omega_n^2)^2}\right\}^{-1}.\end{aligned} \tag{3.3}$$

With use of Eq. (3.2), the above equation can be written as

$$\begin{aligned} c_{sn}^2&=\frac{\Lambda^2}{3\Lambda^2+(\pi^2\Lambda^4/\Delta^4)+(\omega_s^2-\Omega_n^2)^2}\\ &\approx\frac{\Delta^2}{\pi}\cdot\frac{\alpha}{\alpha+(\omega_s^2-\Omega^2)^2}\,,\\ \alpha&=\pi\Lambda^2/\Delta^2\,.\end{aligned} \tag{3.4}$$

Λ and Δ^2 being assumed to be constants of the order $\sqrt{N}$ and N^{-1} respectively. We have therefore neglected $3\Lambda^2$ in the denominator, which is valid for large N.

c_{sn} becomes continuous with respect to Ω_n in the limit of large N and small Δ^2. $N\Delta^2$ approaches to a constant of the order 1 in this limit. And α in Eq. (3.4) approaches to a constant of the order 1 in the same limit.

A state of motion can be generally represented by a superposition of eigen-vibrations. By an eigen-vibration we mean a synchronous oscillation of all particles with eigenfrequency Ω_n and amplitude a_n. The displacement of the j-th oscillator can be described by

$$y_j=\sum_n c_{jn}(a_n\cos\Omega_n t+b_n\sin\Omega_n t)\,. \tag{3.5}$$

We impose the initial condition that, at $t=0$, all the oscillators, except a specified oscillator s, are at rest in their equilibrium position, and this oscillator is displaced by unit distance with vanishing velocity. To satisfy the initial condition, we take

$$a_n = c_{sn}\,, \qquad b_n = 0\,,$$

and then

$$y_j = \sum_n c_{sn} c_{jn} \cos \Omega_n t\,. \tag{3.6}$$

We can see that the amplitude of the oscillator s is continuously damped down with time from Eqs. (3.4) and (3.6). y_s can be represented as

$$y_s = \sum_n c_{sn}^2 \cos \Omega_n t = \frac{\Delta^2}{\pi} \sum_n \frac{\alpha}{\alpha^2 + (\omega_s{}^2 - \Omega_n{}^2)^2} \cos \Omega_n t\,. \tag{3.7}$$

Since the spectrum of frequencies $\omega_j{}^2$ becomes dense about ω_s as remarked before, the normal mode frequencies Ω_n distributed about ω_s as $N \to \infty$.

In Eq. (3.7), the factor $\alpha/(\alpha^2 + (\omega_s{}^2 - \Omega_n{}^2)^2)$ has a sharp maximum around $\Omega_n \sim \omega_s$. Consequently, $\Omega_n{}^2 - \omega_s{}^2$ can be substituted by $2\omega_s(\Omega_n - \omega_s)$, neglecting the second power of $\Omega_n - \omega_s$. It is noted that there is a solution $\Omega_n{}^2$ of the transcendental equation (3.2), in each interval $[\omega_s{}^2 + (n-s)\Delta^2,\ \omega_s{}^2 + (n-1-s)\Delta^2]$ for $n-s = 0, \pm 1, \pm 2, \cdots$. Hence we may use the approximation that, for $\Omega \sim \omega_s$, there are $g(\Omega)d\Omega = (2\omega_s/\Delta^2)d\Omega$ oscillators with frequency between Ω and $\Omega + d\Omega$. Therefore the sum is reduced to the integral

$$\begin{aligned} y_s &= \frac{\Delta^2}{2\pi\omega_s} \sum_n \frac{\beta}{\beta^2 + (\omega_s - \Omega_n)^2} \cos \Omega_n t \\ &= \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{\beta}{\beta^2 + (\omega_s - \Omega)^2} \cos \Omega t \cdot d\Omega \\ &= e^{-\beta|t|} \cos \omega_s t\,. \end{aligned} \tag{3.8}$$

where

$$\beta = \alpha/2\omega_s\,.$$

Thus, we see that the amplitude of the excited oscillator s diminishes to zero after a sufficiently long time, and initial situation will never return.

§ 4. The Response Function

We consider the system with Hamiltonian $\mathscr{H}$, which is composed of two parts; the unperturbed part $\mathscr{H}_0$ which described the natural motion of the systems considered in the previous section, and the external perturbation on the oscillator s: $\mathscr{H}' = -x_s f(t)$, where $f(t)$ is the applied force.

The system is assumed to be in a certain distribution $\rho(\mathscr{H}_0)$ at time $t=0$ in the phase space Γ. We confine ourselves to weak perturbation, for which the linear response is observed through the change of $\Delta\dot{\boldsymbol{x}}_s$, where $\dot{\boldsymbol{x}}(t)$ is the velocity given by $\boldsymbol{x}_s = \boldsymbol{p}_s/m_s$.

We may write the change in $\Delta\dot{x}(t)$ as

$$\begin{aligned} \Delta\dot{\boldsymbol{x}}_s &= -\int d\Gamma \int_{-\infty}^{t} (\boldsymbol{x}_s,\ f)\dot{\boldsymbol{x}}_s(t-t')f(t')dt' \\ &= \int_{-\infty}^{t}\int e^{-i(t-t')\boldsymbol{L}} \dot{\boldsymbol{x}}(f,\ \boldsymbol{x}_s)f(t')dt'd\Gamma\,. \end{aligned} \tag{4.1}$$

where the bracket means the Poisson bracket, and $\boldsymbol{L}$ is the self-adjoint operator introduced by Kirkwood[8)], defined by $i\boldsymbol{L}g = (\mathscr{H}_0,\ g)$. Thus $\dot{\boldsymbol{x}}(t)$ is given by

$$\dot{\boldsymbol{x}}_s(t) = e^{-i\boldsymbol{L}t}\dot{\boldsymbol{x}}_s(0)\,. \tag{4.2}$$

The response $\Delta\dot{\boldsymbol{x}}_s(t)$ may be written as

$$\Delta\dot{\boldsymbol{x}}_s = \int^{t} \phi_{\dot{\boldsymbol{x}}_s \boldsymbol{x}_s}(t-t')f(t')dt'\,. \tag{4.3}$$

The response function is defined, comparing Eq. (4.3), with Eq. (4.1), by

$$\phi_{\dot{\boldsymbol{x}}_s \boldsymbol{x}_s}(t) = -\int d\Gamma(\boldsymbol{x}_s,\ f)\dot{\boldsymbol{x}}_s(t)\,. \tag{4.4}$$

By the use of normal coordinates in the previous section, unperturbed Hamiltonian $\mathscr{H}_0$ is given by

$$\mathscr{H}_0 = \sum_n \{\tfrac{1}{2}P_n{}^2 + \Omega_n{}^2 Q_n{}^2\}\,. \tag{4.5}$$

In terms of the normal coordinates we have

$$x_s = \frac{1}{\sqrt{m_s}} \sum_{n=1}^{N} c_{sn} Q_n\,, \qquad \dot{x}_s = \sqrt{m_s} \sum_{n=1}^{N} c_{sn} P_n\,. \tag{4.6}$$

Thus we obtain

$$\begin{aligned} \phi(t) &= -\sum_{n=1}^{N} \sum_{m=1}^{N} \int c_{sn} c_{sm} P_n P_m (\partial\rho_0/\partial\mathscr{H}_0) \cos \Omega_m t\, d\Gamma \\ &= \sum_{n=1}^{N} c_{sn}^2 \cos \Omega_n t\,. \end{aligned} \tag{4.7}$$

in which we have used the relation

$$\int P_n P_m (\partial\rho_0/\partial\mathscr{H}_0) d\Gamma = -\delta_{nm}\,,$$

and

$$\sum_m c_{sm} e^{-i\boldsymbol{L}t} P_m = \sum_m c_{sm} P_m \cos \Omega_m t\,. \tag{4.8}$$

Since Eq. (4.7) agrees with the right hand side of Eq. (3.7), the response function $\phi(t)$ is given by Eq. (3.8), that is,

$$\phi(t) = e^{-\beta t} \cos \omega_s t\,, \qquad t > 0\,. \tag{4.9}$$

Thus we see that though the response function is a sum of terms periodic in time, it vanishes after a sufficiently long time. The transfer function is defined by

$$\Psi(z) = \int_0^{\infty} e^{-zt} \phi(t) dt\,.$$

Except unimportant factor, we can easily evaluate $\Psi(z)$ from Eq. (4.9) to obtain

$$\Psi(z)=\frac{1}{z+\beta+i\omega_s}+\frac{1}{z-\beta-i\omega_s} .$$

$\Psi(z)$ has pole at $z=-\beta-i\omega_s$ and $-\beta+i\omega_s$ on the left half of the complex z-plane. The poles are equivalent to position of time image charges for induced charge on the surface of the conductor. This fact satisfies the condition which has been proposed by Saito[7]. Now we shall treat the problem quantum-mechanically by a method which is analogous to that of classical mechanics.

The similar expression for the response function can be derived in this case. Poisson bracket are to be replaced by commutators and the distribution function $\rho_0(\mathscr{H}_0)$ is to be replaced by the density matrix. We have

$$\phi_{\dot{x}_s x_s}(t)=\frac{1}{i\hbar}\sum_{k,l}[\rho_0,\, x_s]_{kl}(\dot{x}_s)_{lk}e^{-i(\varepsilon_k-\varepsilon_l)t/\hbar} . \quad (4\ 12)$$

By the use of the same transformation as in the classical case, we obtain Hamiltonian as a sum of those for harmonic oscillators whose eigenfrequencies are given by Ω_n as before. It is easily proved the matrix **C** of the transformation coefficients has the same elements as for the classical mechanics in virtue of the properties of harmonic oscillators.

We take the representation which make $\mathscr{H}_0$ diagonal,

$$\left.\begin{aligned}\mathscr{H}_0&=\sum_k \hbar\Omega_n\left(k+\frac{1}{2}\right),\\ x_s&=\frac{1}{\sqrt{m_s}}\sum c_{sn}Q_n ,\\ \dot{x}_s&=\sqrt{m_s}\sum_n c_{sn}P_n .\end{aligned}\right\} \quad (4.13)$$

In this case we shall assume that the system is initially in the state of thermal equilibrium with temperature T, that is, we assume that

$$\rho_0(\mathscr{H}_0)=\exp\{\beta(F-\mathscr{H}_0)\} .$$

where $\beta=1/kT$, and F is Helmholtz free energy of the system.

By the use of Eqs. (4.12), (4.13) and (4.14), $\phi(t)$ can be written as

$$\begin{aligned}\phi(t)=&\frac{1}{i\hbar}\sum_{n=1}^{N}c_{sn}^2\sum_{k,l}e^{\beta F_n}\\ &\times\{e^{-\hbar\beta\Omega_n(k+(1/2))}-e^{-\hbar\beta\Omega_n(l+(1/2))}\}\\ &\times(k|Q_n|l)(l|P_n|k)e^{-i(k-l)\Omega_n t} .\end{aligned} \quad (4.15)$$

where

$$e^{-\beta F_n}=\sum_{k=0}^{\infty}e^{-\beta\hbar\Omega_n(k+(1/2))}=e^{-\hbar\beta\Omega_n/2}(1-e^{-\hbar\beta\Omega_n})^{-1} .$$

Making use of the relations

$$\left.\begin{aligned}(k|Q_n|k+1)&=\left(\frac{\hbar}{2\Omega_n}\right)^{1/2}\left(k+\frac{1}{2}\right)^{1/2},\\ (k|Q_n|k-1)&=\left(\frac{\hbar}{2\Omega_n}\right)^{1/2}k^{1/2} ,\\ (k|P_n|k+1)&=-\frac{1}{i}\left(\frac{\hbar\Omega_n}{2}\right)^{1/2}k^{1/2} ,\\ (k|P_n|k-1)&=\frac{1}{i}\left(\frac{\hbar\Omega_n}{2}\right)^{1/2}(k+1)^{1/2} .\end{aligned}\right\} \quad (4.16)$$

we sum up over l, and then over k and n

$$\begin{aligned}\phi(t)=&\sum_{n=1}^{N}c_{sn}^2\sum_{k=0}^{\infty}\sqrt{k(k+1)}\\ &\times e^{\beta F_n}e^{-\beta\hbar\Omega_n(k+(1/2))}(1-e^{-\hbar\beta\Omega_n})\cos\Omega_n t .\end{aligned} \quad (4.17)$$

Eq. (4.17) can not be calculated exactly as the factor $\sqrt{k(k+1)}$ induces complicate calculations.

Since except for very low temperature, the main contribution to Eq. (4.17) may arise from the terms of large k values, $\sqrt{k(k+1)}$ can be replaced by $k+\frac{1}{2}$ in Eq. (4.17). We have then

$$\phi(t)=\sum_{n=1}^{N}c_{sn}^2\,\frac{1+e^{-\beta\hbar\Omega_n}}{2}\cos\Omega_n t . \quad (4.18)$$

in which we have used the relations

$$e^{\beta F_n}\sum_{k=0}^{\infty}\left(k+\frac{1}{2}\right)e^{-\beta\hbar\Omega_n(k+(1/2))}=\frac{1}{2}+\frac{1}{e^{\beta\hbar\Omega_n}-1} ,$$

$$\left(\frac{1}{2}+\frac{1}{e^{\beta\hbar\Omega_n}-1}\right)(1-e^{-\hbar\beta\Omega_n})=\frac{1}{2}(1+e^{-\beta\hbar\Omega_n}) .$$

Replacing the sum over n by integration as we have done in the previous section, we obtain

$$\phi(t)=\frac{1}{2\pi}\int_0^{\infty}\frac{\beta}{\beta^2+(\omega_s-\Omega)^2}\cos\Omega t(1+e^{-\hbar\beta\Omega})d\Omega . \quad (4.19)$$

For small coupling constants we get finally for

$$\phi(t)\cong\phi_{\text{class}}\left(\frac{1+e^{-\hbar\beta\omega_s}}{2}\right)$$

This expression is valid only if $\beta\hbar\omega_s\ll 1$. The classical limit can be obtained formally taking the limit $\hbar\to 0$. As in the classical case, the response function for large t really vanishes in the limit of large system.

§ 5. Application to the Calculation of Time of Flight

We shall be concerned here with an application of the method shown in the previous sections. As an application it is of some interest to consider the problem of time of flight of gaseous particle scattered elastically by fixed scattering centers, the number of the incident particles is expected to diminish continuously.

Let us start with the Hamiltonian in momentum representation

$$\mathscr{H}=\sum_{\boldsymbol{k}} \varepsilon_k a_{\boldsymbol{k}}^* a_{\boldsymbol{k}}+\sum_{\boldsymbol{k},\boldsymbol{l}} V_{\boldsymbol{k}\boldsymbol{l}} a_{\boldsymbol{k}}^* a_{\boldsymbol{l}} \, . \tag{5.1}$$

The equation of motion, in Heisenberg representation, for the operator $a_{\boldsymbol{k}}$ is

$$\hbar a_{\boldsymbol{k}}=i[\mathscr{H}, a_{\boldsymbol{k}}]=-i\varepsilon_{\boldsymbol{k}} a_{\boldsymbol{k}}-i \sum_{\boldsymbol{k},\boldsymbol{l}} V_{\boldsymbol{k}\boldsymbol{l}} a_{\boldsymbol{l}} \, . \tag{5.2}$$

$$a_{\boldsymbol{k}}=\sum_n c_{kn} A_{\boldsymbol{n}} e^{-iE_n t/\hbar} \, . \tag{5.3}$$

$$\sum_n c_{ln}^* c_{kn}=\delta_{lk} \, . \tag{5.4}$$

where n stands for the eigen-state which reduces, when interaction vanishes, to the unperturbed level with the wave vector $\boldsymbol{n}$. We have written c_{kn} for $c_{\boldsymbol{k}\boldsymbol{n}}$ and $\delta_{l,k}$ for $\delta_{\boldsymbol{l},\boldsymbol{k}}$. Annihilation and creation operators A_n and A_m^*, for eigenstates satisfy the same commutation relations as $a_{\boldsymbol{k}}$ and a_k^*.

From Eqs. (5.2), (5.3) and (5.4) we obtain

$$(\varepsilon_k-E_n)c_{kn}+\sum_l V_{\boldsymbol{k}l} c_{ln}=0 \, . \tag{5.5}$$

The occupation number $n_k(t)$ in the state k can be written as

$$n_k=(t)\langle a_{\boldsymbol{k}}^* a_{\boldsymbol{k}}\rangle=\mathrm{Tr}\,(a_{\boldsymbol{k}}^* a_{\boldsymbol{k}}\rho) \, . \tag{5.6}$$

where ρ is the density matrix which characterizes the total system.

Inserting Eq. (5.3) to Eq. (5.6), we get

$$n_k(t)=\sum_n \sum_m e^{-i(E_n-E_m)t/\hbar} c_{kn}^* c_{km} \langle A_m^* A_n\rangle \, . \tag{5.7}$$

We have to note the fact that in Heisenberg representation ρ do not depend upon time, but A_n depends upon time.

Now we assume that at t=0, an incident particle was found in the state s, that is, $n_k(0)=0$ $(k\neq s)$, $n_s(0)=1$. To satisfy this initial condition, we shall take $\langle A_m^* A_n\rangle$ equal to $c_{sn}^{*\prime} c_{sm}^*$. Then we obtain

$$n_s(t)=|S|^2 \, , \qquad S=\sum_n |c_{sn}|^2 e^{-i(E_n-E_0)t/\hbar} \, . \tag{5.8}$$

where E_0 is an arbitary constant which can be chosen appropriately so as to facilitate the calculation.

First we shall assume a scattering center at the position $\boldsymbol{R}$, and further that its size is very small compared with the wave length in question, that is, the wave length of the order of the incident particle. If we denote by $v(\boldsymbol{r}-\boldsymbol{R})$ the potential of the scatterer, we have

$$v_{\boldsymbol{k}\boldsymbol{l}}=\lambda e^{-i(\boldsymbol{k}-\boldsymbol{l})\cdot\boldsymbol{R}} \, ,$$

with

$$\lambda=\frac{1}{V}\int v(\boldsymbol{r})d\boldsymbol{r} \, . \tag{5.9}$$

when the scatterer is very small in size. Eq. (5.5) reduces to

$$(\varepsilon_k-E_n)c_{kn}'+\lambda \sum c_{ln}'=0 \, , \qquad c_{kn}'=c_{kn}\cdot e^{i\boldsymbol{k}\cdot\boldsymbol{R}} \, . \tag{5.10}$$

we have therefore the equation determining E_n:

$$\sum_k \frac{1}{\varepsilon_k-E_n}=-\frac{1}{\lambda} \, . \tag{5.11}$$

and, normalizing c_{kn}' by Eq. (5.4), we have

$$c_{kn}'=\frac{c_n}{(\varepsilon_k-E_n)} \, , \qquad c_n^2=\frac{1}{\sum_k \{1/(\varepsilon_k-E_n)^2\}} \, . \tag{5.12}$$

To solve Eq. (5.11) in a closed from we shall simplify the structure of the unperturbed energy levels. This simplification ought to be legitimate. Usually we assume the system which is a regular cube in form. In this case each level is generally three-fold degenerate because of symmetry. The degeneracy, however, can be removed by a slight change in the form of system. We see that we may assume non-degenerate energy scheme. Then it is permitted to set numbering $k=\cdots 1, 2, \cdots$ for the levels, in such a way that the energy of the level with smaller k is lower than that with larger k value. The number k thus defined is to be distinguished with causion from the wave number $|\boldsymbol{k}|$.

An incident particle initially in the level $k=s$ will be shifted to another level by collision with the scattering center. Since the unperturbed level ε_s is not an eigenstate of the total system, the incident particle is scattered to another level with slightly different energy.

Thus it seems legitimate to approximate the unperturbed energy levels near the energy ε_s of the incident particle by levels equidistantly placed. That is

$$\varepsilon_k=\varepsilon_s+(k-s)\varepsilon \, . \tag{5.13}$$

where k runs from $-\infty$ to ∞, and the level distance $\mathcal{E}$ is equal to the inverse of the level density.

By the use of Eqs. (5.11) and (5.13), we get the equation which the eigenvalues E_n satisfy:

$$\frac{\pi\lambda}{\mathcal{E}} \cot \frac{\pi}{\mathcal{E}} E_n = 1 . \tag{5.14}$$

Since this equation is of the same from as Eq. (3.17), we can easily obtain the following results.

$$\left.\begin{aligned} E_n &= E_s + (n-s)\mathcal{E} , \\ E_s &= \frac{\mathcal{E}}{\pi} \operatorname{Tag}^{-1} \frac{\pi\lambda}{\mathcal{E}} + \mathcal{E}_s , \\ c_{sn}' &= \frac{C}{\mathcal{E}[a-(n-s)]} . \end{aligned}\right\} \tag{5.15}$$

where

$$C^2 = \left(\frac{1}{\mathcal{E}^2} \sum_{k=-\infty}^{\infty} \frac{1}{\{k-((\lambda+E_n)/\mathcal{E})\}^2} \right)^{-1} = \frac{\lambda^2}{1+\pi\lambda^2/\mathcal{E}^2} ,$$

and

$$a = -\frac{1}{\pi} \operatorname{Tag}^{-1} \frac{\pi\lambda}{\mathcal{E}} .$$

Now, at $t=0$ there is a incident particle in the level s. At later instant the expectation value of the number of particle in this state is $n_s(t) = |S|^2$ as is given by Eq. (5.8).

Taking the arbitary constant in Eq. (5.8) to $E_s - s\mathcal{E}$, by the use of Eq. (5.15) we get the result

$$\begin{aligned} S &= \sum_{n=-\infty}^{\infty} \frac{C^2 e^{i[a-(n-s)]\mathcal{E}t/\hbar}}{\mathcal{E}^2[a-(n-s)]^2} \\ &= \frac{C^2}{\mathcal{E}^2} \left\{ \pi^2 \operatorname{cosec}^2(\pi a) + \pi[it \cot(\pi u) - |t|] \frac{\mathcal{E}}{\hbar} \right\} , \\ & \qquad 0 < \frac{\mathcal{E}|t|}{\hbar} < 2\pi . \end{aligned} \tag{5.16}$$

In virtue of Eq. (5.15) we obtain from Eq. (5.13)

$$\begin{aligned} n_s(t) &= 1 - \frac{\lambda^2}{\mathcal{E}^2 + \pi^2\lambda^2} \left\{ 2\pi \frac{\mathcal{E}|t|}{\hbar} - \left(\frac{\mathcal{E}t}{\hbar} \right)^2 \right\} , \\ & \qquad 0 \leq \frac{\mathcal{E}|t|}{\hbar} \leq 2\pi . \end{aligned} \tag{5.17}$$

$n_s(t)$ is seen to be a periodic function of $\mathcal{E}t/\hbar$ with period 2π. This strict recurrence is, of course, due to the approximation of equidistant levels given by Eq. (5.13).

Here we have to estimate the order of magnitude of $\lambda/\mathcal{E}$. λ is inversely proportional to the volume V as is seen from Eq. (5.9). $\mathcal{E}$, the inverse of the level density, is also inversely proportional to the volume. If the scattering center has radius δ and potential depth U_0,

$$\lambda = \frac{4\pi}{3} \frac{U_0 \delta^3}{V_0} . \qquad (|\boldsymbol{k}|\delta \ll 1) .$$

If the mass of the incident particle is m, the total cross section is[9]

$$\sigma = 16\pi(mU_0\delta^3/3\hbar^2)^2 .$$

On the other hand, the level density $g(\mathcal{E}_s)$ is given by

$$\frac{1}{\mathcal{E}} = g(\mathcal{E}_s) = V \frac{4\pi}{(2\pi)^3} |\boldsymbol{k}|^2 d|\boldsymbol{k}|/d\mathcal{E}_s .$$

where $\mathcal{E}_s = \hbar^2|\boldsymbol{k}|^2/2m$. Therefore in the order of magnitude

$$\frac{\lambda}{\mathcal{E}} \sim \frac{U_0}{\mathcal{E}_s} (|\boldsymbol{k}|\delta)^3 \sim \sigma^{1/2} |\boldsymbol{k}| .$$

Since δ is assume so small as $|\boldsymbol{k}|\delta \ll 1$, except for very strong scattering center we way assume that

$$|\lambda/\mathcal{E}| \ll 1 .$$

For instance, the wave number of electrons in solid is of the order of the atomic spacing, and we may expect this criterion to be valid for usual disturbing potential in solid.

From Eq. (5.17), the change in $n_s(t)$ with time is primarily governed by the constant

$$\beta = 2\pi \frac{\lambda^2}{\mathcal{E}\hbar} .$$

The time of flight or the life time is β^{-1}, which is of the order

$$\beta^{-1} \sim \frac{V/\sigma}{v} .$$

where $v = \hbar|\boldsymbol{k}|/m$ is the velocity of incidence. Under these circumstances, if these is only one scatterer, the life time is very long. Usual decay can be expected when there are many scattering centers randomly distributed.

Finally we shall assume N scattering centers fixed randomly at $\boldsymbol{R}_1$, $\boldsymbol{R}_2$, $\cdots$, $\boldsymbol{R}_N$. In this case, instead of Eq. (5.9) we have

$$\hbar \dot{a}_{\boldsymbol{k}} = -i\mathcal{E}_k a_{\boldsymbol{k}} - i\lambda \sum_{\mu=1}^{N} \sum_{l} e^{i(\boldsymbol{l}-\boldsymbol{k})\cdot\boldsymbol{R}_\mu} a_{\boldsymbol{l}} .$$

Taking the eigenstates n as before, we write

$$a_{\boldsymbol{k}} = \sum_n D_{kn} A_{\boldsymbol{n}} e^{-iE_n t/\hbar} .$$

Then we obtain

$$\begin{aligned} (\mathcal{E}_k - E_n) D_{kn} = -\lambda \{ & e^{-i\boldsymbol{k}\cdot\boldsymbol{R}_1} \sum_l e^{i\boldsymbol{l}\cdot\boldsymbol{R}_1} D_{ln} \\ & + e^{-i\boldsymbol{k}\cdot\boldsymbol{R}_2} \sum_l e^{i\boldsymbol{l}\cdot\boldsymbol{R}_2} D_{ln} + \cdots \\ & + e^{-i\boldsymbol{k}\cdot\boldsymbol{R}_N} \sum_l e^{i\boldsymbol{l}\cdot\boldsymbol{R}_N} D_{ln} \} . \end{aligned} \tag{5.18}$$

The way to solve this equation is to decompose the orthogonal transformation, represented by D_{kn}, into N step rotations; the first rotation to eliminate the first term in the right hand side of Eq. (5.18), the second rotation to eliminate the second term and so on. Let

$$D_{kn}=D^{(1)}_{kn}e^{-i\boldsymbol{k}\cdot\boldsymbol{R}_1}\ . \tag{5.18$'$}$$

We have

$$(\mathcal{E}_k-E_n)D^{(1)}_{kn}+\lambda\sum D^{(1)}_{ln}$$
$$=-\lambda\{\sum_{\mu\geq 2}{}' e^{-i\boldsymbol{k}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_1)}\sum_l e^{i\boldsymbol{l}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_1)}D^{(1)}_{ln}\ .\} \tag{5.19}$$

Therefore we shall proceed to the second rotation by putting

$$D^{(1)}_{kn}=\sum_m C^{(1)}_{km}D^{(2)}_{mn}e^{-i\boldsymbol{k}\cdot(\boldsymbol{R}_2-\boldsymbol{R}_1)}\ . \tag{5.19$'$}$$

where $C^{(1)}_{km}$ is the coefficient C'_{km} given by Eq. (5.10), i.e.

$$C^{(1)}_{kn}=\frac{C_m{}^{(1)}}{\mathcal{E}_k-E_m{}^{(1)}}\ . \tag{5.20}$$

with the roots $E_m{}^{(1)}$ of the equation

$$\sum_k\frac{1}{\mathcal{E}_k-E_m{}^{(1)}}=-\frac{1}{\lambda}\ . \tag{5.20$'$}$$

and $C^{(1)}_{kn}$ is determined by the condition of ortho-normality.

$$\sum_k C^{(1)*}_{kn}C^{(1)}_{km}=\delta_{n,m}\ . \tag{5.20$''$}$$

Inserting Eq. (5.19′) into Eq. (5.19) we get

$$\sum_m(E_n{}^{(1)}-E_n)C^{(1)}_{km}D^{(2)}_{mn}$$
$$+\lambda\sum_{n\geq 2}{}' e^{-i\boldsymbol{k}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}\sum_l\sum_{m'} e^{i\boldsymbol{l}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}C^{(1)}_{lm'}D^{(2)}_{mn'}=0\ . \tag{5.21}$$

After multiplying (5.21) by $C^{(1)*}_{km'}$ and suming over k, we get, in virtue of Eq. (5.20)″, the result

$$(E_m{}^{(1)}-E_n)D^{(2)}_{mn}+\lambda\sum_{\mu\geq 2,}{}'\sum_k e^{-i\boldsymbol{k}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}C^{(1)*}_{km}$$
$$\times\sum_{m'}\sum_l e^{i\boldsymbol{l}_1\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}C^{(1)}_{lm'}D^{(2)}_{m'n}=0\ . \tag{5.22}$$

where we have interchanged the roles of m and m'

We have therefore to calculate the sums oven $\boldsymbol{k}$ and $\boldsymbol{l}$ in second term of Eq. (5.22). For $\mu=2$ we get immediately, by Eq. (5.22)′

$$\sum_k C^{(1)*}_{km}=\frac{1}{\lambda}C_m{}^{(1)*}\ ,\qquad \sum_l C^{(1)}_{lm'}=\frac{1}{\lambda}C^{(1)}_{m'}\ . \tag{5.23}$$

To get through the calculation we shall here adopt the approximation of equidistant levels given by Eq. (5.8).

Then by Eq. (5.10)

$$C_m{}^{(1)}=\frac{\lambda}{\sqrt{1+\pi^2\lambda^2/\mathcal{E}^2}}\simeq\lambda\ . \tag{5.24}$$

For $\mu\neq 2$ we have

$$\sum_l\frac{e^{-i\boldsymbol{k}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}}{\mathcal{E}_l-E_m{}^{(1)}}C_m{}^{(1)*}\simeq\frac{e^{-i\boldsymbol{m}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}}{\mathcal{E}_m-E_m{}^{(1)}}C_m{}^{(1)*}$$
$$=\frac{1}{2}C_m{}^{(1)*}e^{-i\boldsymbol{m}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}\ . \tag{5.25}$$

where we have assumed λ small and have taken out the largest contribution. A similar equation holds for the sum over l and hence Eq. (5.22) turns out to be

$$(E_m{}^{(1)}-E_n)D^{(2)}_{mn}+\lambda\sum_{m'}D^{(2)}_{mn'}$$
$$+\lambda\sum_{\mu 23}{}'' e^{-i\boldsymbol{m}\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}\sum_{m'}e^{-i\boldsymbol{m}'\cdot(\boldsymbol{R}_\mu-\boldsymbol{R}_2)}D^{(2)}_{m'n}=0\ . \tag{5.26}$$

This equation for $D^{(2)}_{mn}$ has the same form as Eq. (5.18) for $D^{(1)}_{ln}$, and so we can proceed in the same way. We put

$$D^{(2)}_{mn}=\sum_{m'}C^{(2)}_{mm'}D^{(3)}_{m'n}e^{-i\boldsymbol{m}\cdot(\boldsymbol{R}_3-\boldsymbol{R}_2)}\ . \tag{5.26$'$}$$

and eliminate the term $\mu=3$ in the last equation. Then we get an equation for $D^{(3)}_{m'n}$ which is the same in form as Eqs. (5.19) or (5.26).

Thus we can repeat the same procedure and get finally the result

$$D_{kn}=e^{-i\boldsymbol{k}\cdot\boldsymbol{R}_1}\sum_{m'}\sum_{m''}\cdots\sum_{m^{(N-1)}}C^{(1)}_{km'}C^{(2)}_{m'm''}C^{(3)}_{m''m'''}\cdots$$
$$C^{(N)}_{m^{(N-1)}n}\cdot e^{-i\boldsymbol{k}\cdot(\boldsymbol{R}_2-\boldsymbol{R}_1)}\cdot e^{-i\boldsymbol{m}'\cdot(\boldsymbol{R}_3-\boldsymbol{R}_2)}\cdots$$
$$\cdot e^{-i\boldsymbol{m}(N-1)\cdot\boldsymbol{R}_N}\ . \tag{5.27}$$

which expresses N step rotations to bring the states to coincide the eigen-states. For each rotation $C^{(u)}_{mm'}$ is given by an equation analogous to Eq. (5.15). As we are assuming λ small,

$$C^{(u)}_{mm'}=-\lambda/[\lambda+(m'-m)\mathcal{E}]$$
$$E^{(u)}_{m'}-E^{(u-1)}_{m}=\lambda+(m'-m)\mathcal{E}$$
$$E_n=\mathcal{E}_s+N\lambda+(n-s)\mathcal{E}$$

These equations hold for small λ.

We impose the same initial condition as before. That is, at $t=0$, $n_s(0)=1$, $n_k(0)=0$ $(k\neq s)$. This is satisfied by choosing the state $\langle A_m{}^*A_n\rangle=D_{sm}{}^*D_{sn}$. We have

$$n_s(t)=|S|^2\ ,\quad S=\sum_n|D_{sn}|^2e^{-i(E_n-E_0)t/\hbar}\ . \tag{5.29}$$

where E_0 is a constant which can be chosen appropriately.

Under the supperposition that the scatterers are distributed randomly, the equation

$$\sum_{n=-\infty}^{\infty} \frac{e^{i\{\lambda/\varepsilon+(n-m)\}x}}{\{\lambda/\mathcal{E}+(n-m_1)\}\{\lambda/\mathcal{E}+(n-m)\}} e^{-i(\boldsymbol{m}-\boldsymbol{m}_1)\cdot\boldsymbol{R}_\mu}$$

can be replaced by

$$\delta_{m_1,m}\{\pi^2 \operatorname{cosec}^2(\pi\lambda/\mathcal{E})+\pi(-|x|+ix\cot(\pi\lambda/\mathcal{E})\} ,$$
$$0\leq|x|<2\pi . \tag{5.30}$$

where x stands for $\mathcal{E}t/\hbar$; m_1 and m stand for $m^{(N-1)}$ and a similar suffix in $|D_{sn}|^2$. We first sum up over $n-m^{(N-1)}$, next over $m^{(N-1)}-m^{(N-2)}$ and so on. We then split E_n-E_0 as

$$(E_n-E_0)/\mathcal{E}=\{\lambda/\mathcal{E}+(n-m^{(N-1)})\}$$
$$+\{\lambda/\mathcal{E}+(m^{(N-1)}-m^{(N-2)})\}+\cdots$$
$$+\{\lambda/\mathcal{E}+(m'-s)\} .$$

By the repeated use of Eq. (5.30), we obtain finally

$$n_s(t)=\left[1-\frac{\lambda^2}{\mathcal{E}^2}\left\{2\pi\frac{\mathcal{E}|t|}{\hbar}-\left(\frac{\mathcal{E}t}{\hbar}\right)^2\right\}\right]^N .$$

As $\mathcal{E}$ is taken very small, for large N, we get exponential decay of the incident beam;

$$n_s(t)=e^{-\beta|t|} . \tag{5.32}$$

with the decay constant

$$\beta=2\pi\frac{\lambda^2 N}{\mathcal{E}\hbar} .$$

This result agrees with that obtained by usual perturbation treatment. That is, the transition probability from the level l to k is given by

$$p=\frac{2\pi}{\hbar}|V_{kl}|^2 g(\mathcal{E}_k)=\frac{2\pi}{\hbar}\cdot\frac{\lambda^2}{\mathcal{E}} .$$

Hence, one should expect the equation

$$\frac{dn_s}{dt}=-Npn_s .$$

which after integration, gives Eq. (5.32) for $t\geq0$.

§ 6. Concluding Remarks and Acknowledgements

For small system with finite degrees of freedom, the initial state will be reproduced by any desired degree of accuracy. This follows from the general theorem in dynamics due to Poincaré. For large system, however, we may expect, in general, no recurrence in a finite time interval. In fact irreversibility is a very general phenomena common to physical systems. We have confined ourselves to simple systems to clarify irreversibility. However, for the purpose of dealing with more general cases the following way of approximation will be of some value.

To find the approximate expression for c_{sn}, for the first model system of § 2, we may take only the main term of Eq. (2.8) and neglect other terms in which ω_j is far from Ω_n. That is

$$\omega_s{}^2-\Omega_n{}^2\simeq\Lambda_{sn}^2/(\omega_n{}^2-\Omega_n{}^2) ,$$
$$c_{sn}^2\simeq\frac{1}{\Lambda_{ns}^2}(\omega_n{}^2-\Omega_n{}^2)^2\simeq\frac{\Lambda_{ns}^2}{(\omega_s{}^2-\Omega_n{}^2)^2} .$$
$$n\neq s \tag{6.1}$$

However, c_{sn} is to be normalized in such a way that

$$1=\sum_n c_{sn}^2\simeq\int c^2(\Omega)d\Omega . \tag{6.2}$$

The summation over n has be replaced by integration over as N tends to infinity. However, we have to notice the fact that the expression Eq. (6.1) for c_{sn}^2 fails when n is too close to s. Eq. (6.1) means that except for the immediate neighbourhood of ω_s, the number of oscillators in the range $d\Omega$ is

$$c^2(\Omega)d\Omega\simeq g(\Omega)d\Omega\frac{\lambda^2(\Omega)}{(\omega_s{}^2-\Omega^2)^2}\simeq g(\Omega)d\Omega\frac{\lambda^2(\Omega)/4\omega_s{}^2}{(\omega_s-\Omega)^2} . \tag{6.3}$$

For $\Omega\sim\omega_s$ Eq. (6.3) should be modified. The simplest way to satisfy normalization condition Eq. (6.2), is to modify Eq. (6.3) as

$$c^2(\Omega)d\Omega=\frac{1}{\pi}\frac{\beta}{\beta^2+(\omega_s-\Omega)^2}d\Omega , \tag{6.4}$$

where

$$\beta=\frac{\pi}{4}\frac{g(\Omega)}{\omega_s{}^2}\lambda^2(\Omega)$$

Since Eq. (6.4) is equivalent to Eq. (3.9), this sort of way of approximation seems to apply to many cases where exact calculation is not capable.

The author wishes to express his hearty thanks to Prof. Toda of Tokyo University of Education for extremely helpful discussions throughout the entire course of the work.

A New Picture of the Vibration of Linear Lattices

By Jun-ichi HORI

Department of Physics, Hokkaido University, Sapporo

(Received September 9, 1960)

A new version of the method of transfer matrix is presented, which largely simplifies the derivation of eigenfrequency equation, on the one hand, and gives rise to a very simple and vivid picture (vector picture), on the other hand, of the normal vibration for the linear isotopic lattices. By using this version and the vector picture, the wave forms of the extra- and in-band vibrations of the lattices containing a small amount of impurity and the eigenfrequency spectrum of generalized diatomic lattices are discussed, obtaining some interesting conclusions.

§ 1. Introduction

Some years ago the author devised a simple and effective method of treating the problem of vibration of linear lattices (method of transfer matrix), and treated several cases of regular and disordered lattices, obtaining some interesting results[1),2)]. In the present paper, a more effective version of the transfer-matrix method is presented, and some further results obtained by this new version concerning the frequency spectrum of generalized diatomic lattices and the impurity modes of disordered lattice are reported.

In § 2, we first show that, if we use a new representation (vector representation) of the transfer matrices, we can visualize very vividly the vibration of linear lattice as successive regular or random transformations of a complex vector on the complex plane. We shall call such a visualization " vector picture ". It is the main object of the paper to demonstrate how the vector representation and vector picture shed new light on the understanding of linear-lattice vibration.

In § 3, we illustrate by a simple example that the vector picture enables us to derive the eigenfrequency equation in a very simple way and to give a remarkably intuitive explanation for the shift of eigenfrequencies due to impurities.

In § 4, the eigenfrequency equation for the lattice of the type

$$mm\cdots mMM\cdots M$$

and the lattice which contains the above lattice as its unit cell (so-called generalized diatomic lattice) are derived by using the vector representation. It is shown that there is an intimate connection between these two equations.

The vector picture leads to a simple graphical method of calculating the wave forms of normal vibrations. In § 5, we first calculate the wave forms of the impurity vibration and an in-band vibration of the lattice with a single impurity, and compare them with each other. It becomes clear that the former is localized whereas the latter is not. Next the spectra of a lattice with two impurities are calculated for the cases in which the distance between the impurities is maximum and minimum. In contrast to the former case where two impurity frequencies appear, there appears in the latter only one impurity mode: one of the two has got into the band. By calculating as an example the wave form of one of the in-band vibrations, it is shown that all the in-band vibrations have essentially simple harmonic character and are not localized, whether they may be proper in-band vibrations or " got-in " extra-band ones.

In § 6 we enter into discussion on the basis of the equation derived in § 4 of the band structure of generalized diatomic lattices. In addition to the results which prove to be the same as those obtained by Maradudin and Weiss[3)], we get some new results, for example, concerning the wave form of the vibrations corresponding to the frequencies at the boundaries of each band. It is also shown that the existence of forbidden bands can be explained very vividly by vector picture.

For random lattices, the successive transformations of the complex vector become a kind of two-dimensional random walk which forms a Markov process. In view of mathematical difficulties, we leave the analysis of this process for future investigations, and confine ourselves to some comments on the general feature of the process (§ 7). It is also shown that the fact discovered by Dean[4)] that the spectra of disordered diatomic lattices have extremely fine structure, which seems rather strange as judged from the hitherto supported general view that the spectra of disordered lattice have only moderate number of rounded peaks, can be explained very naturally on the analogy of generalized diatomic lattice.

§ 2. Polar Decomposition of the Transfer Matrices and the Vector Picture of Lattice Vibration

An arbitrary finite-dimensional matrix A can be represented as the product of a unitary matrix Z and a non-negative Hermite matrix P (polar decomposition):

$$A=ZP\,, \tag{2.1}$$

where P and Z are given by $(A^*A)^{1/2}$ and AP^{-1}, respectively[5)].

We consider in this paper only the linear lattice containing isotopic atoms. Out of the isotopes composing the lattice we choose a " basic isotope " at our convenience, and use its mass m to define β:

$$\omega^2=(4\lambda/m)\sin^2\beta\,, \tag{2.2}$$

where ω is the frequency and λ is the force constant. Then, according to I*, the transfer matrix corresponding to the atom belonging to this isotope (basic atom) is

$$1+\Lambda=\begin{pmatrix}\exp(2i\beta) & 0\\ 0 & \exp(-2i\beta)\end{pmatrix}, \tag{2.3}$$

and the transfer matrix for other atoms (non-basic atoms) has the form

$$Q=\begin{pmatrix}\exp(2i\beta)(1+i\mathcal{E}\tan\beta) & i\mathcal{E}\tan\beta\exp(-2i\beta)\\ -i\mathcal{E}\tan\beta\exp(2i\beta) & \exp(-2i\beta)(1-i\mathcal{E}\tan\beta)\end{pmatrix}, \tag{2.4}$$

where $\mathcal{E}=M/m-1$, M being the mass of the non-basic atom.**

Let us seek the polar decomposition of Q. Putting

$$\mathcal{E}\tan\beta=\tan\gamma\,, \tag{2.5}$$

the eigenvalues of the matrix Q^*Q come out to be

$$\mu_\pm=(\sec\gamma\pm\tan\gamma)^2\,. \tag{2.6}$$

Therefore the eigenvalues of $P=(Q^*Q)^{1/2}$ are given by

$$\mu_\pm{}^{1/2}=\sec\gamma\pm\tan\gamma\,. \tag{2.7}$$

---

* The author's first paper cited above will be referred to as I in the following.

** Since we treat in this paper only diatomic case, it is unnecessary to use the suffix to distinguish between different non-basic isotopes.

In I, Q was called impurity matrix. Here we avoid this terminology for two reasons. Firstly, in the general diatomic lattice it is meaningless to call one isotope regular and the other impurity. Secondly, even in the case in which one isotope may properly be called impurity, it is often convenient, as will be seen later, to take the impurity atom as the basic one. Then the name " impurity matrix " will give rise to confusion.

We shall always use the letter m for the mass of basic atom, and M for that of non-basic one.

The diagonalization matrix $\boldsymbol{V}$ and $\boldsymbol{V}^{-1}$ of $\boldsymbol{P}$ are easily obtained as

$$\boldsymbol{V}=\begin{pmatrix}\exp(-2i\beta)i(1-i\tan\gamma) & \exp(-2i\beta)i(1-i\tan\gamma)\\ \exp(2i\beta)\sec\gamma & -\exp(2i\beta)\sec\gamma\end{pmatrix} \tag{2.8}$$

and

$$\boldsymbol{V}^{-1}=(i/2\sec\gamma(1-i\tan\gamma))\begin{pmatrix}-\exp(2i\beta)\sec\gamma & -\exp(-2i\beta)i(1-i\tan\gamma)\\ -\exp(2i\beta)\sec\gamma & \exp(-2i\beta)i(1-i\tan\gamma)\end{pmatrix}. \tag{2.9}$$

We get therefrom

$$\boldsymbol{P}=\boldsymbol{V}\operatorname{diag}(\mu_+^{1/2},\mu_-^{1/2})\boldsymbol{V}^{-1}=\begin{pmatrix}\sec\gamma & -i\exp(-4i\beta)\tan\gamma\exp(-i\gamma)\\ i\exp(4i\beta)\tan\gamma\exp(i\gamma) & \sec\gamma\end{pmatrix}, \tag{2.10}$$

and

$$\boldsymbol{Z}=\boldsymbol{Q}\boldsymbol{P}^{-1}=\begin{pmatrix}\exp[i(2\beta+\gamma)] & 0\\ 0 & \exp[-i(2\beta+\gamma)]\end{pmatrix}. \tag{2.11}$$

In the representation in which $\boldsymbol{P}$ is diagonalized, $\boldsymbol{Z}$ becomes

$$\boldsymbol{V}^{-1}\boldsymbol{Z}\boldsymbol{V}=\begin{pmatrix}\cos(\gamma+2\beta) & i\sin(\gamma+2\beta)\\ i\sin(\gamma+2\beta) & \cos(\gamma+2\beta)\end{pmatrix}, \tag{2.12}$$

and consequently $\boldsymbol{1}+\boldsymbol{\Lambda}$ becomes

$$\boldsymbol{V}^{-1}(\boldsymbol{1}+\boldsymbol{\Lambda})\boldsymbol{V}=\begin{pmatrix}\cos(2\beta) & i\sin(2\beta)\\ i\sin(2\beta) & \cos(2\beta)\end{pmatrix}. \tag{2.13}$$

In what follows we shall use this representation throughout, unless otherwise stated, and call it "(complex) vector representation", for the reason which will become clear below. Moreover, we shall denote matrices in this representation by the same letters as has hitherto been used, i. e., by $\boldsymbol{Z}$, $\boldsymbol{P}$, $\boldsymbol{Q}$ and $\boldsymbol{1}+\boldsymbol{\Lambda}$.

Let us use the complex representation for the vector representing the state of each atom, and denote it by $\boldsymbol{x}=x+iy$ or $\boldsymbol{x}=(x,iy)^T$. Then $\boldsymbol{P}$ represents the operation of multiplying the real component x of $\boldsymbol{x}$ by $\sec\gamma+\tan\gamma$ and the imaginary component y by $\sec\gamma-\tan\gamma$ ($\boldsymbol{P}$-transformation). If we operate $\boldsymbol{Z}$ on $\boldsymbol{x}$, the resulting vector $\boldsymbol{x}'$ is, putting $\alpha=2\beta+\gamma$,

$$\boldsymbol{x}'=\begin{pmatrix}x'\\ iy'\end{pmatrix}=\begin{pmatrix}\cos\alpha & i\sin\alpha\\ i\sin\alpha & \cos\alpha\end{pmatrix}\begin{pmatrix}x\\ iy\end{pmatrix}=\begin{pmatrix}x\cos\alpha+iiy\sin\alpha\\ xi\sin\alpha+iy\cos\alpha\end{pmatrix},$$

or

$$\boldsymbol{x}'=(x+iy)\exp(i\alpha)=\boldsymbol{x}\exp(i\alpha). \tag{2.14}$$

This means that $\boldsymbol{Z}$ rotates an arbitrary complex vector $\boldsymbol{x}$ by an angle $2\beta+\gamma$ ($\boldsymbol{Z}$-rotation). Similarly $\boldsymbol{1}+\boldsymbol{\Lambda}$ rotates $\boldsymbol{x}$ by an angle 2β.

The vibration of linear lattice can thus be visualized as successive transformations of a complex vector on the complex plane: At basic atoms, the state vector $\boldsymbol{x}$ is merely rotated by the angle 2β. At non-basic atoms, $\boldsymbol{x}$ is subjected to a stretch (contraction) of its real component by the factor $\sec\gamma+\tan\gamma$ and a contraction (stretch) of its imaginary component by the factor $\sec\gamma-\tan\gamma$, and a following rotation by the angle $2\beta+\gamma$. We shall call this visualization the "vector picture".

§ 3. Vector Picture for the Regular Monatomic Lattice and the Lattice with one Impurity

Consider the linear lattice composed of N isotopic atoms. We adopt as before the cyclic boundary condition. Then if for some β there exist vectors which return to their initial position after N successive transformations as described in § 2, this gives an eigenfrequency according to (2.4). When the number of such vectors is finite, the phase of the vibration with this eigenfrequency is not arbitrary, but is determined uniquely or restricted to those which correspond to these "recurrent" vectors. If every vector is recurrent, the phase of the vibration is arbitrary.

It is well known that the eigenfrequencies of a regular monatomic lattice is given by

$$\beta = n\pi/N\,, \qquad n = 1, 2, \cdots, N/2 \ \text{ or } \ (N-1)/2\,. \tag{3.1}$$

In I it was shown that the phase of vibration is arbitrary except for the vibration at the band-edge. This corresponds to the fact that for regular lattices every transformation of the vector is a simple rotation by the constant angle 2β, and consequently, if $\beta = n\pi/N$, arbitrary vector is recurrent. At the band-edge, the absolute values of the displacements of neighboring two atoms are the same, so that the phase should be considered unique.

Next consider the lattice with one impurity. It we take the regular atom as the basic one, the state vector is subject to $\boldsymbol{P}$-transformation with following $\boldsymbol{Z}$-rotation only once. When the impurity is heavier than the regular atom, $\boldsymbol{P}$-transformation consists of a stretch of the real component and a contraction of the imaginary component, since then $\mathcal{E}>0$ and consequently $\gamma>0$. Fig. 1 shows successive transformations of the vector for this case, from which it is readily seen that in any normal vibration the phase cannot be arbitrary, in harmony with the result obtained in I.

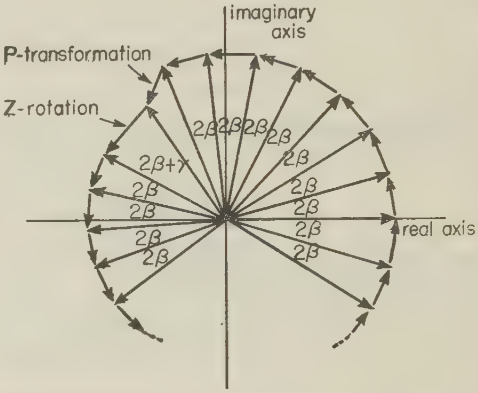

Fig. 1.

If we take the state vector of the atom just before the impurity as the initial vector $\boldsymbol{x}_0 \equiv (x_0 + iy_0)$, the eigenfrequencies are determined by the condition that $\boldsymbol{x}_0$ returns to itself after a $\boldsymbol{P}$-transformation with the following $\boldsymbol{Z}$-rotation and succeeding $N-1$ simple rotations by angle 2β, i.e., by the equation

$$\{x_0(\sec\gamma+\tan\gamma)+iy_0(\sec\gamma-\tan\gamma)\}\exp[i(2\beta+\gamma)]\exp[2i(N-1)\beta] = x_0+iy_0 \tag{3.2}$$

or

$$\left.\begin{aligned} x_0\{(\sec\gamma+\tan\gamma)\cos(2N\beta+\gamma)-1\}-y_0(\sec\gamma-\tan\gamma)\sin(2N\beta+\gamma)=0 \\ x_0(\sec\gamma+\tan\gamma)\sin(2N\beta+\gamma)+y_0\{(\sec\gamma-\tan\gamma)\cos(2N\beta+\gamma)-1\}=0 \end{aligned}\right\}. \tag{3.3}$$

These equations have non-trivial solution only if

$$\cos(2N\beta)-\mathcal{E}\tan\beta\sin(2N\beta)=1\,. \tag{3.4}$$

This is just the eigenfrequency equation derived in I.

From (3.4) we have the relations

$$\tan\gamma=(\cos(2N\beta)-1)/\sin(2N\beta)=-2\sin^2(N\beta)/2\sin(N\beta)\cos(N\beta)=-\tan(N\beta)\,, \tag{3.5a}$$

or

$$\sec\gamma=(N\beta)\,,\quad \cos\gamma=\cos(N\beta)\,,\quad \sin\gamma=-\sin(N\beta)\,,\quad \exp(2Ni\beta)=\exp(-2i\gamma)\,. \tag{3.5b}$$

For the solutions $\beta=n\pi/N$ of (3.4), however, these relations are not valid, for $\sin(2N\beta)=0$. Then (3.5b) should be replaced by

$$\cos(2N\beta+\gamma)=\cos\gamma\,,\qquad \sin(2N\beta+\gamma)=\sin\gamma\,,\qquad \exp(2Ni\beta)=1\,. \tag{3.6}$$

From (3.3) we obtain

$$x_0/y_0=[(\sec\gamma-\tan\gamma)\sin(2N\beta+\gamma)]/[(\sec\gamma+\tan\gamma)\cos(2N\beta+\gamma)-1]$$
$$=[(\sec\gamma-\tan\gamma)\cos(2N\beta+\gamma)-1]/[-(\sec\gamma+\tan\gamma)\sin(2N\beta+\gamma)]\ , \tag{3.7}$$

which becomes

$$x_0/y_0=(\sin\gamma-1)/\cos\gamma=-\cos\gamma/(1+\sin\gamma)\ , \tag{3.8}$$

for the case of (3.5) and

$$x_0/y_0=(1-\sin\gamma)/\cos\gamma=\cos\gamma/(1+\sin\gamma)\ , \tag{3.9}$$

for the case of (3.6).

When we return to the old representation in which Z and $1+\varLambda$ are diagonalized, we get, for the ratio of two components of the vector $\boldsymbol{x}_0$

$$\exp(-4i\beta-2i\gamma)=\exp(-4i\beta-2Ni\beta) \tag{3.10}$$

or

$$-\exp(-4i\beta)\ , \tag{3.11}$$

according as (3.5) or (3.6) is valid. These results are in accord with those obtained in I.

In the present case, the $\boldsymbol{P}$-transformation must be reduced to a simple rotation for $\boldsymbol{x}_0$ to return to itself after N transformations. (3.7) can be regarded as the solutions of this condition. In fact, the condition that $\boldsymbol{P}$-transformation conserves the length of $\boldsymbol{x}_0$ is

$$(\sec\gamma+\tan\gamma)^2x_0^2/y_0^2+(\sec\gamma-\tan\gamma)^2=x_0^2/y_0^2+1\ , \tag{3.12}$$

from which we get

$$x_0^2/y_0^2=[1-(\sec\gamma-\tan\gamma)^2]/[(\sec\gamma+\tan\gamma)^2-1]=(1-\sin\gamma)/(1+\sin\gamma) \tag{3.13}$$

which gives the same ratio x_0/y_0 as is obtained from (3.8) or (3.9).

The angle of rotation by $\boldsymbol{P}$-transformation must be γ for the case of (3.5) and $-\gamma$ for the case of (3.6). This can also be verified by the fact that the equation $\boldsymbol{P}\boldsymbol{x}_0=\exp(i\xi)\boldsymbol{x}_0$, or

$$\pm(\sec\gamma+\tan\gamma)(1-\sin\gamma)+i(\sec\gamma-\tan\gamma)\cos\gamma=\exp(i\xi)(\pm(1-\sin\gamma)+i\cos\gamma) \tag{3.14}$$

is satisfied by $\xi=\pm\gamma$.

In the case of (3.5), every eigenfrequency is smaller than the corresponding one for the regular lattice, since the vector is subjected to an excessive rotation by the angle 2γ, while in the case of (3.6), there are no shifts of eigenfrequencies since the vector is not subjected to any excessive rotation. This result is also in harmony with that attained in I. We thus see that the variation of the eigenfrequencies can be explained very intuitively by the vector picture.

The case of light impurity, i.e., the case $\varepsilon<0$ and $\gamma<0$ can also be discussed in a similar manner. Here, however, it should be remarked that, in order to visualize the operation of transfer matrices as the transformation of the complex vector, it is necessary for the matrix elements of $\boldsymbol{P}$ to be real and for the matrix $\boldsymbol{Z}$ to have the form (2.14), so that $\boldsymbol{Z}$ transforms the vector in such a way that the real component remains real and the imaginary component remains imaginary. For the extra-band frequencies which appear when $\varepsilon<0$, β and consequently γ becomes complex, which invalidates this condition. We should, therefore, take the lightest atom as the basic one, if we wish to use the vector picture also for the extra-band frequencies.

§ 4. The Eigenfrequency Equations for the Lattices of $mm\cdots mMM\cdots M$-type and the generalized diatomic lattice

Consider the lattice of the type

$$\underbrace{mmm\cdots m}_{q}\underbrace{MMM\cdots M}_{p} \tag{4.1}$$

The product of all the transfer matrices (total transfer matrix) $\boldsymbol{h}$ is then

$$\boldsymbol{h}=(\boldsymbol{1}+\boldsymbol{\Lambda})^q\boldsymbol{Q}^p\ . \tag{4.2}$$

Let us calculate $\mathrm{Tr}\,\boldsymbol{h}$. Putting

$$\mathrm{Tr}\,\boldsymbol{Q}=2\cos(2\beta+\gamma)\sec\gamma=2\cos\tau\ , \tag{4.3}$$

we obtain for the eigenvalues of $\boldsymbol{Q}$

$$\rho_\pm=\exp(\pm i\tau)\ , \tag{4.4}$$

and for the diagonalizing matrices

$$\boldsymbol{W}=\begin{pmatrix} -i(\sec\gamma-\tan\gamma)\sin(2\beta+\gamma) & -i(\sec\gamma-\tan\gamma)\sin(2\beta+\gamma) \\ (\sec\gamma+\tan\gamma)\cos(2\beta+\gamma)-\exp(i\tau) & (\sec\gamma+\tan\gamma)\cos(2\beta+\gamma)-\exp(-i\tau) \end{pmatrix}. \tag{4.5a}$$

and

$$\begin{aligned} \boldsymbol{W}^{-1}&=1/[2\sin\tau\sin(2\beta+\gamma)(\sec\gamma-\tan\gamma)] \\ &\times\begin{pmatrix} (\sec\gamma+\tan\gamma)\cos(2\beta+\gamma)-\exp(-i\tau) & i(\sec\gamma-\tan\gamma)\sin(2\beta+\gamma) \\ -(\sec\gamma+\tan\gamma)\cos(2\beta+\gamma)+\exp(i\tau) & -i(\sec\gamma-\tan\gamma)\sin(2\beta+\gamma) \end{pmatrix}. \end{aligned} \tag{4.5b}$$

The we have, putting $2\beta+\gamma\equiv\alpha$,

$$\begin{aligned} (\boldsymbol{1}+\boldsymbol{\Lambda})^q\boldsymbol{Q}^p&=(\boldsymbol{1}+\boldsymbol{\Lambda})^q\boldsymbol{W}\,\mathrm{diag}\,(\exp(ip\tau),\exp(-ip\tau))\,\boldsymbol{W}^{-1}=(1/\sin\tau) \\ &\times\begin{pmatrix} \begin{array}{l} (\sec\gamma+\tan\gamma)\cos\alpha\cos 2q\beta\sin p\tau \\ -\sin[(p-1)\tau]\cos 2q\beta \\ -(\sec\gamma+\tan\gamma)\sin 2q\beta\sin\alpha\sin p\tau \end{array} & \begin{array}{l} i(\sec\gamma-\tan\gamma)\sin\alpha\cos 2q\beta\sin p\tau \\ -i(\sec\gamma+\tan\gamma)\cos\alpha\sin 2q\beta\sin p\tau \\ +i\sin 2q\beta\sin[(p+1)\tau] \end{array} \\ \begin{array}{l} i(\sec\gamma+\tan\gamma)\cos\alpha\sin 2q\beta\sin p\tau \\ -i\sin 2q\beta\sin[(p-1)\tau] \\ +i(\sec\gamma+\tan\gamma)\sin\alpha\cos 2q\beta\sin p\tau \end{array} & \begin{array}{l} -(\sec\gamma-\tan\gamma)\sin\alpha\sin 2q\beta\sin p\tau \\ -(\sec\gamma+\tan\gamma)\cos\alpha\cos 2q\beta\sin p\tau \\ +\cos 2q\beta\sin[(p+1)\tau] \end{array} \end{pmatrix} \end{aligned} \tag{4.6}$$

and

$$\mathrm{Tr}\,\boldsymbol{h}=2\cos 2q\beta\cos p\tau-2\sin 2q\beta\sin p\tau\tan\alpha\cot\tau\ . \tag{4.7}$$

The eigenfrequency equation for the lattice of the type (4.1) is, therefore,

$$F(\beta)\equiv\mathrm{Tr}\,\boldsymbol{h}/2\equiv\cos 2q\beta\cos p\tau-\sin 2q\beta\sin p\tau\tan\alpha\cot\tau=1\ . \tag{4.8}$$

To get the eigenfrequencies, we have only to plot the function $F(\beta)$ and locate the crossings of it with the line representing the constant 1.

In the case of $m<M$, there is no real τ for the values of β near $\pi/2$ (band-edge), since $|\mathrm{Tr}\,\boldsymbol{Q}|$ becomes here larger than 2. We have to put $\tau=\pi+i\tau'$ in such a region to obtain the curve $F(\beta)$ for the whole region of β. As will be seen below (at the end of this section), the point at which the value of $|\mathrm{Tr}\,\boldsymbol{Q}|$ becomes larger than 2 gives the maximum eigenfrequency of the regular lattice composed only of non-basic atoms (M-lattice). The region of complex τ corresponds therefore to the extra-band region of M-lattice. It is of course possible for F(β) to become less than or equal to 1 also in this region.

When $m>M$, τ does not become complex within the band. In this case, however, $F(\beta)$ can be smaller than or equal to 1 for complex β, corresponding to the existence of extra-band frequencies. We should then put $\beta=\pi/2+i\zeta$ in order to obtain the complete frequency spectrum.

We next consider the lattice composed of L lattices of the type considered above, that is, the lattice which has the unit cells of the type (4.1) (the so-called generalized diatomic lattice). Its total transfer matrix $\boldsymbol{H}$ is given by

$$\boldsymbol{H}=\boldsymbol{h}^L . \tag{4.9}$$

Putting

$$F(\beta)=\cos 2q\beta \cos p\tau-\sin 2q\beta \sin p\tau \tan \alpha \cot \tau=\sec \delta , \qquad |F(\beta)|>1 , \tag{4.10a}$$

$$=\cos \sigma , \qquad |F(\beta)|\leqslant 1 , \tag{4.10b}$$

we obtain as the eigenvalues of $\boldsymbol{h}$:

$$\eta_{\pm}=\begin{cases}\sec \delta \pm \tan \delta , & |F(\beta)|>1 , \quad (4.11a)\\ \cos \sigma \pm i \sin \sigma=\exp (i\sigma) , & |F(\beta)|\leqslant 1 . \quad (4.11b)\end{cases}$$

Hence the eigenfrequency equation of the generalized diatomic lattice is

$$\mathrm{Tr}\, \boldsymbol{H}=\eta_+{}^L+\eta_-{}^L=2 . \tag{4.12}$$

In the case of (4.11b), the eigenfrequencies are given by

$$\sigma=2\pi n/L \qquad (n: \quad \text{integer}) , \tag{4.13}$$

since

$$\eta_+{}^L+\eta_-{}^L=2 \cos L\sigma . \tag{4.14}$$

In the case of (4.11a), on the contrary, there are no eigenfrequencies, inasmuch as (4.12) then becomes

$$(1+\sin \delta)^L+(1-\sin \delta)^L=2 \cos^L \delta , \tag{4.15}$$

the left-hand side of which is always larger than unity. We thus see that only the β-values for which $|F(\beta)|\leqslant 1$ can give rise to the eigenfrequencies. In other words, the intervals of β in which the curve $F(\beta)$ lies between $+1$ and -1 give the allowed bands of the frequency spectrum of generalized diatomic lattice. Other intervals correspond to the forbidden bands.

To sum up, the problem of obtaining the eigenfrequencies of the lattice of the type (4.1) and that of obtaining the frequency spectrum of generalized diatomic lattice whose unit cell is of the type (4.1) are reduced to one and the same problem of plotting the curve $F(\beta)$.

It is easy to get the eigenfrequency distribution within each allowed band. We have only to locate the points at which $F(\beta)$ crosses the lines representing the constant values $\cos [2\pi n/L]$ $(n=0, 1, 2, \cdots L/2$ or $(L-1)/2)$. Therefore, if L is even, the β-values for which $F(\beta)=\pm 1$ give the edges of allowed bands. Since the equation $F(\beta)=\pm 1$ or $\mathrm{Tr}\, \boldsymbol{h}=\pm 2$ expresses the condition that the corresponding atoms in the neighboring two unit cells have the same or opposite state vectors, the cyclic boundary condition here adopted for the whole lattice is obviously satisfied when $F(\beta)=\pm 1$, as long as L is even. When L is odd, one edge of each allowed band is given by $F(\beta)=\cos [(L-1)\pi/L]$. Since, however, for large L the value of the right-hand side is almost equal to unity, we may consider that for long lattices both edges of the allowed band are given by $F(\beta)=\pm 1$ whether L may be even or odd.

The fact explained just above means that, in the normal vibrations corresponding to the frequencies at the edges of the allowed band, the atoms at the corresponding positions of the two neighboring unit cells vibrate in the same or opposite directions. For ordinary diatomic lattices this fact is already well known. It will be shown in § 6 that the solutions of $F(\beta)$ $=\pm 1$ in fact give the well-known frequencies at the edges of acoustical and optical branches.

It is to be noted that, for the special case of $L=2$, the eigenfrequency equation is given by $F(\beta)=\pm 1$.

For M-lattice with even N, the equation which gives the eigenfrequencies corresponding to the edges of the band is $\mathrm{Tr}\, \boldsymbol{Q}=\pm 2$, since the total transfer matrix of the unit cell $\boldsymbol{h}$ is now reduced to $\boldsymbol{Q}$. In this case, however, there is only one allowed band, so that $\mathrm{Tr}\, \boldsymbol{Q}=2$

gives the minimum eigenfrequency, i. e., zero, and Tr $\boldsymbol{Q}=-2$ gives the maximum eigenfrequency. If N is odd, the latter is given by Tr $\boldsymbol{Q}=[\cos(N-1)\pi/N]$.

§ 5. Wave Forms of Impurity Vibrations

(i) One light impurity.

As was already noted, we have to take the impurity as the basic atom, in order to use the vector picture for the impurity vibration. This implies that we should consider the case $q=1$ of (4.1). In this case we have

$$F(\beta)=\cos 2\beta \cos p\tau-\sin 2\beta \sin p\tau \tan \alpha \cot \tau \ . \tag{5.1}$$

Fig. 2 shows the curve $F(\beta)$ for the case $p=6$ and $\mathcal{E}=1/2$. In general, if p is odd, the curve first descends to take large negative value as we get into the region $|\mathrm{Tr}\, Q|>2$, but soon begins to ascend rapidly without sloping down again. For even p the behavior is just opposite to the above. In either case, $F(\beta)$ takes the value 1 once and only once in the extra-band region of M-lattice (in this case, the regular lattice), which means that there is only one impurity vibration.

Let us calculate the wave form of this impurity vibration. To begin with, we consider the general lattice of the type (4.1). As the initial vector $\boldsymbol{x}_0$ take the state vector of the last (the leftmost) basic atom. Then $\boldsymbol{x}_0$ is the solution of

$$\boldsymbol{h}\boldsymbol{x}_0=(1+\boldsymbol{\Lambda})^q\boldsymbol{Q}^p\boldsymbol{x}_0=\boldsymbol{x}_0 \ . \tag{5.2}$$

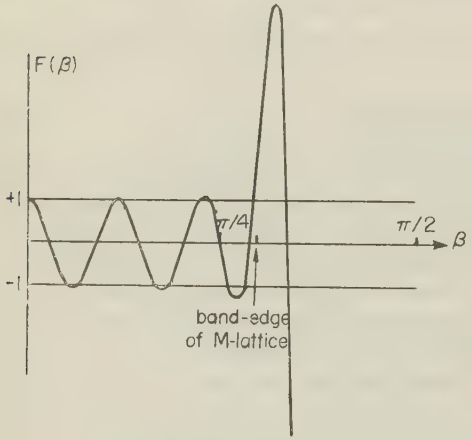

Fig. 2.

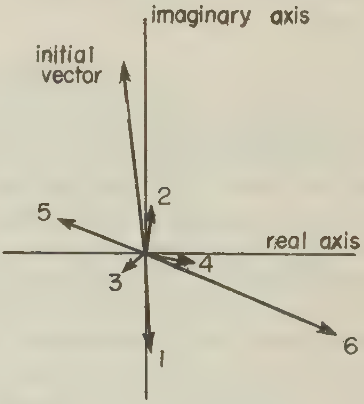

Fig. 3.

The ratio of the two components of $\boldsymbol{x}_0$ can be calculated by using (4.6), with the result that

$$\frac{x_0}{y_0}=\frac{\sin p\tau[\sec\gamma \sin(\alpha-2q\beta)-\tan\gamma \sin(\alpha+2q\beta)]+\sin 2q\beta \sin[(p+1)\tau]}{(\sin\gamma+\tan\gamma)\sin p\tau \cos(\alpha+2q\beta)-\sin[(p-1)\tau]\cos 2q\beta-\sin\tau} \tag{5.3a}$$

$$=\frac{\sin\tau+\sin p\tau[\sec\gamma \cos(\alpha-2q\beta)+\tan\gamma \cos(\alpha+2q\beta)]-\cos 2q\beta \sin[(p+1)\tau]}{(\sec\gamma+\tan\gamma)\sin p\tau \sin(\alpha+2q\beta)-\sin 2q\beta \sin[(p-1)\tau]} \ . \tag{5.3b}$$

The eigenfrequency equation (4.8) is none other than the condition that (5.3a) and (5.3b) should coincide with each other.

Putting $q=1$ in (5.3a) or (5.3b), and giving β the value corresponding to the impurity frequency, the initial vector $\boldsymbol{x}_0$ for the present case is obtained. Fig. 3 shows $\boldsymbol{x}_0$ and its successive transformations for the case $p=6$, $\mathcal{E}=1/2$. It is seen that $\boldsymbol{x}_0$ returns to itself after seven successive transformations, as it should be. It is also seen that the length of the vector at first diminishes rapidly, and afterwards increases rapidly again to return to its initial value. This clearly illustrates the localized property of the impurity vibration.

The localized property can be demonstrated much more concretely if we return to the original representation in which the two components of the state vector represent the displacement of the atom and the difference in displacement of the neighboring atoms. The matrix which transforms the present representation to the original one is, according to (I, 2.5) and (2.11a),

$$UV=\begin{pmatrix} \exp(-2i\beta)i(1-i\tan\gamma)+\exp(2i\beta)\sec\gamma & \exp(-2i\beta)i(1-i\tan\gamma)-\exp(2i\beta)\sec\gamma \\ i(1-i\tan\gamma)-\exp(-2i\beta)i(1-i\tan\gamma) & i(1-i\tan\gamma)-\exp(-2i\beta)i(1-i\tan\gamma) \\ +\sec\gamma-\exp(2i\beta)\sec\gamma & -\sec\gamma+\exp(2i\beta)\sec\gamma \end{pmatrix}. \tag{5.4}$$

Hence the displacement of the atom is given by

$$x'=(\sec\gamma+\sin 4\beta+\tan\gamma\cos 4\beta)x+(\tan\gamma\sin 4\beta-\cos 4\beta)y \tag{5.5}$$

in terms of the real and imaginary component in the vector representation. Fig. 4 shows the actual wave form obtained from Fig. 3 by aid of (5.5).

The in-band vibrations have, on the contrary, no such localized property. Figs. 5 and 6 show the successive transformations of the vector and the wave form, respectively, for the second inband frequency from the band-edge. It is seen that the wave form is nearly simple harmonic and not localized.

For the in-band frequencies we can construct the vector picture also when the regular atom is used as the basic one. The picture becomes even simpler, inasmuch as now all the transformations are simple rotations except the one at the impurity atom, where the vector is transformed by $\boldsymbol{P}$ and $\boldsymbol{Z}$. From this one can see that, for all the in-band frequencies, the amplitudes of successive regular atoms are just equal to the values of a sine-function at regularly spaced points. This is actually the case, as seen in Fig. 6.

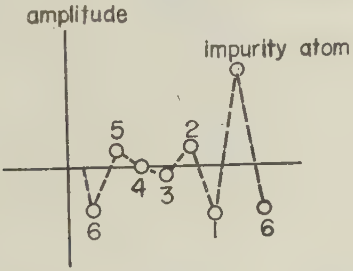

Fig. 4.

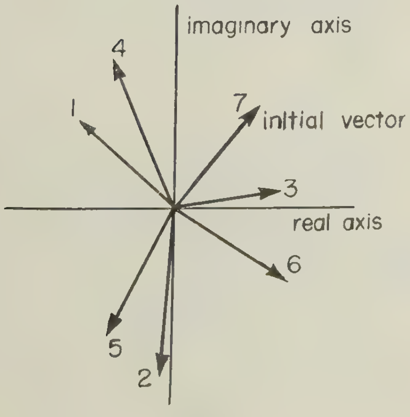

Fig. 5.

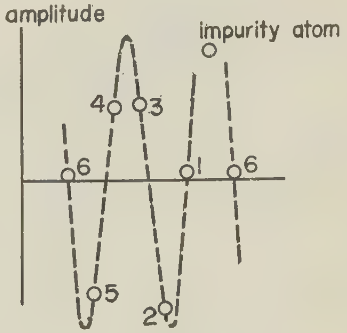

Fig. 6.

(ii) Two light impurities.

Consider first a lattice composed of 14 atoms, of which two are light impurities located at the largest possible distance from each other, i. e., with 6 regular atoms between them. Since such a lattice is a repetition of the lattice of the type considered in (i), the eigenfrequency equation is given by the expression (5.1) put equal to ±1, provided the impurity atom is taken as the basic one. The eigenfrequencies for the case $\varepsilon=1/2$ are given therefore by the points where the curve $F(\beta)$ of Fig. 2 crosses the lines representing ±1. It is seen that two impurity modes now make their appearance. Moreover, the upper mode is antisymmetric and the lower one is symmetric, according to the result obtained in § 4.

Next let us consider the case where the impurities are at the least distance from each other, i. e., they form a couple of the nearest neighbors. Since such a lattice is obtained by putting $q=2$ and $p=12$ in (4.1), the eigen-frequency equation is

$$F(\beta)=\cos 4\beta \cos 12\tau-\sin 4\beta\, 12\tau \tan \alpha \cos \tau=1\ . \tag{5.6}$$

Fig. 7 shows the curve $F(\beta)$, which indicates that an excess in-band frequency appears near the band-edge, whereas one of the two impurity frequencies disappear and the other is shifted to a remarkably higher position. This can be interpreted as that, owing to the mutual interaction of the impurity atoms, two impurity frequencies have been largely separated, and the lower one has got into the band.

From the statement made at the end of (i), it is almost clear that all the in-band vibrations are essentially simple harmonic and not localized, whether they may be proper in-band

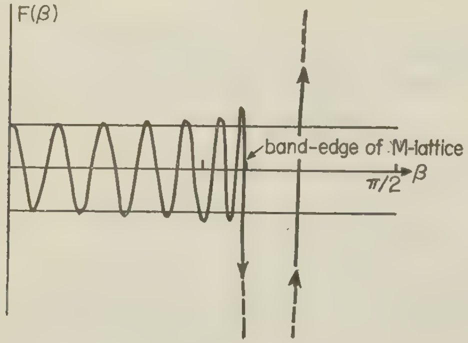

Fig. 7.

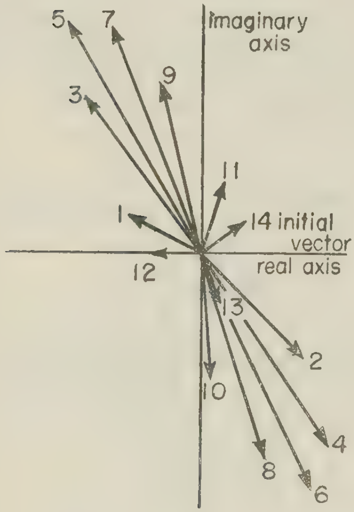

Fig. 8.

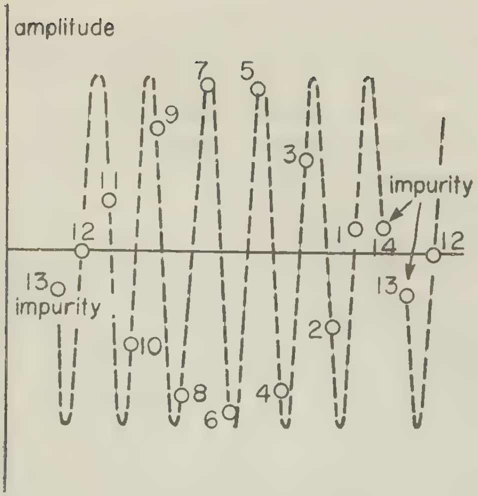

Fig. 9.

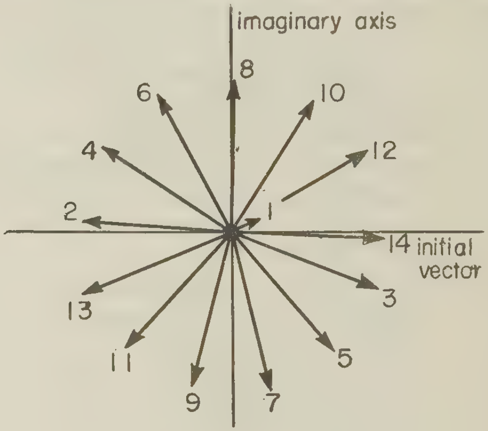

Fig. 10.

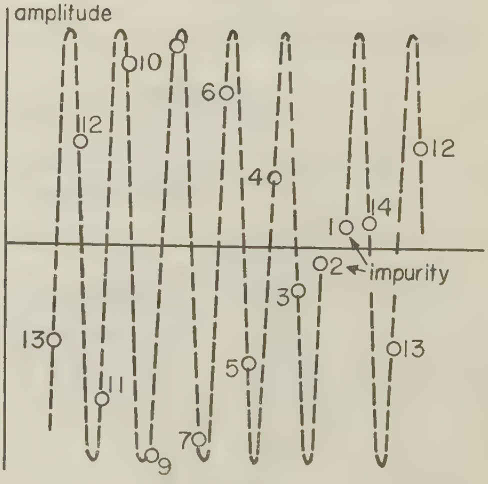

Fig. 11.

vibrations or "got-in" extra-band ones. As an example, Figs. 8 and 9 show the transformations of the vector and the wave form, respectively, for the uppermost in-band vibration, obtained by the same method as described above. They show very vividly that this vibration is no more localized, but has essentially the same character as a simple harmonic wave. This can be seen more clearly if we take the regular atom as the basic one. Figs. 10 and 11 show the vector picture and the wave form, respectively, so obtained.

§ 6. Frequency Spectrum of Generalized Diatomic Lattice

In § 4 is was shown that the frequency spectrum of the generalized diatomic lattice and that of its unit cell is obtained from one and the same curve $F(\beta)$. Therefore, for example, the allowed bands of the lattice in which the mass of every seventh atom is two-thirds of that of host atom, and those of the lattice in which two light atoms appear in pairs in every 13th and 14th positions, are given by the intervals in which each of the curves in Fig. 2 and Fig. 7 lies between $+1$ and -1. The number of allowed bands is thus equal to the number of atoms in the unit cell.

In general, the allowed bands become wider, and the forbidden bands narrower, as the frequency becomes higher. When in particular the basic atom is lighter and fewer than non-basic atoms, the curve $F(\beta)$ falls or rises very rapidly and only once in the extra-band region of M-lattice, the gradient of fall or rise becoming extremely steep as the unit cell becomes longer. The allowed band which originates from this last fall or rise corresponds precisely to the so-called impurity band, which therefore becomes rapidly narrower when the impurities (light atoms) become fewer, and the frequencies therein contained become almost equal to that of the impurity frequency of the unit cell.

Let us now turn to the simplest case of ordinary diatomic lattice, i. e., the case $q=p=1$. In this case we have

$$F(\beta)=\cos 4\beta-\mathcal{E}\tan\beta\sin 4\beta\,, \qquad (6.1)$$

which is plotted in Fig. 12 for the case $\mathcal{E}=1/2$. The figure clearly demonstrates the separation of two branches—optical and acoustical. Edges of each band are given, as already shown, by $F(\beta)=\pm 1$. Corresponding frequencies are calculated to be

$$\left.\begin{array}{lll}
F(\beta)=1, & \sin^2\beta=0, & \omega^2=0: \\
\multicolumn{3}{l}{\quad\text{lower edge of acoustical branch,}} \\
F(\beta)=-1, & \sin^2\beta=1/2(1+\mathcal{E}), & \omega^2=2\lambda/M: \\
\multicolumn{3}{l}{\quad\text{upper edge of acoustical branch,}} \\
F(\beta)=-1, & \sin^2\beta=1/2, & \omega^2=2\lambda/m: \\
\multicolumn{3}{l}{\quad\text{lower edge of optical branch,}} \\
F(\beta)=1, & \sin^2\beta=(\mathcal{E}+2)/2(1+\mathcal{E}), & \\
 & \omega^2=2(M+m)\lambda/Mm: & \\
\multicolumn{3}{l}{\quad\text{upper edge of optical branch,}}
\end{array}\right\}\quad(6.2)$$

in harmony with the well-known result. That also the wave forms of the corresponding vibrations come out to be the same as the old results was already shown in § 4. In the forbidden bands, no initial vector x_0 can return to itself, however often it may be transformed by $\boldsymbol{h}$. Since in the present case $\boldsymbol{h}=(\boldsymbol{1}+\boldsymbol{\Lambda})\boldsymbol{ZP}$, $\boldsymbol{h}$ stretches the real component of the vector by the factor $\sec\gamma+\tan\gamma$ and contracts the imaginary component by $\sec\gamma-\tan\gamma$, and then rotates it by the angle $4\beta+\gamma$. Therefore, at the β a little smaller then $\pi/4$, the vector

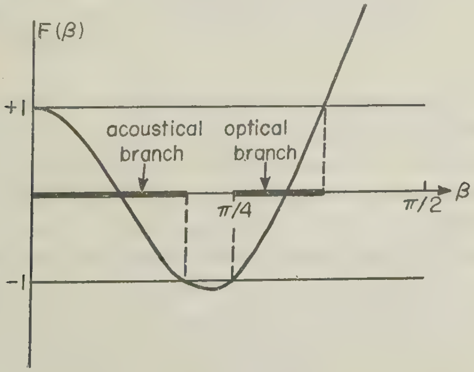

Fig. 12.

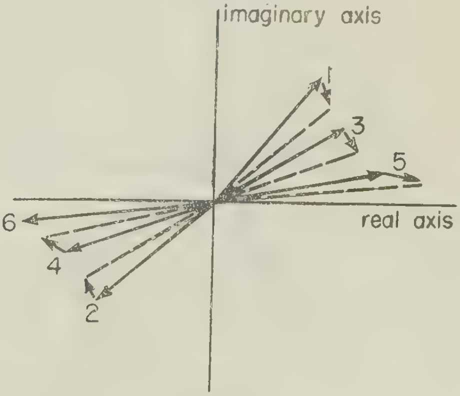

Fig. 13.

picture will become such as shown in Fig. 13. It vividly shows that every initial vector approaches the real axis while it is rapidly elongated, and never returns to its initial position.

Similar explanation applies also to more complicated cases. Consider for example the case $q=1$, $p=2$, $\varepsilon>0$, which is less simple than ordinary diatomic lattice. Now the vector is subjected to the $\boldsymbol{P}$-transformations with succeeding $\boldsymbol{Z}$-rotations repeated twice, and then to the rotation by $\mathbf{1}+\boldsymbol{\Lambda}$. Hence it is expected from the vector picture that the forbidden bands appear at about $\beta=\pi/6$ and $\beta=\pi/3$. In fact the curve $F(\beta)$ is now of the form illustrated in Fig. 14, which shows the appearance of forbidden bands nearly at the predicted positions. Since, however, in the present case $\boldsymbol{P}$-transformation has a larger effect because of its repetition, the forbidden band corresponding to $\beta=\pi/3$ appears at the position somewhat shifted to the smaller β-value. Near $\beta=\pi/4$ there appears no forbidden band, inasmuch as the vector is transformed here in such a way as is shown in Fig. 15, and may be recurrent.

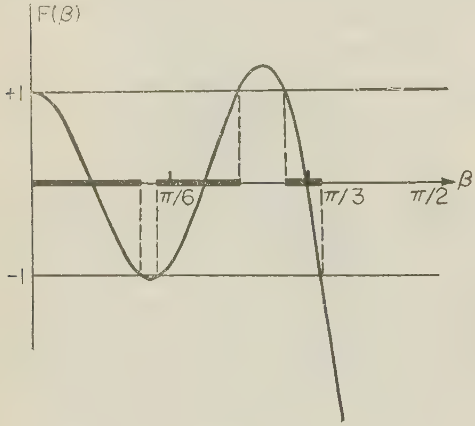

Fig. 14.

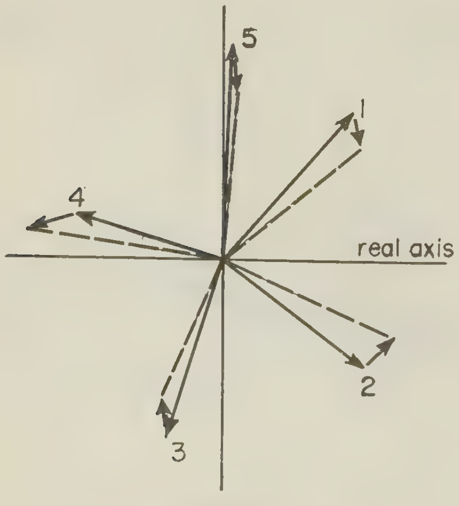

Fig. 15.

For larger p's, however, the transformations of the vector will become more complicated and the condition that no vector should be recurrent will become more subtle. It may be difficult in such a case to predict the band structure merely from the qualitative considerations based on the vector picture.

§ 7. Some Speculations for Random Lattice

In the case of random lattices, the vector is transformed fortuitously, sometimes by $\boldsymbol{Q}=\boldsymbol{ZP}$ and sometimes by $\mathbf{1}+\boldsymbol{\Lambda}$. Only the probability of occurrence of each transformation is known. The series of transformations of the vector becomes therefore a kind of random walk on the complex plane, which forms mathematically a Markov process. It the limiting distribution of this process be obtained for each β-value, it would become possible to calculate the probability of recurrence of any arbitrary initial vector, and hence the frequency spectrum. Unfortunately, there have been only very few investigations on such a process which is discrete in time and continuous in space, except for a general mathematical argument which is too abstract and vague from the view-point of physical application[6). Moreover, in our case, the limiting distribution will become very singular because of the singularity of transition probabilities. Such a situation, which was already encountered by Schmidt[7) in his treatment of lattice vibration by the method of transfer matrices, makes the problem all the more difficult. We therefore leave the analysis of our Markov process for future investigations and restrict here only to some remarks of extremely general nature.

If for some β the process has ergodic or periodic sets, this β-value will give an eigenfrequency at least with some probability, for any vector belonging to these sets will be recurrent with finite probability. If, on the contrary, the process for this β-value has only transient sets, as was the case in the forbidden band of the diatomic latice (Fig. 13), this β will never give an eigenfrequency. The sets of β-values with the former and the latter properties will form the allowed and forbidden bands, respectively. An argument of such a kind is of little use, however, in view of the above-mentioned difficulty of the analysis and consequently of obtaining the concrete ergodic structure of our process.

We can, however, on the analogy of the generalized diatomic lattices, well expect that the frequency spectrum of the random lattice may have an extremely fine structure. For, since the unit cell of the random lattice is the whole lattice itself, the total transfer matrix $\boldsymbol{H}=\boldsymbol{h}$ should turn out a very intricate product of randomly arranged $\boldsymbol{Q}$'s and $(1+\boldsymbol{\Lambda})$'s. The function $F(\beta)$ will then oscillate very rapidly, especially for large β. The set of β-values for which $|F(\beta)|>1$ will then form an assembly of dispersed narrow intervals. The result obtained by Dean[4], that the spectra of disordered diatomic lattice have astonishingly fine structures, can thus be explained in a reasonable way.

Crystal Distortion in Copper Ferrite-Chromite Series

By Haruyuki OHNISHI and Teruo TERANISHI

Department of Physics, Faculty of Science,
Hokkaido University, Sapporo, Japan

(Received March 25, 1960)

The cation distributions in copper ferrite-chromite series and the copper ferrite quenched from high temperatures are measured by X-ray diffraction method. The lattice parameters are also measured as a function of chromium ion content and of temperature. The critical fractions of copper ions on 16d and 8a sites for the occurrence of bulk crystal distortion from cubic to tetragonal symmetry are determined. The critical temperature for the distortion of copper ferrite is 360°C. This crystal distortion depends only upon the copper ion distribution. The abrupt appearance of distortion and coexistence of two phases, cubic and tetragonal, near the critical fraction and the critical temperature suggest that this distortion is of the first order as predicted by the statistical theory. From the aging of the distortion, the activation energy for copper ion to migrate from 16d site to 8a site is obtained. From the comparison of the critical fraction of copper ion in this series with those in other mixed spinels, the origin of this crystal distortion is discussed.

§1. Introduction

It has been known that some spinel-type oxides have lower symmetry than cubic below some critical temperatures. Snoek[1] and Bertaut[2] reported that copper ferrite is cubic above 760°C and is tetragonal with the axial ratio c/a>1 below this temperature. On the other hand some investigators observed anomalous behaviours in magnetization[3], initial permeability[4] and specific heat[5] at about 360° C. The detailed study on the meaning of these temperature values has not yet been given. Copper chromite ($CuCr_2O_4$) is also known to be tetragonal at room temperature with the axial ratio less than one.

The origin of the crystal distortion in certain compounds containing transition metal ions was discussed already by several investigators. Goodenough and Loeb[6] examined the role of covalency of the transition metal ions, and explained that the origin of the distortion of copper ferrite was square covalent bond of copper ions at octahedral sites. Dunitz and Orgel[7] discussed the distortion from the point of view of the crystalline field theory. According to their theory the Jahn-Teller effect in the ligation of some transition metal ions gives rise to the lattice distortion. Since the cupric ion is expected to have Jahn-Teller effect in both tetrahedral and octahedral ligand, the tetragonal distortions of copper ferrite and chromite are explained directly from their theory, and the difference in axial ratio is ascribed to the difference of the ligand of the cupric ion in the two spinels. (Copper ferrite has an inverse spinel structure, while copper chromite has a normal spinel structure.)

Statistical problem of the temperature dependence of the distortion relating with the distribution of transition metal ions was treated by Finch et al.[8] Wojtowicz[9] investigated this problem in detail and refined the theory. Kanamori[10] wrote down the microscopic Hamiltonian as a sum of the interaction energy relating to the distortion and the electronic state of cations. He explained the distortion at 0°K and also its temperature dependence.

In the present paper the results of a detailed experimental study of the distortion in the copper ferrite-chromite series are given. Their cation distributions were determined by means of the intensity measurement of X-ray diffraction lines. Variation of c/a was observed as a function of temperature and also of the ratio of copper ions distributed in the two sites of spinel lattice. Kinetic study of the distortion was also made by annealing the quenched specimen at various temperatures. From the present study it was concluded that the lattice distortion is a cooperative phenomenon. The meaning of the two critical temperatures (360°C and 760°C) was also given clearly. Moreover, the origin of distortion was discussed, comparing the critical cation distribution for the occurrence of distortion of this series with those of other series.

§ 2. Preparation of Specimens

All specimens are prepared by usual ceramic technique. CuO is obtained from copper carbonate by calcination, Fe_2O_3 from iron oxalate and Cr_2O_3 from ammonium dichromate. These oxides are mixed in a desired proportion and fired at 900°C in the air for two weeks and then cooled down to room temperature at the rate of 0.5°C/min. This rather low firing temperature prevents eventual reduction of cupric ion.

Specimens which contain more chromium ions than 50 at. % are fired at 700°C for several weeks in order to eliminate the formation of $CuCrO_2$ phase which has been observed after the firing at 900°C. Chemical analysis assures that the metal compositions of all specimens are correct within 3 wt. %. According to X-ray diffraction all specimens include no other phase than spinel and hausmannite phases.

§ 3. Experimental Procedure

For the determination of lattice parameter and cation distribution, "Norelco" and "Geigerflex" X-ray diffractometers are used. Their temperature variations are determined by using high and low temperature attachments.

The intensity of the X-ray diffraction line is expressed as

$$I=\gamma\cdot p\cdot L(\theta)\cdot|F|^2\cdot A(\theta)\cdot T(\theta)\ ,$$

where γ is a constant, p multiplicity of plane (hkl), $L(\theta)$ Lorentz and polarization factor, $|F|$ structure factor, $A(\theta)$ absorption factor and $T(\theta)$ is a temperature factor.

In the geometry of the diffractometers used, the absorption factor can be put as constant[11]. The temperature factor is also constant, since the relevant correction to the intensity ratio is considered to be less than 3%.*

In determining the cation distribution, we

---

* Bacon and Roberts obtain 500°K as the Debye temperature of magnesium ferrite[12]. Assuming the same Debye temperature for copper ferrite, the ratio of the temperature factors of two lines does not change so much from 300°K to 700°K.

ratio of T / temperature	$\frac{T(220)}{T(400)}$	$\frac{T(422)}{T(400)}$
300°K	1.026	0.987
700°K	1.030	0.976

assume that chromium ions occupy mainly octahedral sites. This assumption is very reasonable when we consider the experimentally determined cation distributions of other chromites[13] and the preference energy of chromic ion for octahedral site[14]. Therefore, the cation distribution of the copper ferrite-chromite series is expressed by the formula

$$(Cu_xFe_{1-x})[Cu_{1-x}Fe_{1+x-t}Cr_t]O_4 ,$$

where ( ) and [ ] mean tetrahedral and octahedral sites, respectively.* For copper chromite itself, we consider that some amount of chromium ion situates on tetrahedral sites and so the formula is

$$(Cu_xCr_{1-x})[Cu_{1-x}Cr_{1+x}]O_4 .$$

We measured intensities of (111), (220), (440) and (422) lines. Intensity ratios $I(111)/I(400)$, $I(220)/I(400)$ and $I(422)/I(400)$ are considered to be most sensitive to the cation distribution parameter x[15].

It is not allowed to ignore the oxygen parameter, u, for the calculation of structure factor. Especially u has a large effect on the ratio $I(220)/I(400)$ because with increasing of u $I(400)$ decreases while $I(220)$ increases[16]. The change in u of about 0.4% corresponds to the change in x of about 10% for copper ferrite. We determined u-values experimentally only for two end members of the series, $CuFe_2O_4$ and $CuCr_2O_4$, and for other specimens we assumed that u varies linearly from $CuFe_2O_4$ to $CuCr_2O_4$.

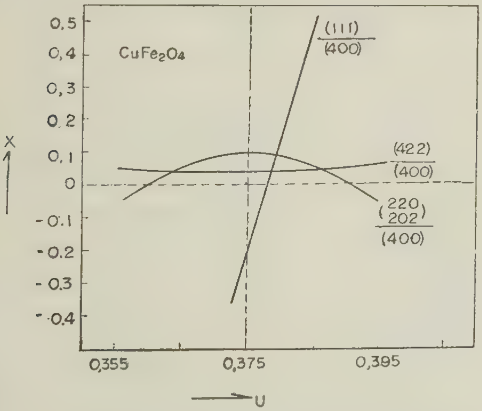

Fig. 1. The curves of cation distribution parameter versus oxygen parameter for $CuFe_2O_4$.

$CoK\alpha$ radiation is used for iron rich specimens and $CuK\alpha$ radiation for chromium rich specimens. As the atomic scattering factors we used the values calculated by Dascola and von Nagy[17]. Corrections due to the anomalous depression of scattering near the absorption edge were also made for atomic scattering factors[18].

In the diffractometers used, the particle size of specimen affects largely the intensity of diffraction line. The particle size of our specimens spreads over from 100μ to 2μ just after the firing, but it is reduced to within 10μ~2μ by a few hour's grinding. This particle size will produce only a few percent deviation of intensity[11].

§4. Experimental Results

1. *Cation distribution and Crystal structure of* $CuFe_{2-t}Cr_tO_4$ *at room temperature*

Fig. 1 and Fig. 2 indicate the relation between u and x obtained for three intensity ratios of slowly cooled $CuFe_2O_4$ and $CuCr_2O_4$,

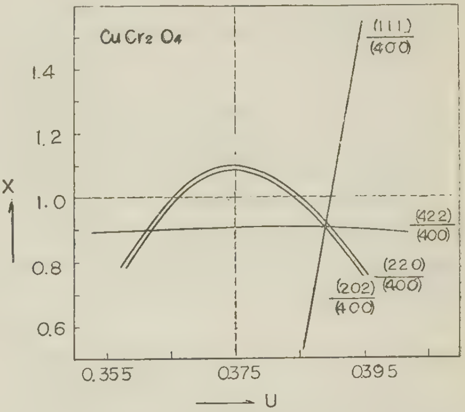

Fig. 2. The curves of cation distribution parameter versus oxygen parameter for $CuCr_2O_4$.

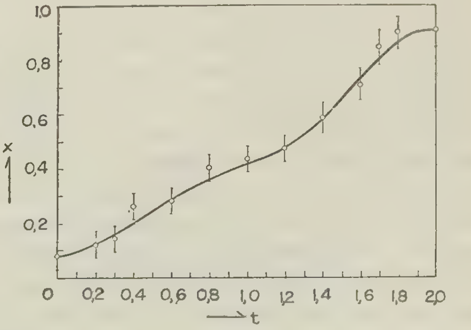

Fig. 3. The relation between the cation distribution parameter and the chromium content.

* The geometry of the spinel lattice has been described in detail by E. W. Gorter, Philips Res. Rep. **9** (1954) 295.

respectively. From these diagrams, $x=0.08\pm0.05$, $u=0.380\pm0.003$ for $CuFe_2O_4$ and $x=0.90\pm0.06$, $u=0.389\pm0.003$ for $CuCr_2O_4$ are obtained as the most appropriate values. These x values are in good agreement with those obtained by Bertaut[2)] and by Bertaut and Delorme[19)].

In Fig. 3 the fraction of cupric ion in 8a site, x, changing with chromic ion content, t, are illustrated. x values of mixed compositions are corrected by assuming that u changes linearly from $CuFe_2O_4$ to $CuCr_2O_4$. These x values agree well with values[20)] obtained previously by microphotometric method. For the specimen $CuFe_{0.8}Cr_{1.2}O_4$ intensity measurement was carried out by using two radiations, CoKα and CuKα, and there is no great difference between x values obtained from both radiations. This will prove the correctness of the procedure used.

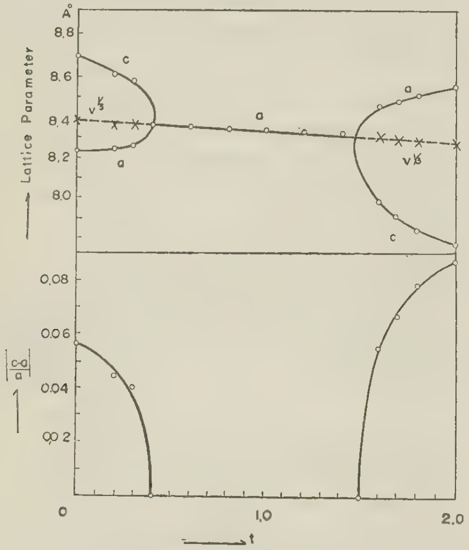

Fig. 4. The lattice parameter and the tetragonality versus chromium content.

Lattice parameters and axial ratio c/a of the series at room temperature are illustrated in Fig. 4. The series has a tetragonal structure with c/a>1 in the range $0\leq t\leq0.3$ and that with c/a<1 in the range $1.6\leq t\leq2.0$. In the range $0.4<t<1.4$, cubic structure is realized and the lattice parameter decreases linearly with increasing t just as expected by Vegard's law. As is shown, cube root of the unit cell volume in the two tetragonal ranges can be plotted on the same straight line with the lattice parameter in the cubic range. Therefore it will be seen that no volume change is present as a result of the distortion. It is noticed that in the sample $t=1.6$ additional weak lines of cubic spinel structure were also observed.

2. *Temperature dependence of crystal structure of* $CuFe_{2-t}Cr_tO_4$

In Figs. 5 and 6 are shown the temperature dependence of lattice parameters of $CuFe_2O_4$ and $CuCr_2O_4$. Temperature dependence of axial ratio is also plotted in Figs. 7 and 8. As is shown, slowly cooled $CuFe_2O_4$ transforms from cubic to tetragonal structure at 360°C[21)]. This critical temperature is quite different from that given by Bertaut (760°C). The origin of this discrepancy will be made clear in the later sections. As illustrated in Figs. 7 and 8 the axial ratio decreases rather sharply at the critical temperature and two phases, cubic and tetragonal, are usually ob-

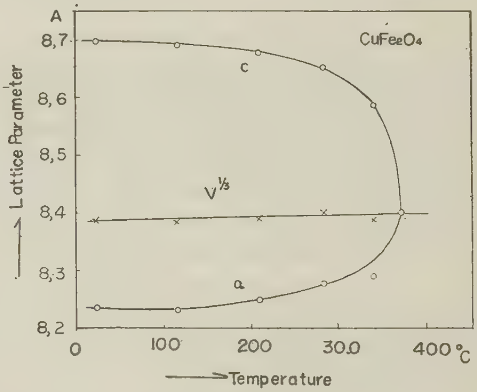

Fig. 5. The temperature variation of lattice parameter for $CuFe_2O_4$.

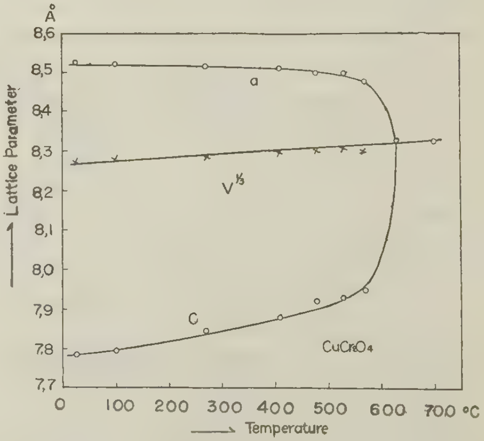

Fig. 6. The temperature variation of lattice parameter for $CuCr_2O_4$.

served at the critical temperature. Although there is a possibility that the temperature is not uniform in the sample in case of X-ray measurement, we believe that the appearance of two phases is essential. It is noticed that a rather large thermal hysteresis of transformation (from 20°C to 50°C) was observed at the critical temperature.

The cation distribution at high temperature was not determined definitely because of the insufficient accuracy of the intensity measurement.

Being cooled to liquid nitrogen temperature, more three samples, $CuFe_2O_4$ quenched from 810°C, $CuFe_{0.4}Cr_{1.6}O_4$ and $CuFe_{0.6}Cr_{1.4}O_4$ were found to undergo distortion. In all cases, however, they do not exhibit a single phase but two phases, cubic and tetragonal, down to liquid nitrogen temperature. As the temperature is lowered, intensities of cubic phase lines decrease while those of tetragonal phase lines increase. But relative intensities of tetragonal phase lines remain unchanged.

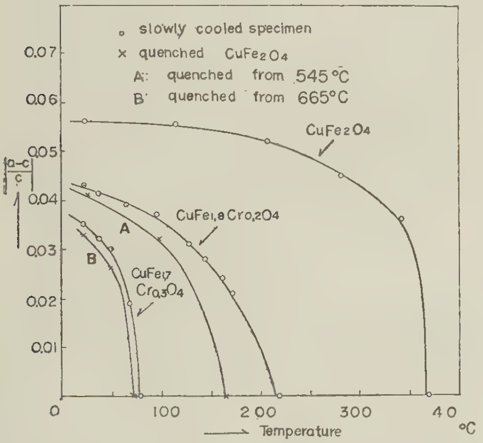

Fig. 7. The temperature variation of tetragonality for iron rich copper ferrite-chromite and quenched copper ferrite.

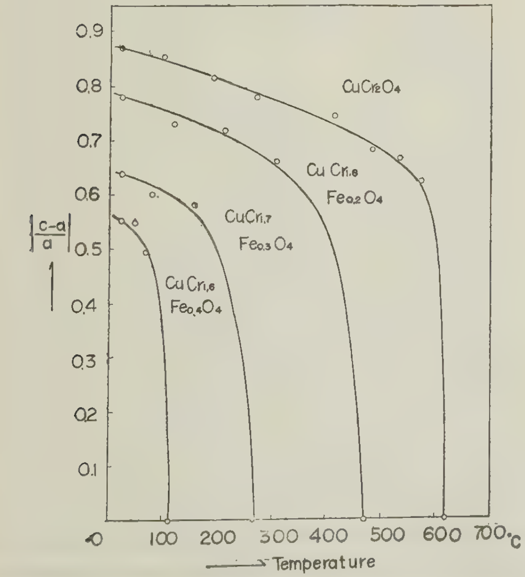

Fig. 8. The temperature variation of tetragonality for chromium rich copper ferrite-chromite.

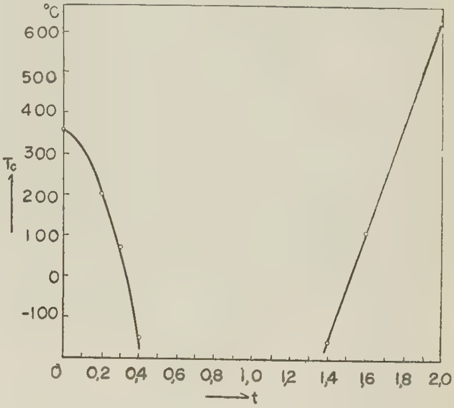

Fig. 9. The critical temperature versus chromium content.

The critical temperatures are plotted against the chromium content in Fig. 9. The critical temperature was defined as such a temperature below which two phases emerge into a single cubic phase. Over the range $0.6<t<1.2$ there appears no structural change in the temperature range down to the liquid nitrogen temperature.

3. *Cation distribution and structure of quenched* $CuFe_2O_4$

We examined crystal structures of $CuFe_2O_4$ quenched from various temperatures in order

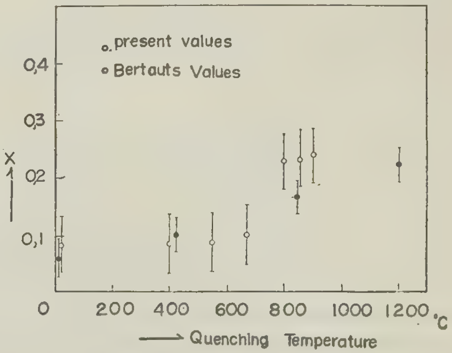

Fig. 10. The cation distribution parameter versus quenching temperature for $CuFe_2O_4$.

to clarify the meaning of the critical temperature 760°C which had been presented by Bertaut as the transition temperature from cubic to tetragonal. In Figs. 10 and 11, cation distribution parameter x and lattice parameters are plotted against the temperature from which the samples are quenched. In Fig. 10, the result obtained previously by Bertaut is also plotted. There is no appreciable discrepancy between Bertaut's values and ours. It should be noted that the parameter x increases sharply from 0.1 to about 0.2 at about 750°C. For samples quenched from 720°C and 740°C we observed the diffraction lines of both tetragonal and cubic structures and the intensity ratios of tetragonal phase-lines to cubic phase-lines depend on the quenching method. There is no appreciable volume change for all specimens in accordance with the result of Fig. 4.

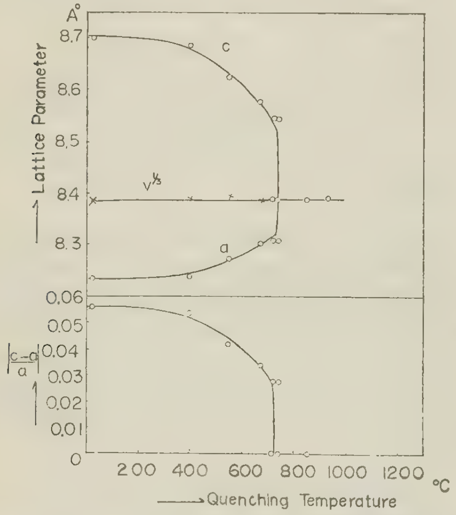

Fig. 11. The lattice parameter and the tetragonality versus quenching temperature for $CuFe_2O_4$.

Although the study of the quenching effect is not in detail for samples with chromium ion, it is certain that no change of crystal structure takes place for the samples that have tetragonal structure with $c/a<1$.

4. *Temperature dependence of crystal structure of quenched* $CuFe_2O_4$

We have measured the temperature dependence of lattice parameter of $CuFe_2O_4$ that had been quenched from various temperatures. Results are already shown in Fig. 7 by curves A and B. The figure illustrates that the quenching gives the same effect on the distortion as the addition of chromium ion.

The critical temperatures of quenched samples are plotted against the quenching temperature in Fig. 12. The sample quencned from 720°C has the critical temperature which is equal to room temperature.

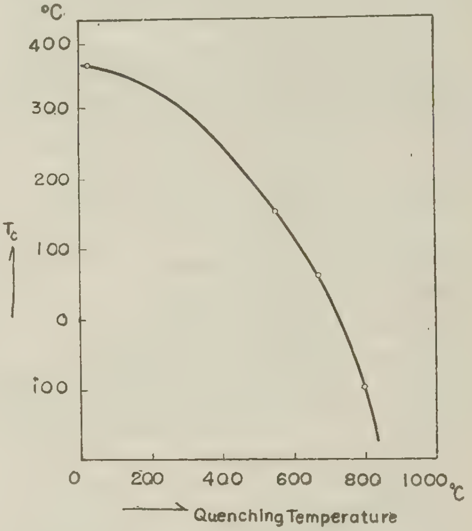

Fig. 12. The critical temperature versus quenching temperature for quenched $CuFe_2O_4$.

5. *Time variation of crystal structure of* $CuFe_2O_4$

The lattice parameters of quenched $CuFe_2O_4$ exhibit a time variation in isothermal annealing at the intermediate temperature range. This phenomenon was observed by the following procedure. Copper ferrite specimens are first quenched from 805°C. They are cubic at room temperature. These samples are inserted at a desired temperature and after the isothermal annealing of a desired time one of these samples is quenched to room temperature and then lattice parameter is observed. This procedure is repeated with changing the temperature of anneal and also the time of anneal. The results are shown in Fig. 13 in which axial ratios are plotted against the annealing time. Although the sample annealed at 450°C transforms into tetragonal structure only after 5 minutes, the sample annealed at 320°C remains cubic even after 80 hours. It means cations commence to migrate easily at about 360°C. Thus for the slowly cooled copper ferrite, cupric ions will commence to migrate nearly at the critical temperature on heating. However, this fact will not produce a large effect upon the observed behaviour of the temperature variation of lattice parameters because it requires at most two hours in order to make all measurements of the diffraction lines from room temperature to 360°C.

The slowly cooled specimen becomes two phases, cubic and tetragonal, after two hours' annealing at 360°C.

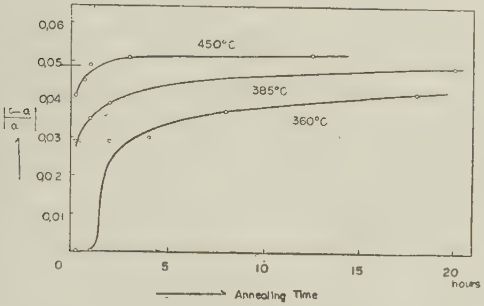

Fig. 13. The variation of tetragonality with annealing time for quenched $CuFe_2O_4$.

§ 5. Discussion

1. *Crystal distortion and cation distribution*

In view of our results on the temperature variation of lattice parameter of copper ferrite the above mentioned magnetic and thermal anomalies occurring at 360°C are definitely due to the structural change from tetragonal to cubic, and the temperature 760°C is only the quenching temperature which provides such a cation distribution that the room temperature is the critical temperature. Some investigators[22] have obtained the activation energy which is required for cupric ion to migrate from 16d site to 8a site on the basis of thermodynamical theory. This activation energy, however, is obtained from the cation distribution which is determined from the magnetic measurement, assuming the Néel theory of ferrimagnetism. Now, we can similarly obtain the activation energy from the aging of lattice parameter of the quenched copper ferrite, assuming that the lattice parameter and the lattice distortion depend upon the copper ion content on the 16d site.

By assuming a simple relaxation process, we can get from the experiment in Fig. 13 the relaxation times of 600 sec. and 60 sec. for the annealing at 385°C and 430°C, respectively. These values give the activation energy of $\Theta=1300$°K, being in good agreement with those of the other authors.

2. *Origin of the lattice distortion*

Now for the iron rich samples we plott the axial ratio and the critical temperature against the parameter x in Figs. 14 and 15, respectively. It is evident from Fig. 14 that the axial ratio depends only upon x, the fraction of copper ion on 8a site, no large difference being recognized between samples containing chromic ion and those quenched from high temperatures. The critical temperature also depends only upon the parameter x and it decreases linearly with increasing x. In Figs. 16 and 17 axial ratio and the critical temperature are plotted against the parameter x for the chromium rich samples. Their behaviours are just the same as those of the iron rich samples, except the fact that the axial ratio

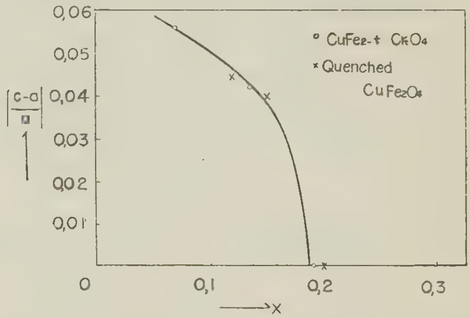

Fig. 14. The variation of tetragonality with cation distribution parameter for iron rich copper ferrite-chromite and quenched copper ferrite.

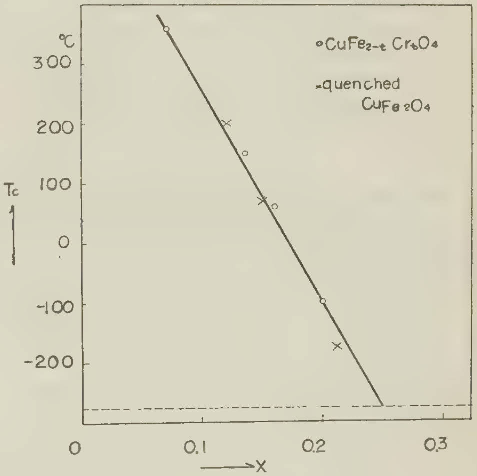

Fig. 15. The variation of critical temperature with cation distribution parameter for iron rich copper ferrite-chromite and quenched copper ferrite.

is less than one in this case. According to Dunitz and Orgel[7] copper ions on 8a site cause such distortion that the axial ratio is less than one. Therefore the distortion in the chromium rich specimen will be due to copper ions on 8a site.

From Figs. 14 and 16 it is obvious that there is no distortion with $c/a>1$ for $x>0.2$ and no distortion with $c/a<1$ for $x<0.65$. That is to say, for the bulk distortion with $c/a>1$ it is required that 16d site is occupied by copper ions more than 0.8. On the other hand for the distortion with $c/a<1$ it is required that 8a site is occupied by copper ions more than 0.65.

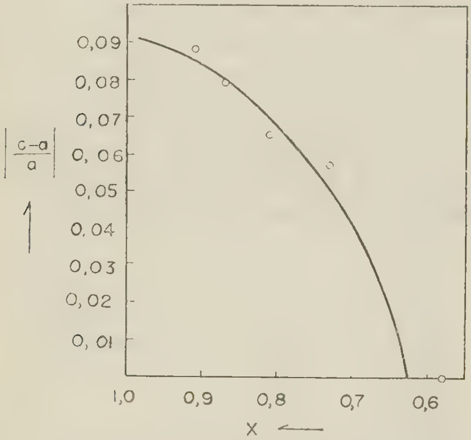

Fig. 16. The variation of tetragonality with cation distribution parameter for chromium rich copper ferrite-chromite.

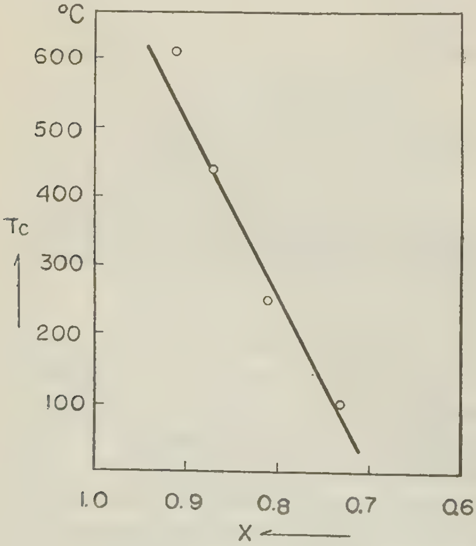

Fig. 17. The variation of critical temperature with cation distribution parameter for chromium rich copper ferrite-chromite.

Delorme[24] examined in detail lattice distortions of the series A) $Cu_{1-x}Ni_xFe_2O_4$, B) $Cu_{1-x}Mg_xFe_2O_4$, C) $Cu_{1-x}Co_xFe_2O_4$ and D) $Cu_xZn_{1-x}Cr_2O_4$. According to his experiment maximum values of x above which distortion with $c/a>1$ no longer takes place are 0.35, 0.275 and 0.25 for the series A), B) and C), respectively. For the series D) minimum value of x below which distortion with $c/a<1$ no longer takes place is 0.55. He did not determined the copper ion distribution in all these series. From the consideration of crystal energy and experimental results it will be able to consider that almost all copper ions situate on 16d site for the series A), B) and C); and on 8a site for the series D)[23]. Comparing our results with those by Delorme, minimum values for the distortion of the copper ion fraction on 16d site and 8a site obtained from the series $CuFe_{2-t}Cr_tO_4$ are greater than those obtained from the series A), B), C) and D). This means that in the present series, $CuFe_{2-t}Cr_tO_4$, more large amount of copper ions on either site, 16d and 8a, is required than in the series A), B), C) and D) for the occurrence of the distortion. According to Dunitz and Orgel the directions of distortion by copper ions on 8a and 16d sites are opposite and therefore these distortions will be partly compensated. In the series $CuFe_{2-t}Cr_tO_4$ copper ions occupy both sites, 8a and 16d, and this compensation effect will be realized to a certain degree. Therefore, in order that the distortion takes place, larger amount of copper ions is necessary to situate on a specific site for the series $CuFe_{2-t}Cr_tO_4$ than for the series where copper ions situate only in either site, 8a or 16d.

Similarly, the smaller values of x for the series B) and C) than those for the series A) will also be explained by the fact that some fraction of cupric ions is situated on 8a site, and the compensation takes place in the two former series.

3. *Co-operative phenomenon*

In the preceding chapter it is shown that the origin of the lattice distortion in the series $CuFe_{2-t}Cr_tO_4$ will be the Jahn-Teller effect of cupric ion Cu^{2+} as suggested by Dunitz and Orgel[7]. In order to explain the observed bulk distortion some statistical treatments are required. Finch, Sinha and Sinha[8] have investigated this problem and found that the temperature and composition dependences of the lattice distortion are just like as the order-disorder problem of binary alloy. Wojtowicz[9] and Kanamori[10] examined this problem in detail and predicted that this transformation is thermodynamically of the first order.

It is noteworthy to mention that axial ratio drops off with temperature rather sharply at the critical temperature for $CuFe_2O_4$ (Fig. 8), and two phases, tetragonal and cubic structure, are simultaneously found in some cases. Although the detailed discussion of the cooperative mechanism of distortion has not been given here, these facts will support that the transformation is of the first order.

§ 6. Acknowledgements

The authors wish to express their hearty thanks to Prof. Miyahara for continuous encouragement and valuable discussions. They are also much indebted to Dr. Yamadaya for his suggestion about the first order transition and to Dr. Wojtowicz and Dr. Kanamori for sending us their manuscripts prior to publication.

Distribution of Interstitials and Vacancies Produced by an Incident Fast Neutron

By Masayuki YOSHIDA

*Japan Atomic Energy Research Institute, Tokaimura, Nakagun, Ibarakien, Japan**

(Received August 11, 1960)

The distribution of the interstitial-vacancy (I–V) pairs produced in such a substance as germanium by successive knock-on is discussed. Calculation of the distribution is performed basing on the formula proposed by Bohr and Seitz and Koehler and applying the Monte-Carlo Method. Ratio of the close I–V pairs to the total I–V pairs produced by an 10^4 eV first knocked-on atom is about 60%. Taking into account the replacement collision, decrease of about 40% in the total number of the I–V pairs is obtained and the ratio becomes 30%. The decrease in the total number reduces the difference between the total number deduced from calculation and that obtained by experiment. The following results are also obtained. The interstitials and vacancies are distributed in several groups. They exist in the region enveloped by a sphere of about from 50 to 100 atomic distances of diameter. There is no tendency that the concentrated damaged region spreads in the incident direction of the first knocked-on atom and that the interstitials distribute in the outer part of the concentrated damaged region.

§ 1. Introduction

By the high energy particle irradiation on solid, atoms are displaced from their normal lattice sites and the physical properties of the solid change. The mechanism of displacement of atoms has been discussed by many researchers and a several kinds of models have been proposed. Interstitial-vacancy pair production, thermal spike¹⁾ and displacement spike²⁾ are representative ones. Not only the thermal spike and displacement spike may bring the concentrated damaged region in solid, but also the I–V pair production would bear a similar region if an incident particle is massive. That is, a first knocked-on atom by an incident fast neutron can have sufficiently large energy to knock-on succesively other stationary atoms and these knocked-on atoms may form the concentrated damaged region. On the other hand, a first knocked-on atom by electron or γ-ray can not have so large energy as to knock-on successively other stationary atoms and the concentration of knocked-on atoms will not occur. The idea of concentrated damaged region has been supported by the experimental results that there are differences in annealing behaviours between neutron- and electron-irradiated copper³⁾,⁴⁾ and of resistivity change of germanium by neutron and γ-ray irradiation⁵⁾,⁶⁾. The concentrated damaged region has also been suggested for deuteron bombardment on gallium-antimonide⁷⁾ and germanium⁸⁾.

Among the above models, assumption for the I–V pair production model is the most reasonable and the model shows straightforwardly the displacement of atoms. If the transfered energy to an atom by an incident particle is so small that, at the most, only one or two atoms are influenced, the I–V pair production model can be applied for it. This may be the case for an electron or γ-ray irradiation. In order to compare the effect of a neutron and an electron irradiation, we had, therefore, better assume the model even for a neutron irradiation.

Here we discuss the distribution of the I–V pairs produced in such a substance as germanium by successive konck-ons, which is calculated basing on the formulas proposed by Bohr⁹⁾ and Seitz and Koehler¹⁰⁾ and applying the Monte-Carlo Method¹¹⁾.

§ 2. Assumptions for Calculations

The energy of a primary knocked-on atom produced by a neutron of 2 MeV, which is the average energy of fast neutrons in an atomic reactor, distributes from zero to 10^5 eV.

This energy is consumed by exciting electrons until it decreases to I_c given by[12)]

$$I_c = \frac{M}{m} \frac{I_t}{8}$$

where M and m are mass of an moving atom and an electron respectively and I_t is excitation energy of a valence electron to the conduction band. I_c is then about 1.2×10^4 eV for germanium. Therefore, we may put 10^4 eV for the energy of the first knocked-on atom in the successive collisions.

We assume that the screened interaction potential is expressed by

$$\frac{Z^2 e^2}{r} \exp(-r/a)$$

where Z is the atomic number of the nucleus, e is the electronic charge, r is the distance of the moving and the stationary atom and a is screening constant given by $a_h/Z^{1/3}$ in which a_h is the Bohr radius of the hydrogen atom.

If the screening constant a is larger than the de Broglie's wave length $\lambdabar$ of the moving atom but is smaller than the classical distance of closest approach b in Coulomb interaction, the collision can be treated by hard sphere collision in classical mechanical method. b and $\lambdabar$ are given by

$$\frac{(Ze)^2}{b} = \frac{\mu V^2}{2}$$

and

$$\lambdabar = \hbar/\mu V$$

respectively where μ is the reduced mass of the two particles, V is the relative velocity before collision and $\hbar$ is the Plank's constant devided by 2π. a, b and $\lambdabar$ for a moving germanium atom with an energy of 10^4 eV are $a = 0.17$ Å, $b = 3.0$ Å and $\lambdabar = 0.0001$ Å. Thus the conditions for hard sphere collision

$$a > \lambdabar$$
$$b > a$$

are satisfied. Even if the energy of the moving atom decreases to 10 eV the above conditions are satisfied. We can, therefore, treat all of the collisions following the primary knock-on as the hard sphere collision which gives isotropic scattering in the center of gravity system.

We assume in addition that the atoms in a solid in question distribute randomly. We shall take no account of crystal structure of the solid. The assumption may be correct as the approximation. Then, the free path of the moving atom in the solid can be given by exponential distribution.

Threshold energy E_d for displacement of atoms from normal lattice sites by collision has been measured and calculated by many researchers[13)] for germanium, silicon and copper. We adopt $E_d = 25$ eV and assume that the probability of the displacement changes abruptly from zero to unity as the energy received by the struck atom passes through the value E_d. Influence of the relation between the probability and the received energy upon total displacement cross section has been discussed by Corbett et al.[4)], and they concluded that it is not so large. The above assumption for the threshold energy means that there is a cylindrical potential well around the collision site, depth of which is E_d. The energy E_d of the total energy received by the struck atom must be consumed by climbing up the well and the rest will become the kinetic energy of the struck atom, which we use to calculate the mean free path. If the received energy is smaller than E_d, the struck atom will suffer several times of collision at the bottom of the well and will return to the original site. After the atom climbs up the well, it never falls down to the original site. Although the radius of the cylinder is not certain, it may be two or three atomic distances. It is neglected in the calculation of free path.

§ 3. Calculations

In the following section, suffix i indicates the value after the ith collision and a prime indicates the value for the struck atom. $i=1$ corresponds to the first knocked-on by a fast neutron. ξ is a uniformly distributing random number from zero to unity and adopted from the IBM library[14)].

In Fig. 1 a vector $\vec{l_i}$ corresponds to a free path between ith and $i+1$th collision. Components $x_{i,i-1}$, $y_{i,i-1}$ and $z_{i,i-1}$ of the vector $\vec{l_i}$ in the Cartesian co-ordinates X_{i-1}, Y_{i-1} and

Z_{i-1} are shown, where Z_{i-1} axis consists with incident direction of a moving atom, or $\vec{l}_{i-1}$, and X_{i-1} and Y_{i-1} axes are decided from $i=2$ collision as shown later. The components in the spherical co-ordinates l_i, θ_i and φ_i are also shown. The components $x_{i,i}$, $y_{i,i}$ and $z_{i,i}$ of $\vec{l}_i$ in the Cartesian co-ordinates X_i, Y_i and Z_i, where Z_i axis consists with $\vec{l}_i$ and Z_{i-1}, Z_i and Y_i axes are in the same plane, are $(0\ 0\ l_i)$.

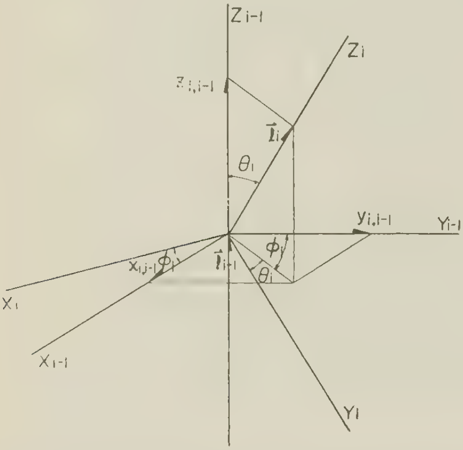

Fig. 1. Vectors $\vec{l}_{i-1}$ and $\vec{l}_i$, the directions and magnitudes of the moving atom before and after collision, in the Cartesian co-ordinates.

As the collision can be regarded as isotropic, the probability that the energy of a moving atom after ith collision is in the range of E_i and E_i+dE_i is given by

$$f(E_i)dE_i=dE_i/E_{i-1}\ .$$

Then E_i is given by

$$E_i=\xi E_{i-1}\ .$$

As the free paths have an exponential distribution, the probability that free path of a moving atom with energy E_i is in the range of l_i and l_i+dl_i is given by

$$f(l_i)dl_i=\frac{1}{\lambda_i}\exp(-l_i/\lambda_i)dl_i\ .$$

Then l_i is given by[11]

$$l_i=-\lambda_i\log\xi\ ,$$

where λ_i is the mean free path and given by

$$\lambda_i=1/n_0\pi R_i^2$$

and

$$E_i=\frac{(Ze)^2}{R_i}\exp(-R_i/a) \qquad (1)$$

in which n_0 is the number of atoms in unit volume.

For a struck atom the energy after displacement from normal lattice site must be $E_i'-E_d$ and this value is used instead of E_i in (1).

As the energy and momentum are conserved, the deflection angle θ_i and θ_i' of the moving and struck atoms after ith collision from the incident direction of the moving atoms are given by

$$\theta_i=\mathrm{Cos}^{-1}\sqrt{E_i/E_{i-1}}$$

and

$$\theta_i'=-\mathrm{Cos}^{-1}\sqrt{E_i'/E_{i-1}}\ .$$

Minus sign in θ_i' corresponds to the fact that θ_i and θ_i' are in the opposite directions with regards to Z_{i-1} axis taking $\varphi_i=\varphi_i'$.

As φ_i is an optional value from zero to 2π, it is given by

$$\varphi_i=2\pi\xi\ .$$

In the above calculations, l_i, θ_i, ϕ_i and their primed values are given.

In the next calculations there are no differences in the primed and non-primed values. The relation between $x_{i,i-1}$, $y_{i,i-1}$, $z_{i,i-1}$ and l_i, θ_i, φ_i is given by

$$\begin{bmatrix} x_{i,i-1} \\ y_{i,i-1} \\ z_{i,i-1} \end{bmatrix}=\begin{bmatrix} \cos\varphi_i & \cos\theta_i\sin\varphi_i & \sin\theta_i\sin\varphi_i \\ -\sin\varphi_i & \cos\theta_i\cos\varphi_i & \sin\theta_i\cos\varphi_i \\ 0 & -\sin\theta_i & \cos\theta_i \end{bmatrix}\begin{bmatrix} 0 \\ 0 \\ l_i \end{bmatrix}$$

$$=[A_i]\begin{bmatrix} 0 \\ 0 \\ l_i \end{bmatrix}.$$

If the relation between $x_{i,i-1}$, $y_{i,i-1}$, $z_{i,i-1}$ and $x_{i,1}$, $y_{i,1}$, $z_{i,1}$, the components of $\vec{l}_i$ in the basic Cartesian co-ordinates, is given by

$$\begin{bmatrix} x_{i,1} \\ y_{i,1} \\ z_{i,1} \end{bmatrix}=[B_{i-1}]\begin{bmatrix} x_{i,i-1} \\ y_{i,i-1} \\ z_{i,i-1} \end{bmatrix},$$

the vector $\vec{l_i}$ is expressed in the basic Cartesian co-ordinates by

$$\begin{bmatrix} x_{i,1} \\ y_{i,1} \\ z_{i,1} \end{bmatrix} = [B_{i-1}][A_i]\begin{bmatrix} 0 \\ 0 \\ l_i \end{bmatrix} . \qquad (2)$$

By putting

$$[B_i]=[B_{i-1}][A_i] \, , \qquad (3)$$

(2) becomes

$$\begin{bmatrix} x_{i,1} \\ y_{i,1} \\ z_{i,1} \end{bmatrix} = [B_i]\begin{bmatrix} 0 \\ 0 \\ l_i \end{bmatrix} .$$

As we choose the Cartesian co-ordinates X_1, Y_1 and Z_1, where Z_1 axis consists with the direction of $\vec{l_1}$, to be the basic Cartesian co-ordinates, $[B_1]$ is given by

$$[B_1]=\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} .$$

And we can find successively $[B_i]$ by (3). As X_1 and Y_1 axes of the basic Cartesian co-ordinates are optional, it is convenient to choose the direction decided by φ_2 to be X_1 and Y_1 axes.

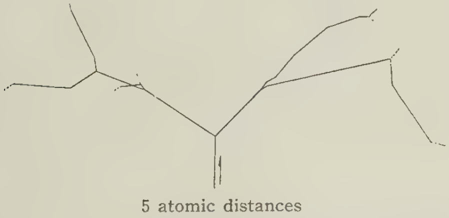

Fig. 2. Y–Z components of 480 eV branch of 10^4 eV first knocked-on atom. Tracks of knocked-on atoms are shown by full lines. Dotted lines correspond to interstitials and their directions and magnitudes are optional. The cross points of full and dotted lines indicate vacancies.

By the above method, $x_{i,1}$, $y_{i,1}$ and $z_{i,1}$ are calculated until E_i becomes smaller than E_d. All of the calculations were performed by IBM 650 at the Japan Atomic Energy Research Institute. 480 eV branch of a 10^4 eV primary knocked-on atom is shown in Fig. 2. If the energy of a moving atom is smaller than E_d, (1) does not give a good approximation and the moving atom can not knock-on the stationary atom any more. Its mean free path is smaller than 2 atomic distances according to (1). It collides with stationary atoms several times then it rests there as an interstitial atom. Tracks of interstitial atoms are shown by dotted lines in Fig. 2. The direction and length of dotted lines are optional. In other words, a dotted line shows that there must be an interstitial atom in one or two atomic distances from the cross point of dotted and full line.

§ 4. Discussion

We practiced the above calculations 6 times for the first knocked-on atom of the energy of 10^4 eV. Two typical distributions of the interstitials and the vacancies are shown in Figs. 3 to 6 for X–Z and Y–Z components. In order to emphasize the interstitials and the vacancies, they are expressed by the white and black spots of a diameter of about one atomic distance and are pictured so as to avoid overlapping. Therefore, the positions of the spots do not necessarily indicate the exactly calculated positions and some of the tracks of moving atoms are omitted.

Taking into account of the statistical characteristics of the calculations, the more the number of times of the calculations, the better the result. In our calculations the numbers of collision for one time are 231, 226, 216, 227, 230 and 214 respectively. Snyder and Neufeld[15] have calculated the number of collision for isotropic collision. The number is 225 according to their result if E_1 and E_d are taken to be 10^4 and 25 eV. The results of our practical and their theoretical calculations are in fairly good agreement. We think, therefore, that there is not large error in discussing general situation of the defects produced by the collision from our calculations.

There are four types of collisions near the threshold energy, which include replacement collision[16]. First; The energy of the moving atom after collision is still large and it progresses forward further. The stationary atom receives larger energy than the threshold energy and is displaced from its original lattice site but its kinetic energy after diplacement is smaller than the threshold energy and it can knock-on other stationary atom no further. In this case, one vacancy and one interstitial, or close I–V pair, are produced. Second; The energy of the moving atom becomes smaller than the threshold energy after collision and it can knock-on other atom no further. On the other hand, the stationary atom receives large energy and it can knock-on other stationary atom further after displaced from its original lattice site. The mean free path of the moving atom with energy below 25 eV is below 2 atomic distances as is given by (1) and it is not clear whether the moving atom becomes the interstitial or drops back to the vacant lattice site. In this case one vacancy and one interstitial, or close I–V pair, are produced or only the replacement of the moving and the knocked-on atoms occures. Third; It is the combination of First and Second. Both of the moving and the struck atom can knock-on other atoms no further. Close I–V pair and one interstitial or one interstitial are produced. Fourth; Even if the energy of the moving atom is larger than E_a, it can happen that it does not give a sufficient value of energy to the stationory atom

Notice

A: Total number of the I–V pairs assuming all of the moving atoms with energies below 25 eV after collision become interstitials.

B: Number of the close I–V pairs of A.

D: Total number of the I–V pairs assuming all of the moving atoms with energies below 25 eV after collision can not become interstitials.

E: Number of the close I–V pairs of D.

and after a several times of such a collision, it losses most of the energy and becomes the interstitial. In this case the distance of the interstitial and the vacancy is larger as compared with the former three cases. These four cases are listed in Table I. In the above classification we consider the two extreme cases that the close I–V pair is produced and not in Second and Third. We will call them Case 1 and Case 2. The ratios of the number of the close I–V pairs to that of the total I–V pairs are listed in lines C and F in Table I.

Since all of the calculations hitherto proceeded are idealized ones and other process such as annealing are never considered, the results must be compared with irradiation experiments done at liquid helium temperature, where all of the I–V pairs produced by irradiation will be conserved without annealing. The Oak Ridge group find[3] that in copper and aluminium about 40 and 50% of the damage anneal below 60°K respectively. Our calculation is done for germanium but we have not any special consideration upon crystal structure. Our results, therefore, can be applied to copper and aluminium. By our results the ratios of the close I–V pairs to the total I–V pairs are about 60 and 30% for Case 1 and Case 2 respectively.

The method by Snyder and Neufeld has been used to calculate the number of defects produced by irradiation of high energy particles. And it has been found that the calculated number is larger than the experimental number[17]. The number of the I–V pairs in Case 1 corresponds to the above method. There are several reasons that the calculated number is larger than the experimental number. For instance behaviour of the moving atom with energy below 25 eV after collision must be taken into accounts. The decrease of about 40% in the total number of the I–V pairs is seen in Case 2.

Considering the number of the I–V pairs, Case 2 is better than Case 1. The ratio of the close I–V pairs to the total I–V pairs is about 30% in Case 2 and it is 10 and 20% smaller than the annealing ratio of the damage below 60°K for copper and aluminium respectively. The annealing of the damage below 60°K is caused mainly by the close I–V pairs. Discrepancy of 10 and 20% shown above must be caused by the assumptions in § 2 and the fact that the values calculated for germanium are used for other substances.

The following results can be known from Figs. 3 to 6. The interstitials and the vacancies are distributed in several groups. They exist in the concentrated damaged region which is enveloped by a sphere of about from 50 to 100 atomic distances of diameter. There is no tendency that the concentrated damaged region spreads in the incident direction of the first knocked-on atom and that the interstitials distribute in the outer part of the concentrated damaged region.

The concentrated damaged region in germanium may cause energy levels of electrons and holes in a forbidden band due to defects to have band structure. We found⁶⁾ that the energy level of neutron-irradiated germanium has band structure and that of γ-ray irradiated germanium is fairly discrete. The experimental results agree with the idea of the concentrated damaged region.

On the Electron Emission From Oxide Coated Cathode Subject to Strong Electric Field

By Chokichiro SHIBATA
Research Division, Nihon Musen, Mitaka, Tokyo

(Received August 12, 1960)

The electron emission from the oxide coated cathode was measured in a wide range of electric field intensity, where a deviation from Shottky effect appears.

The phenomena could be explained by considering the emission increase by avalanche effect in the oxide layer. The calculation of the enhanced emmission current was performed and compared with the measured results.

§ 1. Introduction

When the anode voltage is sufficiently higher than the voltage just enough to draw the thermal saturation current from the cathode, we have the so-called Schottky current given by the following formula[1],

$$i_0 = i_s \exp\left(e^{3/2}\sqrt{E}\,/\kappa T\right), \qquad (1)$$

where e is the electronic charge, E the field intensity and i_s is the thermal saturation current given by Richardson's formula[2]. In the Schottky region, the $\log i_0$ *vs.* $\sqrt{E}$ curve should show a straight line and its gradient gives $e^{3/2}/\kappa T$. It is known that for the oxide coated cathode the gradient is several times larger than the Schottky's theoretical value, but the relation between $\log i_0$ and $\sqrt{E}$ remains to be a straight line[3),4)].

The author has found the fact that, in a very strong electric field such as is encountered in high power magnetrons and klystrons, the electron emission from the oxide coated cathode differs from the formula (1). It was also found that the phenomena is highly dependent upon the structure of the oxide matrix[5].

In this paper, the data measured by the author are presented, which can not be explained by the existing theories. Further, a theoretical formula is derived by considering the avalanche effect in the oxide matrix in order to clarify the mechanism of the anomalous emission.

Measurements of both the resistance of the oxide layer and the electron mean free path in the matrix are described and the results were used for the evaluation of the theoretical formula. The measured values are compared with the calculation from the formula. Both show a fair agreement in tendency.

§ 2. Electron Emission in Strong Electric Field

2.1 *Measuring method and apparatus*

Test tubes were small gap diodes as shown in Fig. 1. The anode consisted of a single tungsten rod 4 mm in diameter to which a radiator was attached for cooling. The cathode was made of a nickel disc 6 mm in diameter.

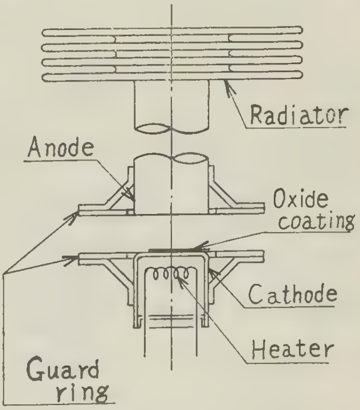

Fig. 1. The construction of the test diode.

In order to reduce the anode loss, the area of the oxide coating was limited to 2 mm in diameter. Guard rings were attached to both the anode and the cathode for making the field uniform. Tubes of the first kind (abridged No. 1) had cathodes of SrBa $(CO_3)_2$ coating, about 50 μ in thickness. Tubes of the second kind (abridged No. 2) were prepared by making treatment on tubes No. 1 after completing all the measurement with them, as follows. Wet hydrogen gas was injected into a tube

No. 1 and the cathode heated in that atomosphere, and then the tube was exhausted and treated in the ordinary ways. After these treatments, the No. 2 cathode is considered to be more sintered and far less porous than the No. 1 cathode. Table I shows an example on the shrinkage of the cathode matrix. The anode currents i were measured for No. 1 and No. 2 cathodes at various temperatures and anode voltages. The measuring circuit is shown in Fig. 2. To avoid the overheating of the anode and the destruction of the cathode matrix by high current, the pulsed measurements were adopted in the high voltage region, while the DC measurements were performed at low voltages (below about 2,000 V), because the pulse modulator was unstable at such low voltages. The pulse width was 1 μs, pulse repetition rate 500 p.p.s. and the duty cycle 5/10000.

Table I.

Sprayed thickness of $BaSr(Co_3)_2$	No. 1 after exhausting treatment	No. 2 after exhausting treatment
100 μ	70 μ	40 μ

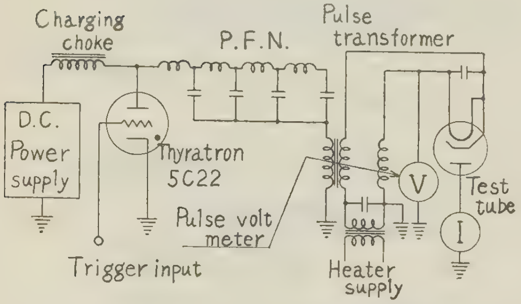

Fig. 2. The circuit for pulse measurement.

2.2 *Experimental results and discussions*

The currents measured at various temperatures for various anode voltages are plotted versus the square root of the field intensity in Fig. 3 and Fig. 4 for No. 1 and No. 2 cathodes respectively. According to the Schottky formula, $\log i$ *vs.* $\sqrt{E}$ curves should show straight lines. However, noticeable deviations are clearly seen in Fig. 3, while the deviations are rather less noticeable for No. 2 cathode as shown in Fig. 4, but in the low field region where DC measurements were carried out, the linearity is well kept excepting in the space charge limited region, as shown in Fig. 5. The dependence of $\log i/T^2$ upon $1/T$ is shown in Fig. 6. As to the Schottky current, this relation should show a straight line, but it seems to be correct only in the low voltage region (DC measurement) as seen in Fig. 6. The gradient of the Schottky line is given by

$$d\log i_0/d\sqrt{E} = e^{3/2}/\kappa T\ . \qquad (2)$$

The measured and computed values of the gradient $d\log i/d\sqrt{E}$ are plotted against $1/T$ in Fig. 7. The lines for DC measurements (weak field) using both No. 1 and No. 2, and for pulsed measurements (strong field) using No. 2 are parallel with the Schottky-theoretical

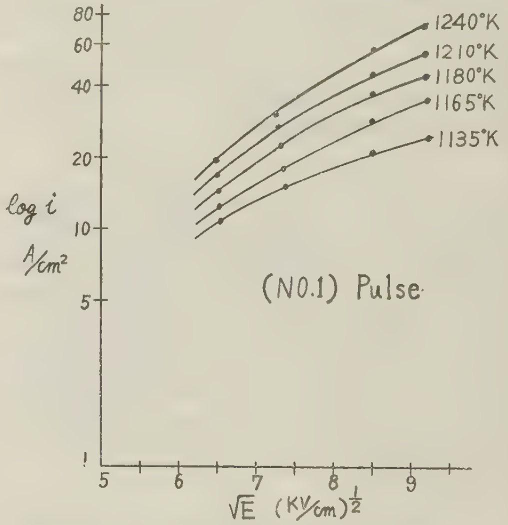

Fig. 3. $\log i$ *vs.* $\sqrt{E}$ for No. 1 cathode.

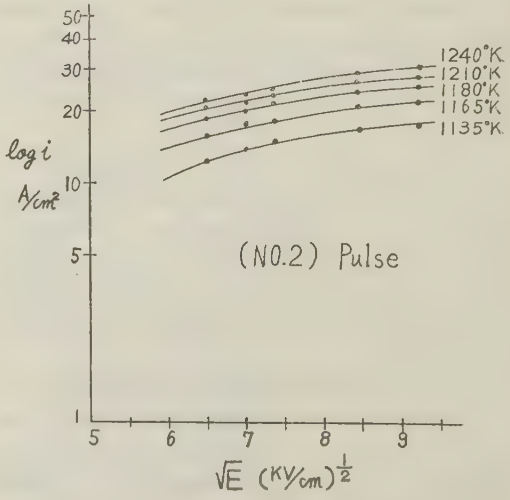

Fig. 4. $\log i$ *vs.* $\sqrt{E}$ for No. 2 cathode.

line, but the line for pulsed emission from No. 1 cathode is far from parallel. From these results, we can see that under very strong field such as of a few ten thousands volts per centimeter, the mechanism of the high emission current from oxide coated cathode differs from the Schottky effect.

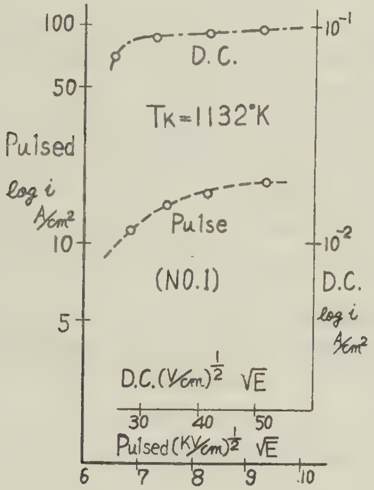

Fig. 5. Comparison between $\log i$ *vs.* $\sqrt{E}$ relations for No. 1 cathode in pulse and *DC* measurements.

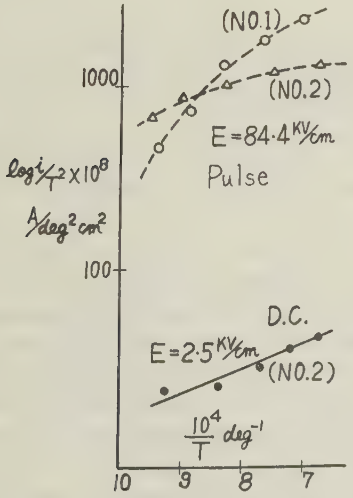

Fig. 6. The temperature dependence of $\log i/T^2$ for No. 1 and No. 2 cathodes.

2.3 *Discussion on the existing theories of the anomalous emission from oxide coated cathode*

There have been published several studies about the anomalous emission from oxide cathode, which deviates from the Schottky effect.

The first is that the deviation has been attributed to the nonuniformity of the electric field at the surface of the cathode caused by the inhomogeneity of the work function of the surface[6]. However, since the partial difference of work function between patches on the cathode surface is no more than a few volts, it will contribute to deviation from a straight line only in the low voltage region. So, it may be put out of consideration in such a very strong field as is associated with our present problem. The second is that the deviation is due to the local high field on the oxide surface, resulting from the ruggedness of the cathode surface[3),4)]. Even if this effect is taken into consideration, since the structure of the cathode surface does not be changed with the temperature the dependency of $\log i/T^2$ upon $1/T$ must remain a straight line.

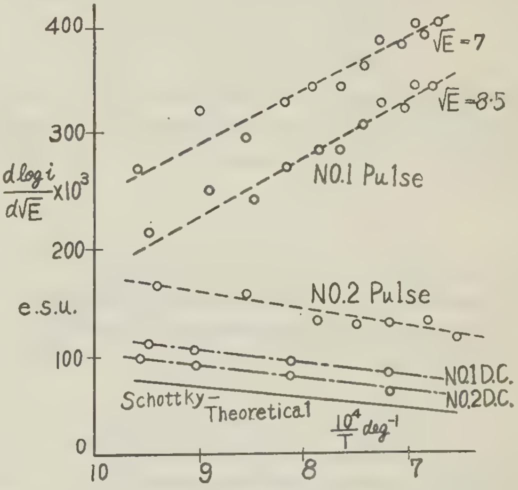

Fig. 7. The temperature dependence of the gradient $d \log i/d\sqrt{E}$.

In the low voltage region this relation seems to be correct, but in the high voltage region and especially in the case of No. 1 cathode, the deviation from a straight line is clearly seen in Fig. 6, and besides, in Fig. 7 the gradient becomes opposite to the Schottky-theoretical line in some cases. Thus, the existing theories do not seem to be able to explain the deviation from the Schottky formula. The author has succeeded in explaining the deviation by considering the electron multiplication in the oxide matrix.

§ 3. Electron Multiplication due to Secondary Emission

3.1 *Possibility of avalanche in the oxide matrix*

Metson has shown that the whole cathode current is thermionically emitted at the cathode core surface and passes vacuum-wise through the pores of the matrix in the temperature range higher than 900°K[7]. An electron which has travelled through the pores without impact and gained a sufficient velocity to emit secondary electrons, will cause secondary electrons at an impact with an oxide particle. The circumstances are very similar to the electron moving between gas molecules, which after travelling some distance makes an impact with gas molecules, ionizes them, and increases the number of electrons[8].

Let n_0 be the initial number of electrons and L the mean free path. The number n which made first impacts between $x=a$ and $x=b$ $(b>a)$ is expressed by

$$n=\int_a^b \frac{n_0}{L}\exp\left(-\frac{x}{L}\right)dx \tag{3}$$

and the number n_1 which make first impacts between $x=a$ and $x=b$ and then travel until $x=d$ $(d>b)$ without impacts is given by

$$n_1=\int_a^b \frac{n_0}{L}\exp\left(-\frac{d}{L}\right)dx\ . \tag{4}$$

In this paper, the theory is constructed in a similar manner to the electron discharge in gas on the basis of the following assumptions in which the author's fundamental concepts are included.

(i) The number of primary electrons emitted at the cathode core is determined by the Schottky current according to the formula (1), depending on the temperature and the field intensity there.

(ii) The electron motion is only in the direction towards the anode.

(iii) The coefficient of secondary electron gain α should vary with the primary electron velocity, but for the simplicity we assume in the following that the gain in zero below a certain value (V_c) of the accelerating voltage and becomes a constant value α when the voltage has reached V_c and remains it afterwards.

(iv) We assume that the electric field in the matrix is uniform, so the field intensity in the matrix is given by

$$E=\frac{V_l}{l}\ ,$$

where l is the thickness of the matrix layer and V_l is the potential of the oxide surface.

(v) The path L_c through which the electron must travel to obtain the accelerating voltage V_c is

$$L_c=\frac{V_c}{V_l}l \tag{5}$$

and the electron velocity corresponding to V_c is given by

$$v_c=\sqrt{\frac{2l}{m}V_c}\ .$$

Electron that makes impact after travelling a path less than L_c is assumed to start from there with zero velocity, without being multiplied.

The electron that has travelled more than L_c will produce α secondary electrons at an impact, which start from there with zero velocity.

3.2 *Enhanced current in the case of* $2L_c>l\geq L_c$

In the case of $L_c>l$ or $V_c>V_l$, the formula (1) can be applied. In this section, the simplest case, when $2L_c>l\geq L_c$ is considered.

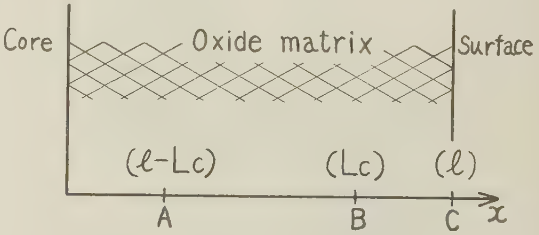

Fig. 8. The section of the cathode.

In Fig. 8, the surface of core metal is denoted by 0 and the surface of oxide matrix by C. Electron can be multiplied by α times at an impact if it is accelerated to more than V_c. After m times repetition of these impacts, the number of electrons will be multiplied by α^m. In the general case, $nL_c>l\geq(n-1)L_c$, m takes values, $1, 2, 3, \cdots (n-1)$. When $n=2$ as in the present case, we have only to consider the case of $m=1$.

Referring to Fig. 8, only the following two groups of electrons are considered for the calculation of α time multiplication.

(a) Electrons which make the first impacts between B and C.

(b) Electrons which make impacts between 0 and A, and next impacts between B and C after having travelled L_c or more.

The currents of electrons of groups (a) and (b) are given by the following formulas

$$i_1=\int_{L_c}^{l}\frac{i_0}{L}\exp\left(-\frac{x_1}{L}\right)dx_1=i_0\left\{\exp\left(-\frac{L_c}{L}\right)-\exp\left(-\frac{l}{L}\right)\right\} \tag{6}$$

and

$$i_2=\int_0^{l-L_c}dx_2\int_{x_2+L_c}^{l}\frac{i_0}{L^2}\exp\left(-\frac{x_1}{L}\right)dx_1=i_0\left\{\exp\left(-\frac{L_c}{L}\right)-\frac{l+L-L_c}{L}\exp\left(-\frac{l}{L}\right)\right\}, \tag{7}$$

where i_0 is the primary current starting from the core surface and is determined by the formula (1). Let the current of the other electrons which can not cause secondary electrons be denoted by i_3. Then we have

$$i_0=i_1+i_2+i_3\ .$$

The observed emission current i_0' is given by

$$i_0'=\alpha(i_1+i_2)+i_3=i_0+(\alpha-1)(i_1+i_2)\ . \tag{8}$$

Using (6) and (7) we get

$$i_0'=i_0[1+(\alpha-1)\{2\exp(-A)-\exp(-B)(2+B-A)\}] \tag{9}$$

where $A=\frac{L_c}{L}=\frac{V_c}{V_l}\frac{l}{L}$, and $B=\frac{l}{L}$.

Substituting $p=\frac{V_c}{V_l}$, we obtain

$$A=pB \qquad \text{or} \qquad p=\frac{L_c}{l} \tag{10}$$

and

$$i_0'=i_0\{1+(\alpha-1)[2\exp(-pB)-\exp(-B)\{2+B(1-p)\}]\}\ . \tag{11}$$

The condition for l is expressed by

$$2>\frac{1}{p}\geq 1\ . \tag{12}$$

3.3 *Theoretical formula of the general case*

The method described in 3.2, can be extended to the general case of $nL_c>l\geq(n-1)L_c$. Substituting $f(x)=\exp(-x/L)$, the current i_m of the electrons which cause α^m time multiplications is given by the expression:

$$i_m=i_0[\textstyle\sum_1(\phi_1(l)+\phi_2(l)+\phi_3(l)+\phi_4(l))+\sum_2(\phi_1(x_1)+\phi_2(x_1)+\phi_3(x_1)+\phi_4(x_1))]\ , \tag{13}$$

where

$$\textstyle\sum_1=\sum_{j_m=1}^{n-m-1}\ \sum_{j_{m-1}=1}^{(n-2)-j_m}\ \sum_{j_{m-2}=1}^{(n-2)-j_{m-1}}\cdots\sum_{j_h=1}^{(n-2)-j_{h+1}}\cdots\sum_{j_1=1}^{(n-2)-j_2}\ , \tag{14}$$

$$\textstyle\sum_2=\sum_{j_m=1}^{(n-m)-(m-1)}\ \sum_{j_{m-1}=1}^{(n-m)-(m-2)-j_m}\ \sum_{j_{m-2}=1}^{(n-m)-(m-3)-(j_m+j_{m-1})}\cdots\sum_{j_h=1}^{(n-m)-(h-1)-\sum_{k=h+1}^{m}j_k}\cdots\sum_{j_1=1}^{(n-m)-\sum_{k=2}^{m}j_k}\ , \tag{15}$$

and

$$\phi_1(x_1)=\int_{j_m L_c}^{l-[(n-1)-j_m]L_c} dx_m \int_{x_m+j_{m-1}L_c}^{l-[(n-1)-(j_m+j_{m-1})]L_c} dx_{m-1}\cdots\int_{x_{h+1}+j_h L_c}^{l-[(n-1)-\sum\limits_{k=h}^{m} j_k]L_c} dx_h\cdots$$
$$\times\int_{x_2+j_1L_c}^{l-[(n-1)-\sum\limits_{k=1}^{m} j_k]L_c}\frac{f(x_1)}{L^m}dx_1\ , \qquad (16)$$

$$\phi_2(x_1)=\int_{0}^{l-(n-1)L_c} dx_{m+1}\int_{x_{m+1}+j_m L_c}^{l-[(n-1)-j_m]L_c} dx_m\cdots\int_{x_{h+1}+j_h L_c}^{l-[(n-1)-\sum\limits_{k=h}^{m} j_k]L_c} dx_h\cdots$$
$$\times\int_{x_2+j_1L_c}^{l-[(n-1)-\sum\limits_{k=1}^{m} j_k]L_c}\frac{f(x_1)}{L^{m+1}}dx_1\ , \qquad (17)$$

$$\phi_3(x_1)=\int_{l-(n-1)L_c+j_mL_c}^{(1+j_m)L_c} dx_m\int_{x_m+j_{m-1}L_c}^{(1+j_m+j_{m-1})L_c} dx_{m-1}\cdots\int_{x_{h+1}+j_hL_c}^{\left(1+\sum\limits_{k=h}^{m} j_k\right)L_c} dx_h\cdots$$
$$\times\int_{x_2+j_1L_c}^{\left(1+\sum\limits_{k=1}^{m} j_k\right)L_c}\frac{f(x_1)}{L^m}dx_1\ , \qquad (18)$$

and

$$\phi_4(x_1)=\int_{l-(n-1)L_c}^{L_c} dx_{m+1}\int_{x_{m+1}+j_mL_c}^{(1+j_m)L_c} dx_m\cdots\int_{x_{h+1}+j_hL_c}^{\left(1+\sum\limits_{k=h}^{m} j_k\right)L_c} dx_h\cdots\int_{x_2+j_1L_c}^{\left(1+\sum\limits_{k=1}^{m} j_k\right)L_c}\frac{f(x_1)}{L^{m+1}}dx_1\ . \qquad (19)$$

$\phi_1(l)$, $\phi_2(l)$, $\phi_3(l)$ and $\phi_4(l)$ in (13) are given by substituting $f(l)$ for $f(x_1)$ in the formulas (16), (17), (18) and (19) respectively.

Using (13), the enhanced current to be observed is given by the formula:

$$i_0'=\sum_{m=1}^{n-1}[i_0+(\alpha^m-1)i_m]\ . \qquad (20)$$

---

§ 4. Measurement of Resistance of Oxide Layer and Estimation of V_l

It is very difficult to directly measure the surface potential V_l of the matrix when a heavy current is passing through it. So we shall attempt to determine the value of V_l at each temperature of the cathode as the product of the resistance and the current passing through the matrix given in Fig. 3 and Fig. 4.

4.1 *Method of measuring resistance*

The measurement of the cathode layer resistance was performed in a similar way to Metson's[8] but the prove was not inserted in the matrix. The construction of the experimental tube is shown in Fig. 9 and the circuital arrangement for measurement of the potential and the current between base cores is shown in Fig. 10. Each heating current was adjusted so as to maintain the temperature of each core at the desired value. First the potential difference V_0 between both cores was observed when no voltage was applied on the oxide layer. Then applying the volt-

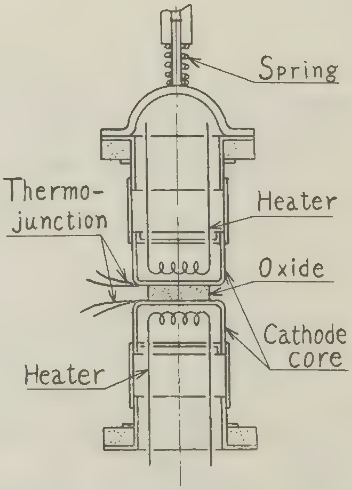

Fig. 9. The construction of the test tube for measuring oxide layer resistance.

age between cores the current was fixed at some value I_1 and the potential difference V_1 between cores was again observed. In measuring the potential difference, attention was paid not to pick up currents through the circuit for measuring the potential difference. The zero method was adopted by making use of potentiometer.

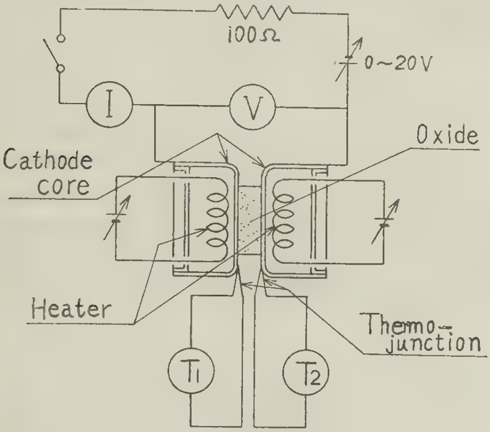

Fig. 10. The circuit for resistance measurement.

The resistance of the oxide layer is then given as follows:

$$R=\frac{1}{I_1}(V_1-V_0)\,. \tag{21}$$

4.2 *Results of measurement*

The value of the oxide layer resistance thus obtained is plotted as a function of $1/T$ as shown in Fig. 11. Using the values of resistance in Fig. 11 and the values of current in Fig. 3 and Fig. 4, the surface potential V_l is estimated as shown in Fig. 12 and Fig. 13. It is seen that V_l is higher than 100 volts in almost the whole range of measurement for No. 1 cathode while it is below 100 volts for No. 2 cathode.

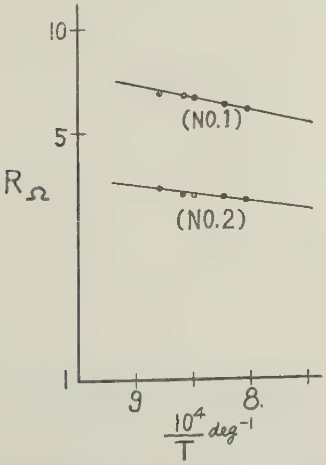

Fig. 11. The temperature dependence of the oxide layer resistance.

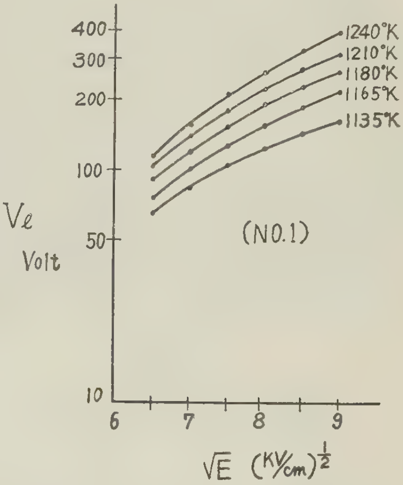

Fig. 12. The temperature dependence of the surface potential for No. 1 cathode.

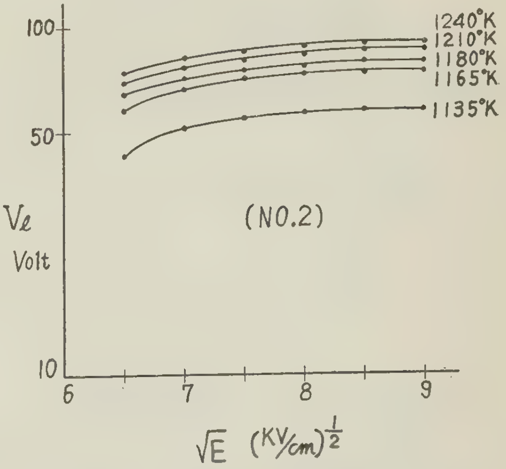

Fig. 13. The temperature dependence of the surface potential for No. 2 cathode.

§ 5. Mean Free Path of Electron in the Oxide Matrix

5.1 *Principle of measurement*

The measurement of the mean free path of electron in the oxide matrix was performed according to the following principle. In Fig. 14, let n_0 be the number of electrons incident on the oxide matrix, then the number of electrons which have passed through the matrix without impacts is given by:

$$n_1 = n_0 \exp\left(-\frac{l}{L}\right).$$

Let the incident electrons have an uniform velocity $v_0 = \sqrt{\frac{2e}{m} V_0}$ and the cathode core be at the potential V_0. If the potential drop of the matrix surface against the core is ΔV_0, the electrons produced at impacts should have velocities less than $\Delta v_0 = \sqrt{\frac{2e}{m} \Delta V_0}$ at the core surface. On the other hand, the electrons which arrive at the base core without impacts should have the velocity v_0. Thus the velocity distribution of electrons at the base core must be as shown in Fig. 15. If a retarding potential is applied to the base core, only those electrons which have velocities sufficient to overcome the retarding potential can arrive at the core. Thus the current versus retarding potential can be represented by a curve as shown in Fig. 16. The current at the zero retarding potential is given by incident electrons corresponding to n_0 and the current at higher voltages near $-V_0$ is equal to i_1 corresponding to n_1. Thus the mean free path L is given by the formula:

$$L = -l \Big/ \log \frac{i_1}{i_0}. \qquad (22)$$

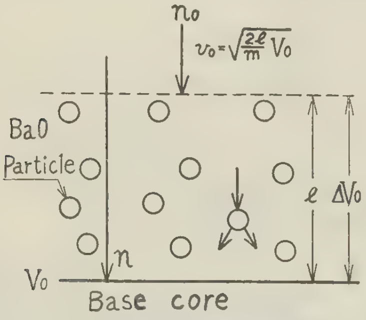

Fig. 14. A schematic representation of electron behaviour in the oxide matrix.

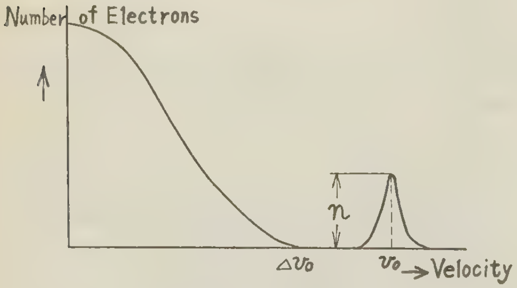

Fig. 15. The velocity distribution of electrons at the core surface.

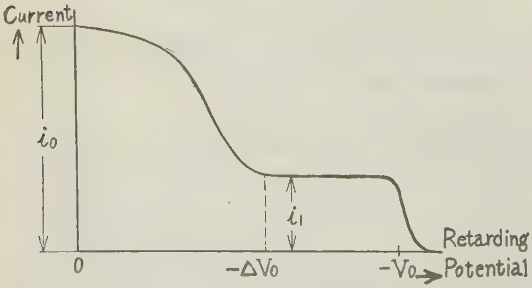

Fig. 16. The current *vs.* retarding potential on the core.

5.2 *Experimental procedure and results*

The measuring arrangement is shown in Fig. 17, where K_1 is the cathode which supplies the primary electrons, A the accelerating grid, B the shielding plate, C the Faraday cage for suppressing stray electrons and K_2 is the cathode on which the oxide matrix to be measured is coated. In Fig. 17, V_0 is fixed at a predetermined value (200 V) and by varying V_1, the potential of K_2 is adjusted to be negative against A. The measured value of the current passing through the matrix is

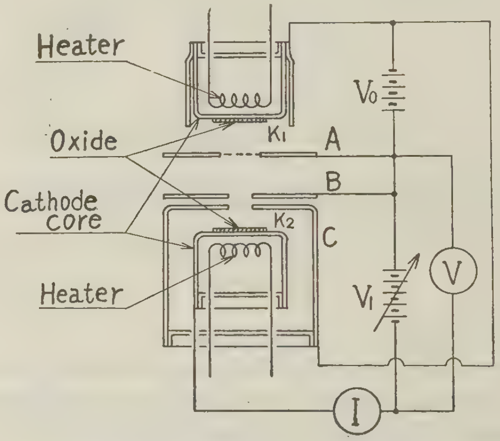

Fig. 17. The construction of the test tube and the arrangement for mean free path measurement.

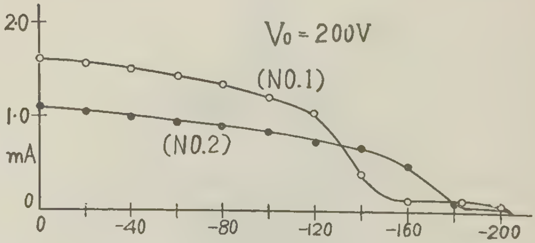

Fig. 18. Measured currents *vs.* retarding potential on the core.

shown in Fig. 18. Using the formula (22) and the values of current in Fig. 18, the values of the mean free path are obtained as shown in Table II.

Though precise reports on the measurement of the mean free path of electron in the oxide matrix have not been reported, it is generally believed that the mean free path is of the order of the size of oxide particles and pores, which is about a few microns. The measured values in Table II seem to be somewhat larger. The reason for it is not clear but the following circumstances must be considered.

Table II.

Cathode	i_1	i_0	$\log i_0/i_1$	l	L
No. 1	0.11mA	1.6mA	3,314	56 μ	20.9 μ
No. 2	0.04mA	1.1mA	2,677	32 μ	9.65 μ

In our measurement, the electrons which make elastic impacts with oxide particles are equivalent to the electrons which make no impacts. So, the mean free path we obtained might have resulted in the larger value. However, such values just fit the fundamental concepts, since the elastic impacts are regarded ineffective.

§ 6. Comparison between Numerical and Experimental Results

Bruining has measured the variation in the coefficient of secondary emission gain α of BaO with the incident electron voltage V_p, which is shown by the solid line in Fig. 19. In order to simplify the calculation, we assume that α is zero under a certain value of V_p (that is, V_c) and is a constant value at and beyond V_c, as approximated by the broken line taking $V_c=100$ volts and $\alpha=4$ in the mean.

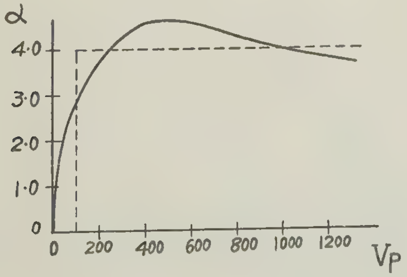

Fig. 19. The secondary emission coefficient *vs.* accelerating voltage.

It can be seen at once from this value of V_c and the values of V_l in Fig. 13 why the avalanche effect is not remarkable for No. 2 cathode. As is seen in Fig. 12, V_l for No. 1 cathode ranges from less than 100 volts to more than 100 volts, but as an approximation the formula (11) is used here for No. 1. First, DC measurements were performed at various cathode temperatures to obtain the thermal saturation currents i_s, which were reduced to the zero field. The i_s *vs.* T curve is shown in Fig. 20. Using the values of i_0 which are obtained by applying the i_s on the formula (1), the enhanced currents i_0' are derived from the formula (11). The curves in Fig. 21 which show the relation between i_0' and $\sqrt{E}$ at various cathode temperatures have a very

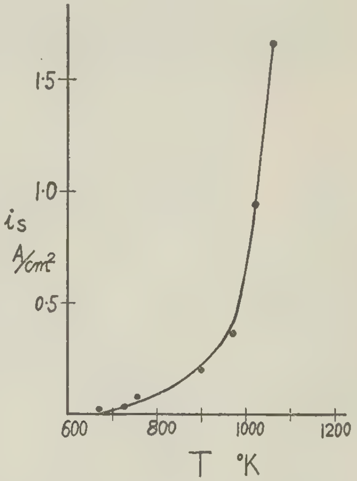

Fig. 20. The temperature dependence of the thermal saturation current.

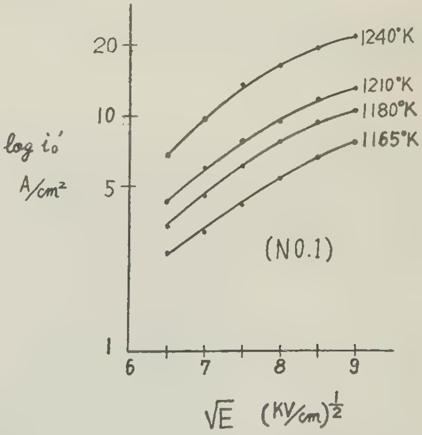

Fig. 21. Computed curves for $\log i_0'$ *vs.* $\sqrt{E}$ for No. 1 cathode.

similar tendency to the curves in Fig. 3. Numerical discrepancies are thought to be due chiefly to the following reasons. First, some approximation procedures were taken in the calculation. Secondly, DC measurements were performed to determine the values of i_s. It is well known that the values by pulsed measurements are often several times larger than the values by DC measurements because of the initial decay of the emission, especially when a pulse of short width is used[4]. The gradient of the curves in Fig. 21, that is $d \log i_0'/d\sqrt{E}$, has been calculated as shown in Fig. 22. These gradients are opposite to the Schottky-theoretical one, and they agree in tendency with the experimental curves for No. 1 in Fig. 7. In the case of No. 2 cathode, since it is so much sintered that the surface potential is very low and the mean free path is also small, the multiplication does not occur and the gradient is similar to the Schottky line.

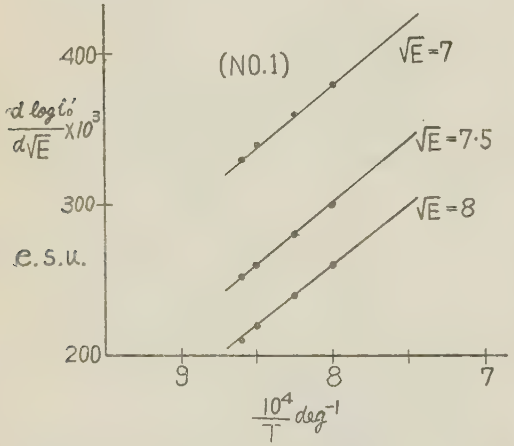

Fig. 22. Computed curves from Fig. 21 for the gradients $d \log i_0'/d\sqrt{E}$ *vs.* $1/T$.

§7. Conclusion

It has been shown that the electron emission current from the oxide coated cathode in the very strong field is enhanced beyond the Schottky effect by the avalanche effect in the oxide matrix. In the temperature range of our measurements, the behaviours of electrons in the oxide matrix are considered as follows.

(i) The primary electrons starting from the core surface are the thermal saturation currents or Schottky currents corresponding to the temperature and the field intensity at that place.

(ii) The electrons moving vacuumwise in the oxide matrix are classified as follows:

(a) The electrons which pass through without impacts or make impacts with oxide particles with velocities less than a critical velocity v_c. These electrons after impacts will start with zero velocity from the positions of impact in the matrix.

(b) The electrons which make impacts after having been accelerated in the matrix to the velocity higher than v_c in the matrix. These electrons will be multiplied α times at each impact, and then they start with zero velocity from the positions of impact.

(iii) The electrons transfered from solid n-type semi-conduction will act to keep the potential constant at each part of the matrix in spite of the electron multiplication. The measured emission current i_0' is the summation of the currents caused by the electrons belonging to (ii)-(a) and (ii)-(b). Since the result of calculation from formula (11) is in fair agreement in tendency with the experimental result, it seems that the above described model can explain the mechanism of the emission in the very strong field.

Resistivity Striations in Germanium Single Crystals

By Hiroshi UEDA*
Musashi Works, Hitachi Ltd. Kodaira-machi, Tokyo

(Received August 25, 1960)

Resistivity striations resulting from periodic distribution of impurities have been observed in single crystals of germanium grown horizontally. The period of the striations ranges from 0.1 to 0.6 mm, depending upon growth conditions. It is proportional to the average growth rate and inversely proportional to the temperature gradient within the crystal near the solid-liquid interface. This relation can be explained by assuming the supercooled state in the course of germanium crystal growth by the zone leveling technique. By the repeated supercooling and recovery from it, the crystalization proceeds periodically, resulting in the periodic change of the transient growth rate and the periodic segregation of impurities.

§ 1. Introduction

Periodic resistivity variations have been observed in germanium crystals grown horizontally. Two methods of detecting minute resistivity variations were developed. One is selective electrolytic etching and the other is micro potential scanning. The two methods, when properly correlated, can yield full information about the resistivity variations both qualitatively and quantitatively.

The period of the resistivity striation ranged from 0.1 mm to 0.6 mm, and 30 to 50 per cent resistivity variations are observed. In the case of the vertically pulled crystals this effect was very small.

At first we attributed this effect to outer conditions[1),2)] of crystal growth such as a temperature controller, furnace pulling mechanism, line voltage fluctuations, etc. But the period resulting from these fluctuations do not coincide with that of resistivity striations. Furthermore, we used high power batteries as the power source of the furnace, eliminated the temperature controller, and took special care to get smooth furnace movement. But in spite of these, resistivity striations were still present. So, it was concluded that the cause of these phenomena was purely internal.

Definite relation was shown to exist between the period of the striations, the growth rate and the temperature gradient near the solid-liquid interface. In this paper we show that this relation can be explained by assuming the existence of supercooled state in the crystalizing solid-liquid interface of germanium.

§ 2. Preparation of Samples and Observation of Striations

Germanium single crystals were grown by the zone leveling technique, using intrinsic zone-refined polycrystals and intrinsic seed crystals. For n type, antimony was doped to control the resistivity, ranging from 0.1 to 20 Ω cm. The test bars were cut from zone leveled crystals to include two end surfaces perpendicular to the growth direction, the other surfaces being parallel to the growth direction. All surfaces were lapped by #4,000 carborandum, and a lead wire was soldered,

---

* Present address: Central Research Laboratory, Hitachi, Ltd. Kokubunji, Tokyo, Japan.

Samples were electrolytically etched in 10% KOH solution anodically. The conditions for current density are not critical, 0.1 to 0.3 A/cm², and can be determined by preliminary tests. Etching time ranges from 1 to 2 minutes, and the temperature of electrolyte is about 70°C. An example thus treated is shown in Fig. 1. From Fig. 1 we see that the side surfaces during crystal growth have curved surface. The latter was confirmed as follows. A p-n junction was made by proper doping in the course of crystal growth. In Fig. 2 a p-n boundary is revealed and striation patterns run parallel to the p-n boundary. Fig. 3 shows the interface between the seed crystal and the grown crystal. As in Fig. 2, striations run parallel to the boundary. In this case the seed crystal was made by the Czochralski method, and did not exhibit striations.

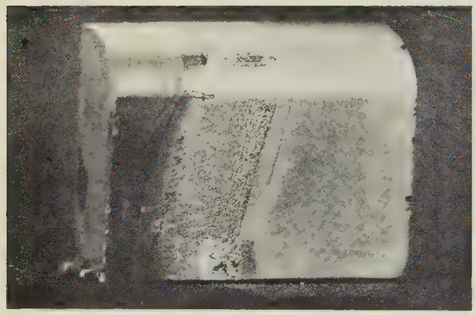

Fig. 2. A *p-n* junction and striations shown by electrolytic etching.

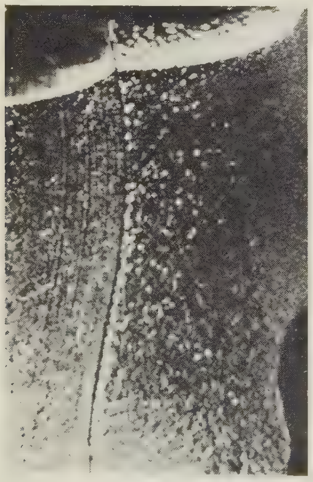

Fig. 3. A solidification line of a zone leveled crystal.

§ 3. The Measurement of Resistivity Striations

Measurements of resistivity of semiconductor are usually carried out by the four probe method[3]. But this method is not adequate to determine the minute resistivity variations in a localized small portion. We used one probe potential scanning method. D. C. voltage was applied across the sample and potential profile was taken by scanning the tungsten probe along the sample, using the micromanipulator. The sample should be in a form of rectangular bar. The bar should be cut so that the long dimension in the direction of scanning should be perpendicular to the equiresistivity planes. These planes can be marked with this electrolytic etching. From the derivatives of the potential profile resistivity can be estimated. Fig. 4 shows an example of resistivity variations in a zone leveled single crystal. In Fig. 4, the arrows indicate the deep etched portions of the same sample. Comparing the period of etched striations with that of resistivity striations, the agreement is very satisfactory.

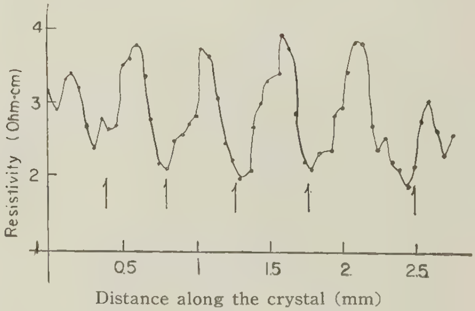

Fig. 4. Resistivity plotted by micro potential scanning. Arrows indicate deep etched portion of the same sample.

§ 4. Resistivity Variations and Growing Conditions

4.1 *Czochralski method versus horizontal zone leveling*

Using the above mentioned two methods, a comparison was made between variations in Czochralski crystals and horizontally grown crystals. It was found that vertically grown crystals showed very small resistivity variations, but in some samples of horizontally pulled crystals variations over 50 per cent were found. A typical result is shown in Fig. 5. As shown in Fig. 3. the Czochralski crystal showed no etched striation pattern.

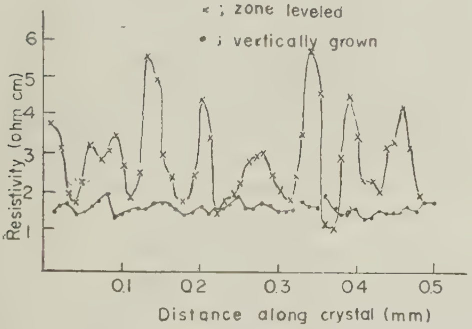

Fig. 5. Resistivity plots, taken from zone leveled germanium and vertically grown crystal.

4.2 *Annealing effects*

If a crystal which has resistivity striations were subjected to heat treatment, a diffusion process would take place and striations would disappear. To confirm this effect, a sample of *n* type 2Ω cm horizontal crystal was annealed at 910°C for 10 hours. The sample which showed about 50% variations at first showed variations much less than 10% after heat treatment.

4.3 *Striations and outer growing conditions*

We thought at first that the striation should be attributed to the fluctuations of the growing conditions such as furnace temperature, rate of pulling, gas atmosphere. We checked carefully above conditions. For instance, we used a high power battery to heat the furnace to eliminate the effect of line voltage fluctuation. Various pulling mechanisms were used, but the striations appeared. To eliminate the effect of atmosphere fluctuation, some crystals were pulled in vacuum. But the striations still appeared.

§ 5. The Period of Resistivity Striations

In the next step, we tried to vary the period of the resistivity striations by changing the growing conditions.

First, we changed the pulling speed of furnace. To drive the zone-leveling furnace, a synchronous motor and oscillator with variable frequency were used. The result is shown in Fig. 6 that the period of the resistivity varies linearly to the pulling speed.

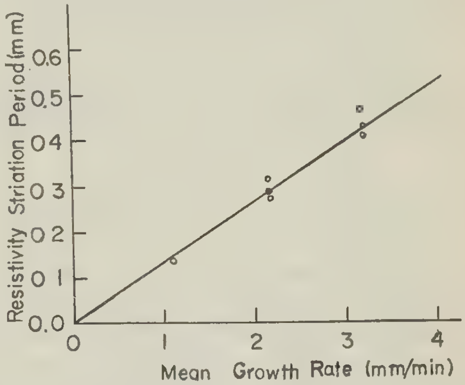

Fig. 6. Relation between striation period and mean growth rate.

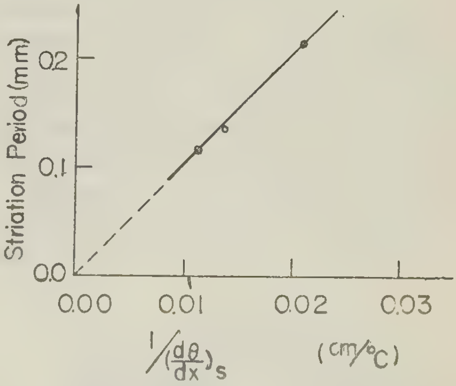

Fig. 7. Relation between striation period and temperature gradient.

Next, we tried to find the relations between the striation period and temperature gradient in the crystal near the solid-liquid interface. The temperature gradient of the furnace was varied by adding either after-heater furnace or after-cooling tube to the main furnace. Three conditions were established which correspond to temperature gradient respectively 47°C/cm, 73°C/cm and 90°C/cm. Striation observations on the crystals thus obtained showed that the periods of the striations are inversely proportional to the temperature gradient. In Fig. 7, a typical result is shown for mean growth rate, $R=1$ mm per minute. Results of the above mentioned two experiments are summarized in the following relation.

$$d=c\frac{R}{(d\theta/dx)_s}\,, \tag{5.1}$$

were

d: period of the resistivity striations (mm)
R: mean growth rate (mm/min)
$(d\theta/dx)_s$: temperature gradient (°C/mm)
c: constant

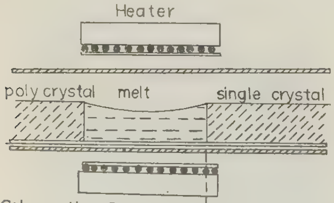
By selecting units as described, the numerical value of c was about one in our experiments.

§ 6. Discussions

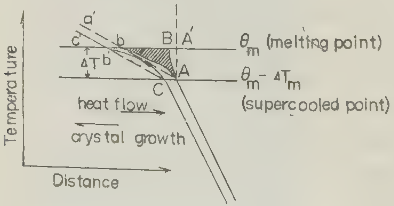
6.1 *Discussion on the causes of the resistivity striations*

As to the possible cause of the resistivity striations we considered that the growth rate of germanium crystal is not uniform, but changes periodically even though the furnace pulling was smooth and uniform.

It is well known that the segregation coefficient between solid and liquid varies with the variation of the growth speed of crystals[4]. So, if there exists a periodic variation of crystal growth speed, there appears a periodic variation in the apparent segregation coefficient, and thus, periodic impurity distribution may result. To explain why periodic variation in growth speed occurs, we considered the effect of supercooling. As will be shown in the next section, definite supercooling degree ΔT°C exists in crystallization of germanium. If germanium melt is cooled slowly enough, it does'nt solidify at its melting point θ_m°C, but supercooling of ΔT°C is required to start solidification. Once solidification begins, the latent heat of fusion is produced and the temperature of melt rises ΔT°C. After reaching the melting point, solidification stops.



(a) Schematic Configuration



(b) Temperature distribution

Fig. 8. Temperature distributions near the solid-liquid interface in horizontal growing crystal.

Fig. 8(a) and (b) show schematically the single crystal growing in the zone-leveling furnace and the temperature distribution near the solid-liquid interface respectively. In Fig. 8(b), the direction of heat flow is indicated. Temperature distribution a'Aa shows the state in which supercooling reaches its maximum value ΔT_m°C. As the furnace moves to the left, the temperature of the solid-liquid interface falls under this threshold $\theta_m-\Delta T_m$°C, and solidification begins suddenly to the left over the AA' surface and the position of interface moves to the left. The latent heat of fusion being produced, the temperature near the interface rises rapidly and the temperature gradient in the melt decreases. While the temperature of interface reaches the melting point θ_m and the crystal growth stops, heat is accumulated in the melt in front of the solid-liquid interface, and its temperature distribution becomes as shown in a'bBAa in Fig. 8(b). Then the position of the interface is indicated as B of the same figure. This process (recovery from supercooling) is completed in relatively short time, and so the movement of the furnace can be neglected. When the crystal growth stops, the latent heat of fusion is no longer produced, and the heat accumulated in the melt flows to the right through the solid-liquid interface. During this process, the temperature of solid-liquid interface falls gradually, keeping the supercooling state. When the temperature of the interface reaches its limit $\theta_m-\Delta T_m$, the furnace is located to the left by the amount of $AC(=A'B)$. Temperature fall of the interface is mainly caused by the thermal conduction in the ingot and not by the temperature gradient of the furnace. This can be shown by the measured value of the temperature gradient and the growth rate. At the end of this process, the temperature distribution becomes c'Cc as shown in the figure. It is similar to the initial temperature distribution a'Aa. Thus, the same process is repeated periodically and the crystal grows periodically with the period AC.

According to the above consideration, the experimental formula (5.1) can be derived as follows:

$$Q = T\cdot\left(\frac{d\theta}{dx}\right)_s\cdot\kappa\ .$$

Where Q is the heat to be carried away to the solid through the interface,

$(d\theta/dx)_s$ is the temperature gradient in the solid near the interface,

T is the time necessary for the process $\overrightarrow{BC}$,

κ is the thermal conductivity in the solid.

In this expression T means the time necessary for the process $\overrightarrow{BC}$, but process $\overrightarrow{AB}$ is assumed to be very short, so T can be thought to be equal to the time interval of the whole process. As the crystal is growing at the mean speed R, the period of striation is represented by the following relation.

$$d = RT = \frac{QR}{\kappa(d\theta/dx)_s}\ .$$

Thus we obtained the same relation as (5.1). To compare this formula with experiments, the numerical value of Q must be estimated. Q can be considered approximately as the heat accumulated in the volume ΔABb (Fig. 8).

$$Q \doteqdot \rho\cdot C_p\cdot\Delta T/2\cdot\overline{bB}\ .$$

Where ρ is the density

C_p is the specific heat.

As the excess temperature we take the half of the supercooling T and as the bB we take the half of the melt zone length. In our experiment zone length is 4 cm, and ΔT is 30°C as shown in next section. We get

$$Q = 5.5\times0.09\times30/2\times2.0 = 15\ \text{cal/cm}^2\ .$$

The value of κ can be taken as 0.1 watts/cm. deg. near the melting point[5], so we get

$$Q/\kappa = 1.0\ \text{degree min/mm}\ .$$

The agreement with our experiment is very satisfactory.

6.2 *Supercooling of germanium*

To examine the supercooling character of germanium, the following experiments were made. Zone refined germanium was melted in the quartz crucible and cooling curve was determined. Typical curve was shown in Fig. 9. ΔT of this figure is called the supercooling degree. Supercooling degree was measured at the various cooling rate. Fig. 10 shows the relation between ΔT and the cooling rate. In our ordinary zone leveling experiments ΔT can be taken as constant, that is about 30°C.

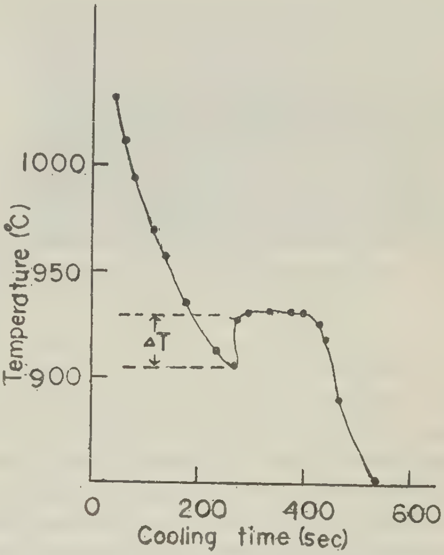


Fig. 9. Typical cooling curve of germanium.

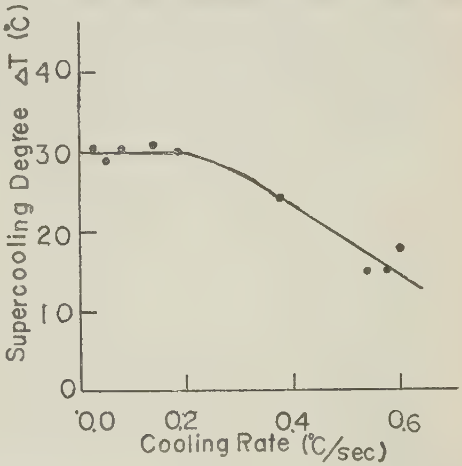

Fig. 10. Supercooling degree and cooling rate.

6.3 *Periodic variation of the melt temperature*

According to the above mentioned mechanism of crystal growth, periodic variation of the melt temperature should exist in the melt in front of the interface. Measurements were made by a temperature recorder of 0.05°C sensitivity[6].

The periodic temperature is shown in Fig. 11. The period of variation coincides with the value determined from the resistivity striations, so this periodic temperature variation can be considered to have the same origin as that of striations.

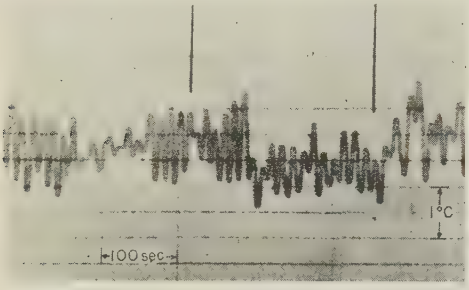

Fig. 11. Temperature variation in the melt during crystalization.

§ 7. Conclusions

Resistivity striations were observed in germanium single crystal grown horizontally. All possible outer fluctuations which should affect the growth conditions were eliminated, but the striations still remained and we attributed the cause of striations to internal phenomena. We tried some experiments to change the period of striations and obtained an experimental formula concerning to the striation period and growing conditions.

As mentioned in the previous sections, the cause of periodic resistivity variations can be explained by assuming that the supercooled state plays an important role in crystal growth, and we derived an equation relating to striation period and growing conditions. We evaluated its numerical value and obtained a good agreement with experimental formula.

§ 8. Acknowledgement

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 1, JANUARY, 1961

X-ray Studies on Precipitation of Metastable Centers in Mixed Crystals $NaCl$-$CdCl_2$

By Kazuo SUZUKI*

Radiation Laboratory, the Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokai, Ibaraki

(Received August 6, 1960)

Mixed crystals $NaCl$-$CdCl_2$ containing a few mole per cent of $CdCl_2$ were examined by X-ray method. By a certain heat treatment, precipitates of a structure having f.c.c. lattice with lattice constant twice as that of the matrix are formed within the matrix. By another heat treatment, there appear diffuse spots corresponding to the intensity distribution of rods extended to the directions of $<100>$ at odd-order reciprocal-lattice points of the above mentioned structure. Crystal structure of the precipitates, which is identified to be $CdCl_2\cdot 6NaCl$, are determined, and at the same time, main features of the diffuse reflexions are explained on the basis of the structure.

§ 1. Introduction

Preston[1] and Guinier[2], and afterwards many authors[3],[4], reported on characteristic diffuse reflexions in X-ray photographs from single crystals of age-hardening alloys at different stages of the hardening. Some of these reflexions are interpreted in terms of rod-like distributions of intensity weight in reciprocal space, and are ascribed to Guinier-Preston zones, or thin plate-like regions, formed in the matrix by segregation of solute atoms.

In previous X-ray studies of mixed crystals of $NaCl_2$ and $CaCl_2$[5],[6],[7],[8], the present author found that the solid solutions containing a few mole per cent of $CaCl_2$ give diffuse diffraction patterns similar to those observed in certain kinds of age-hardening alloys. The observed patterns could be explained by assuming the formation of plate-like regions in the matrix, into which Ca^{++} ions, Cl^- ions and vacancies segregate in an atomic arrangement similar to the crystal structure of $CaCl_2$.

In the present investigation the mixed crystals $NaCl$-$CdCl_2$ are dealt with by the X-ray method, and in particular, diffuse reflexions similar to those found in the case of $NaCl$-$CaCl_2$ are studied. It is revealed that these diffuse reflexions are due to the precipitation of a compound $CdCl_2\cdot 6NaCl$.

§ 2. Phase Diagram for the $NaCl$-$CdCl_2$ System

Phase diagram for the system $NaCl$-$CdCl_2$ was given by Brand[9] by means of thermal analysis (Fig. 1). In drawing the phase boundaries, he presumed the existence of the compound $CdCl_2\cdot 2NaCl$ from the fact that the mixed crystals containing 33.3 mole per cent of $CdCl_2$ showed the longest plateau in cooling curves. It is to be noticed, however, that the

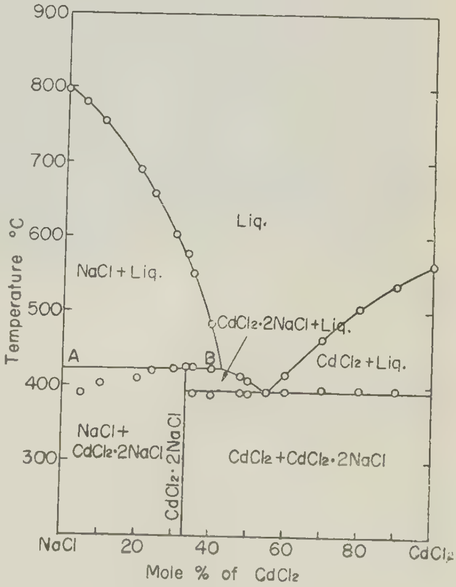

Fig. 1. Phase diagram for $NaCl$-$CdCl_2$ system. (H. Brand)

experimental points indicated by circles in Fig. 1 show a marked deviation from a horizontal boundary *AB* at lower concentrations of $CdCl_2$.

---

* This work was done when the author was in Tokyo Institute of Technology, Oh-Okayama, Meguro, Tokyo.

The present author repeated the cooling-curve measurement for powder mixtures containing 1, 2, 3, 5, 10, 15, 20 and 33.3 mole per cent of $CdCl_2$. Results were in good accordance with those of Brand so far as the measured range of concentrations is concerned, and confirmed again the deviation of the solidus from the horizontal line.

Table I. Intensity change of powder lines in X-ray photographs from mixed crystals $NaCl$-$CdCl_2$ with different concentrations of $CdCl_2$. Indices *hkl* are referred to superstructure, *hk·l* are referred to $CdCl_2 \cdot 2NaCl$.

20	trace	vvw	s	>1
33.3	—	—	s	∞

Debye-Scherrer photographs were also taken on the specimens used for the thermal analyses. The photographs are shown in Fig. 2, in which it is seen that two kinds of extra lines gradually appear with increase of the $CdCl_2$ content.

The first kind of extra lines begin to appear from 1 mole per cent concentration of $CdCl_2$, and become most distinct in the region of 2~10 mole per cent concentration of $CdCl_2$, and vanish at near 20 mole per cent $CdCl_2$. The change of the intensity of these lines with the $CdCl_2$ content according to a visual estimation is shown in Fig. 3 (*b*) in an arbitrary scale, and are also listed in Table I. These extra lines can be indexed by half integers such as 1/2, 1/2, 1/2; 3/2, 1/2, 1/2; 5/2, 3/2, 1/2; etc., indicating the fact that they are due to a structure having a superstructre unit

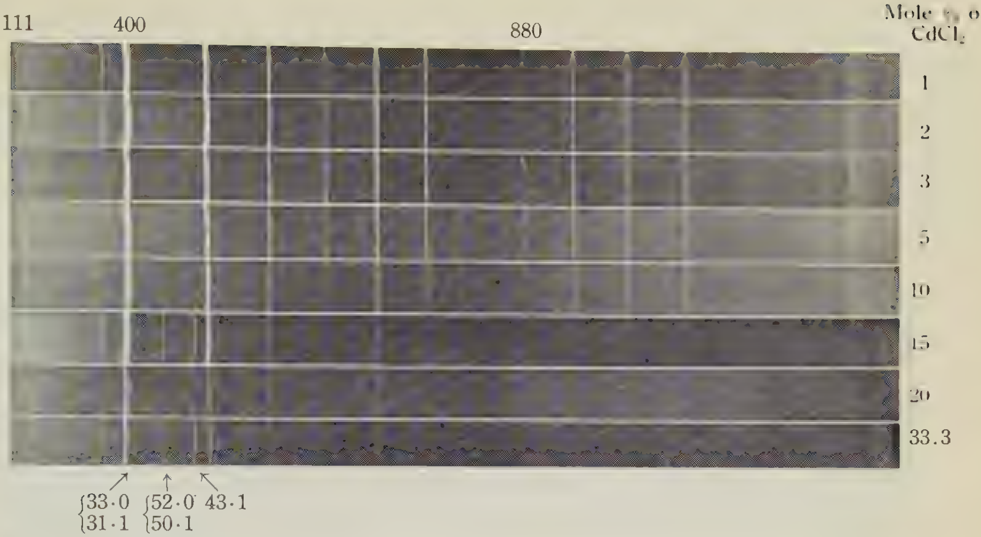

Fig. 2. Series of powder photographs for mixed crystals NaCl-CdCl$_2$ with different contents of CdCl$_2$, which have been cooled slowly to room temperature from the melts. Filtered Cu radiation, 30 kV, 15 mA, 0.5~1 h. Camera radius 5.74 cm.

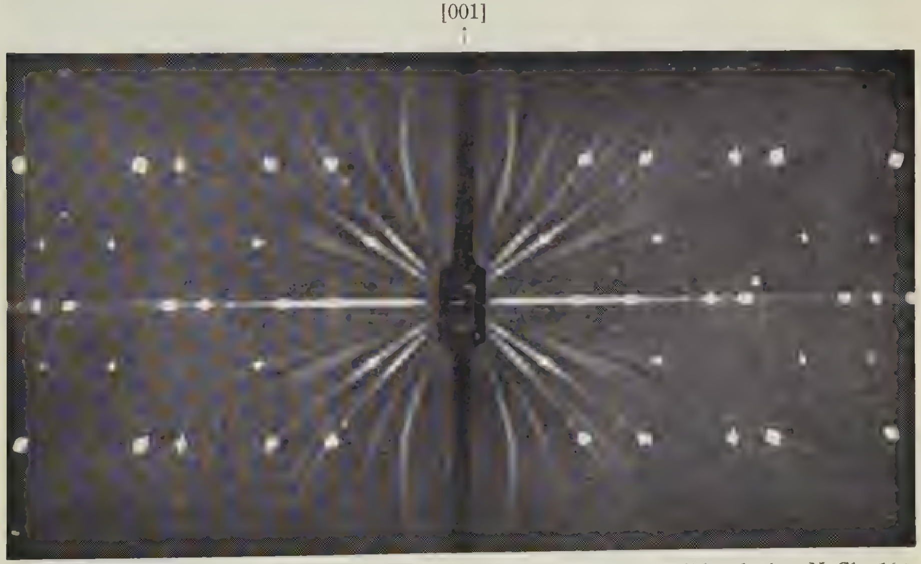

Fig. 4. Rotating-crystal X-ray photograph for a single crystal of solid solution NaCl+1% CdCl$_2$ which has been cooled very slowly to room temperature from 500°C. [001] axis rotation. Filtered Cu radiation, 40 kV, 10 mA, 6 h. Cylindrical film.

cell which is twice as that of NaCl matrix in linear dimension. We shall see later, that these lines are ascribed to the formation of the compound CdCl$_2$·6NaCl, and that this composition is chemically justified.

The second kind of extra lines begin to appear from 2 mole per cent of CdCl$_2$, and become stronger with increase of the CdCl$_2$ content. For 33.3 mole per cent CdCl$_2$, which corresponds to the composition CdCl$_2$:2NaCl, the pattern becomes exclusively composed of this type of lines. Thus, we can presume that the second kind of extra lines are due to the CdCl$_2$·2NaCl compound. These lines can be indexed by assuming a rhombohedral unit cell of dimension $a_0=9.92$Å, $\alpha=118°\ 18'$.* In Table II, the calculated lattice spacings are compared with those observed. The number, n, of chemical units contained in the unit cell can be estimated from the relation $n=\rho v_0/M$, where ρ is the density of the crystal, M the mass of the chemical unit, and v_0 the unit cell volume. For $CdCl_2 \cdot 2NaCl$ samples, ρ is measured to be 3.03, $M(CdCl_2 \cdot 2NaCl)=4.951 \times 10^{-22}$ g and $v_0=3.275\times 10^{-22}$ cm^3. The value of n is then found to be equal to 2.005, which is very close to 2.

---

* By using hexagonal unit cell, the dimension is given by $a_0=17.04$Å, $c_0=3.93$Å, $c_0/a_0=0.231$.

As revealed by the above X-ray studies, we are encountered with the fact contradicting the phase diagram shown in Fig. 1, that three kinds of phases, namely the α-phase or the

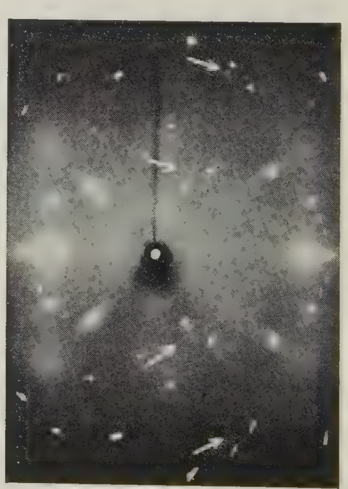

Fig. 7. Stationary-crystal X-ray photograph for a single crystal of solid solution NaCl+1% $CdCl_2$ which has been quenched from 200°C. [001] axis vertical. $\varphi=19°$. Unfiltered Cu radiation, 36 kV, 15 mA, 5 n. Cylindrical film. Diffuse reflexions are indicated by arrows.

NaCl matrix, the $CdCl_2 \cdot 2NaCl$ compound, and the $CdCl_2 \cdot 6NaCl$ compound having superstructure, co-exist at room temperature in the region of the $CdCl_2$ concentration from 2 to 20 mole per cent. This contradiction can, however, be removed by assuming a metastable phase diagram for the formation of $CdCl_2 \cdot 6NaCl$. Fig. 3 (*a*) shows schematically the phase boundaries for the range of low $CdCl_2$ concentrations, by superposing those corresponding to the presumed metastable phase diagram related to the formation of $CdCl_2 \cdot 6NaCl$ on to those of the stable phase diagram related to the formation of $CdCl_2 \cdot 2NaCl$.

If the formation of $CdCl_2 \cdot 2NaCl$ and $CdCl_2 \cdot 6NaCl$ takes place simultaneously by two independent processes according to both of the phase diagrams, the co-existence of the three

kinds of phases may be explained. Further, if we assume that the solidus for the metastable phase diagram lies at lower temperature than that for the stable one, as shown in Fig. 3 (*a*), the observed deviation of the solidius from the horizontal line may be qualitatively understood.

The existence of the phase boundary between α and $\alpha + CdCl_2 \cdot 6NaCl$ is confirmed by the X-ray observations on single crystals described in the next section.

§ 3. X-ray Observations on Single Crystals of the Solid Solutions NaCl-$CdCl_2$

a) *Experimentals*

Single crystals of solid solutions NaCl-$CdCl_2$ were prepared from pulverized mixtures of NaCl and $CdCl_2 \cdot 2\frac{1}{2}H_2O$. The molten mixture in a ceramic crucible was kept in an electric furnace at a temperature slightly higher than the melting point for about 1 hour, and then was solidified gradually by moving the crucible to cooler portions in the furnace with a constant velocity (*ca.* 3 mm/h). Single crystals of the size of about 1 cm^3 were easily obtained in this way.

The crystals were transparent when $CdCl_2$ content is less than 1∼2 mole per cent.* The crystals were shaped for X-ray examination by cutting by a razor brade and etching in water.

Heating and quenching of specimens were performed in a small vessel made of thin nickel foil (0.07 mm thickness). The quenching to room temperature after heating at a desired temperature for a desired duration was done by drawing out the vessel from the furnace and placing it immediately on a copper plate at room temperature.

---

* Implication of the percentage is the same as in the case of the mixed crystals NaCl-$CaCl_2$[6].

Stationary-crystal and rotating-crystal X-ray photographs were taken at room temperature, using either unfiltered or nickel filtered Cu radiations, or crystal-monochromated Cu radiations by a LiF single crystal.

b) Precipitation of the CdCl$_2$·6NaCl phase

The diffraction patterns from the single crystal samples change with the heat treatment. In what follows, the observation for the [001] rotation photographs obtained from the solid solution NaCl-CdCl$_2$ containing 1 mole per cent CdCl$_2$ is described for an example.

When the crystal is kept at 500°C and then cooled very slowly to room temperature, weak extra Bragg reflexions appear superposing on the reflexions due to the NaCl matrix, indicating that the precipitation of a new phase has occurred within the matrix at temperatures lower than 500°C. The extra reflexions lie on layer lines intermediate between those due to the NaCl matrix (Fig. 4). By the use of monochromated radiation it was confirmed that the extra reflexions are present also on equatorial, 2nd and 4th layer lines of the NaCl matrix (Fig. 5). All of these reflexions could be indexed by assuming the face-centred cubic lattice with the lattice constant twice as that of the matrix, and it is clear that these superstructure reflexions and the superstructure lines found in Debye-Scherrer photographs (§ 2) are due to the same crystal structure.

When this sample was kept at 500°C for 1 hour and was then quenched to room temperatures, all the extra superstructure reflexions disappeared. When the same sample was reheated at 200°C for 1 hour and was then quenched to room temperatures, the extra superstructure reflexions appeared again, though the superstructure spots were weak and rather diffusive.

Since, as already quoted, the structure giving rise to the superstructure reflexions is identified to be the CdCl$_2$·6NaCl compound, the above observations show the fact that there exists the α-phase, or the uniform solid solution of NaCl-CdCl$_2$, in the range of low CdCl$_2$ concentrations, and that the boundary between the α-phase and the mixed phase of α+CdCl·6NaCl lies between 200°∼500°C for 1 mole per cent concentration of CdCl$_2$. The position of the boundary between α and α+CdCl$_2$·6NaCl is roughly drawn in Fig. 3 (*a*) by considering this experimental result.

c) Diffuse reflexions

In order to study the initial stage of precipitation of the CdCl$_2$·6NaCl phase, stationary-crystal X-ray photographs were taken with unfiltered Cu radiations. Either [001] or [101] axis of the crystal was set vertically, and the angle φ between the horizontal [0$\bar{1}$0] axis and the direction of incident beam was successively changed.

When the sample, having the structure of the homogeneous α-phase formed by a suitable heat treatment, was kept at room temperature for several months, there appear extra superstructure reflexions as shown in Fig. 6. These spots are weak and not well defined, indicating that the sizes of the precipitates are very small.

When this sample is re-heated at 200°C for 1 hour and then quenched to room temperature, the broad reflexions are separated into groups of spots (Fig. 7). This phenomenon is analogous to that occurred in the case of NaCl-CaCl$_2$ mixed crystals[5),6)]. Fig. 8 shows the cases in in which the sphere of reflexion passes near the (111) point.* For $\varphi=23°$, in which the (111) point is inside of the sphere of reflexion, the diffuse spots form a triangle with the apex located at the nearer side of the direct spot, while for $\varphi=34°$, in which the (111) point lies outside of the sphere of reflexion, the apex of the triangle is at the farther side of the direct spot. From the change of the shape of the diffuse spot with φ, the distribution of weights in the reciprocal-lattice space could be determined as follows:

(i) All the odd-order super-reciprocal-lattice points are accompanied with $\langle 100\rangle_r$ rods;**

(ii) Neither even-order super-reciprocal-lattice points, nor main reciprocal-lattice points due to the NaCl matrix, are accompanied with the rods.

The fact (i) shows that, in the matrix, vacancies as well as Cd^{++} ions segregate parallel to {100}, forming thin {100} platelets. The characteristic (ii) will be discussed in § 5.

§ 4. Crystal Structure of CdCl$_2$·6NaCl

The structure determination of the crystal having super unit cell revealed by the above mentioned X-ray observations could be performed on single crystal samples composed of this substance only, which were fortunately obtained as follows.

---

* Indices are referred to super-reciprocal-lattice points.

** As to the meaning of the suffix r, see ref. 6), p. 705.

When the mixture of NaCl containing about 33 mole per cent of $CdCl_2$ was melt in a plutinum crucible and crystallized by the same procedure as described in § 2, almost all parts of the products obtained were polycrystals, but sometimes a few specks of transparent single crystals distinguished by orthorhombic forms of the size of the about $1 \times 1 \times 1\,mm^3$ were found distributing in the polycrystalline parts. It was confirmed by the Laue method, that these single crystals have cubic symmetry. The reflexions in the rotating-crystal X-ray photograph (Fig. 9) could be indexed by assuming f.c.c. lattice with the lattice constant twice as that of NaCl crystal.* The comparison of over-all features of Fig. 9 and Fig. 4 or 5 shows that the single crystals thus obtained and the precipitates in the homogeneous α-phase as described in § 3 are of the same structure.

In taking X-ray photographs, samples were made as thin as possible (*ca.* 0.2 mm in diameter), because of a large absorption of the specimen.* The intensity of the Bragg reflexions was measured using a microphotometer.

By chemical analysis performed on a collected mass (*ca.* 8 mg) of single crystals, it was found that molar concentration of $CdCl_2$ in these single crystals is 13.9 per cent. This value is nearly equal to 14.3 mole per cent, which corresponds to the compound having the composition $CdCl_2 \cdot 6NaCl$.

As the structure of $CdCl_2 \cdot 6NaCl$ has a super unit cell of the NaCl matrix, it is supposed that the main framework of the NaCl matrix is succeeded by the structure of $CdCl_2 \cdot 6NaCl$. It should, however, be assumed for the formation of $CdCl_2 \cdot 6NaCl$ that, when a Na^+ ion in the NaCl matrix is replaced by a divalent Cd^{++} ion, another Na^+ ion should be correspondingly removed from a lattice site, leaving a positive ion vacancy in the matrix, so as to maintain the electrical neutrality of the structure. It is reasonable to assume that the original unit cell volume of NaCl lattice can contain exactly one half the $CdCl_2 \cdot 6NaCl$ chemical unit, when the volumes of each kind of ions and also of the positive ion vacancies are taken into account. As the volume of the super unit cell is eight times as that of the NaCl matrix, it is concluded that the number, n, of the chemical unit $CdCl_2 \cdot 6NaCl$ in the unit cell is four, namely the unit cell in the $CdCl_2 \cdot 6NaCl$ structure must contain 24 Na^+ ions, 4 Cd^{++} ions, 32 Cl^- ions and, besides, 4 positive ion vacancies.

Since the extinction rule of reflexions other than that characteristic of the face-centred cubic lattice has not been observed, the possible space groups are T^2-F23, T_h^3-Fm3, T_d^2-F43m, O^3-F43 and O_h^5-Fm3m. T_d^2-F43m may, however, be discarded because it is hard to find probable positions of 24 Na^+ ions by this space group. The other space groups are identical regarding the positions for which the number of equivalent positions are small, as is expected to be the case for atoms in the present structure. Thus, we can assume without losing generality that the structure of $CdCl_2 \cdot 6NaCl$ belongs to the holohedral cubic space group O_h^5 as similarly as the case of NaCl.

Then, possible positions for the ions in $CdCl_2 \cdot 6NaCl$ are assumed in the following way: Four Cd^{++} ions occupy the sites (4*a*). For 24 Na^+ ions, there are two possibilities, either (24*d*) or (24*e*). However, (24*e*) should be discarded in connection with the positions of Cd^{++} ions. Positions of 32 Cl^- ions are placed at (8*c*) and (24*e*), considering the framework of the NaCl matrix. The positions of vacancies are then determined as (4*b*). Thus, the positions of ions (including those of vacancies) are written as follows:*

$(0, 0, 0;\ 0, \frac{1}{2}, \frac{1}{2};\ \frac{1}{2}, 0, \frac{1}{2};\ \frac{1}{2}, \frac{1}{2}, 0)+$
Cd^{++} : (4*a*) $0, 0, 0;$
vacancy: (4*b*) $\frac{1}{2}, \frac{1}{2}, \frac{1}{2};$
Na^+ : (24*d*) $0, 1/4, 1/4;\ 1/4, 0, 1/4;\ 1/4, 1/4, 0;\ 0, 1/4, 3/4;\ 3/4, 0, 1/4;\ 1/4, 3/4, 0;$
Cl^- : (8*c*), (24*e*) $1/4, 1/4, 1/4;\ 3/4, 3/4, 3/4;\ x, 0, 0;\ 0, x, 0;\ 0, 0, x;\ \bar{x}, 0, 0;\ 0, \bar{x}, 0;\ 0, 0, \bar{x}.$

---

* Some of the low-order reflexions such as 111, 311 etc. show splitted structures due to strong absorption of the sample containing the heavy Cd^{++} ions.

* The sites of vacancies are described here in order to indicate explicitly what Na^+ ions have been removed from the matrix.

Fig. 10 shows the arrangement of ions in the (100) plane of the proposed unit cell, in which the dashed lines indicate the unit cells of the original NaCl matrix. In this structure, Na^+ ions at the centers of the faces of the original NaCl matrix lattice are retained, and Na^+ ions at the corners of the original cells are replaced by Cd^{++} ions and vacancies alternately, forming a face-centred cubic lattice with the unit cell edge, a_0, twice that of the NaCl lattice. All the Cl^- ions are also retained except for small displacements. It is convenient to use in place of x the parameter δ defined by $x=1/4-\delta$, representing the displacement of each Cl^- ion towards the nearest Cd^{++} ion from the original position as illustrated by arrows in Fig. 10.

The intensities, J, of the reflexions of the rotation photograph are given by the following formulae:

$$J=I_0\cdot Q\cdot j\cdot A\cdot V\,, \tag{1}$$

$$Q=C\cdot P\cdot L\cdot|F(hkl)|^2\cdot\exp(-2\mathrm{M})\cdot 1/v_0{}^2\,, \tag{2}$$

$$\begin{aligned}F(hkl)=&\{1+\exp\pi i(h+k)+\exp\pi i(k+l)\\&+\exp\pi i(l+h)\}\times[f_{\mathrm{Cd}}+2f_{\mathrm{Na}}(\exp\tfrac{1}{2}\pi ih\cdot\cos\tfrac{1}{2}\pi k\\&+\exp\tfrac{1}{2}\pi ik\cdot\cos\tfrac{1}{2}\pi l+\exp\tfrac{1}{2}il\cdot\cos\tfrac{1}{2}\pi h)\\&+2f_{\mathrm{Cl}}\{\cos\tfrac{1}{2}\pi(h+k+l)+\cos2\pi hx+\cos2\pi kx\\&+\cos2\pi lx\}]\,.\end{aligned} \tag{3}$$

I_0 is the intensity of the incident X-ray beam, j the multiplicity, A the absorption factor, V the volume of the specimen immersed in the incident beam, C square of the classical e-

lectronic radius, P and L the polarization and the Lorentz factors respectively, $\exp(-2M)$ the Debye-Waller temperature factor, v_0 the unit cell volume, and f_{Cd}, f_{Na} and f_{Cl} are the atomic structure factors for Cd^{++}, Na^{+} and Cl^{-} ions, respectively. The absorption factor was obtained from the International Tables[10] by assuming the cylindrical form for the specimen, with $\mu r \sim 3.0$, where μ is the linear absorption coefficient and r the radius of the specimen. The tabulated values of the absorption factors can be applied approximately also to layer lines other than the equator by replacing r by the value $r(1+\sec\psi_n)/2$, where ψ_n is the angle given by the relation $\tan\psi_n = x_n/R$, x_n being the distance from the n-th layer line to the equatorial line, and R the radius of the cylindrical film. Actually, however, the factor $(1+\sec\psi_n)/2$ is almost equal to unity for the 1st, the 2nd and the 3rd layer lines of the present rotation photograph. The factor $\exp(-2M)=\exp\{-2B(\sin\theta/\lambda)^2\}$ was roughly estimated by assuming the characteristic temperature equal to that of pure NaCl, i.e., $\Theta=281°\mathrm{K}$, and the average atomic weight $(CdCl_2 \cdot 6NaCl)/15=35.6$. B thus calculated is 1.23×10^{-16} at room temperature.

Calculated intensities for $\delta=0$ are listed in Table III. In this Table and also in Fig. 11, we can see a fairly good agreement between observed and calculated intensities, although there are a few exceptions, for instance the observed intensities of 511, 911 are too strong, and those of 331, 333 are too weak.

Agreement between the observed and calculated intensities can be improved by assuming a finite value of δ. For example, calculated intensities for $\delta=1/36$ are listed in Table III, and are also shown in Fig. 11. However, the further refinement of the perameter δ is postponed, because of lack of the accuracy of the observed intensities, owing to the large absorption of the samples.

§ 5. Discussions

As is confirmed in the above section, the main skeleton of the NaCl structure is retained in the structure of $CdCl_2 \cdot 6NaCl$ fairly well, being accompanied only with very small displacements of Cl^- ion sites, even though there take place the replacement of Na^+ ions by Cd^{++} ions and the formation of positive ion vacancies. This result suggests that the precipitation of $CdCl_2 \cdot 6NaCl$ may take place in the NaCl matrix with very small activation energy, without producing long range disturbances in the NaCl matrix lattice.

With the knowledge of the unit cell structure of $CdCl_2 \cdot 6NaCl$, we can explain the characteristic features of the $\langle 100 \rangle_r$ rods mentioned in § 3 (*c*), that they appear only at odd-order indices of the super-reciprocal-lattice points, but not at even-order reciprocal-lattice points.

At the early stage of the precipitation, Cd^{++} ions are assumed to segregate in thin plate-like regions, or platelets, parallel to {100} of the matrix lattice, forming there complete or incomplete $CdCl_2 \cdot 6NaCl$ structure.

The structure amplitude, F', due to a platelet contributing to the diffuse scattering is expressed by[6)]

$$F' = S \cdot f', \tag{4}$$

$$f' = -\sum_{\text{cell}} + \sum_{\text{cell}}', \tag{5}$$

$$\sum_{\text{cell}} = \sum_{n} f_n \exp(2\pi i \boldsymbol{h} \cdot \boldsymbol{r}_n),$$

$$\sum_{\text{cell}}' = \sum_{N} f_N' \exp(2\pi i \boldsymbol{h} \cdot \boldsymbol{r}_N), \tag{6}$$

where S is the shape function for the platelet concerned, i.e., it is the sum over all the representative points of the unit cells of the precipitates contained in the platelet. The summations $\sum_{n}$ and $\sum_{N}$ are taken over the lattice points within a unit cell of the precipitates, f_n and $\boldsymbol{r}_n$ are the scattering factor and position vector of the n-th atom in the original matrix lattice respectively, and f_N' and $\boldsymbol{r}_N$ those of the N-th atom in the structure of the precipitate respectively, and $\boldsymbol{h}=(\boldsymbol{s}-\boldsymbol{s}_0)/\lambda$, where $\boldsymbol{s}_0$ and $\boldsymbol{s}$ are the unit vectors of the directions of incident and scattered X-rays respectively, and λ the wave-length of X-rays.

When the unit cell structure of the platelet is assumed to be that of $CdCl_2 \cdot 6NaCl$, (5) is written as

$$\begin{aligned} f' = &\{1+\exp\pi i(h+k)+\exp\pi i(k+l)+\exp\pi i(l+h)\} \\ &\times[-f_{Na}\{1+\exp\pi i(h+k+l)\}+f_{Cd} \\ &+2f_{Cl}\{\cos\tfrac{1}{2}\pi h(1-\cos 2\pi h\delta)+\sin\tfrac{1}{2}\pi h\cdot\sin 2\pi\delta \\ &\quad +\cos\tfrac{1}{2}\pi k(1-\cos 2\pi k\delta)+\sin\tfrac{1}{2}\pi k\cdot\sin 2\pi\delta \\ &\quad +\cos\tfrac{1}{2}\pi l(1-\cos 2\pi l\delta)+\sin\tfrac{1}{2}\pi l\cdot\sin 2\pi\delta\}], \end{aligned} \tag{7}$$

where δ is the same as what appeared in § 4. As was stated in § 4 (Table III, Fig. 11), main features of the structure of $CdCl_2 \cdot 6NaCl$ are represented fairly well by the case of $\delta=0$. Then, (7) reduces simply to

$$\begin{aligned} f' = &\{1+\exp\pi i(h+k)+\exp\pi i(k+l)+\exp\pi i(l+h)\} \\ &\times[-f_{Na}\{1+\exp\pi i(h+k+l)\}+f_{Cd}]. \end{aligned} \tag{8}$$

This expression results in the following relations:

(i) $f'_{odd}=4f_{Cd}$ for odd-order super-reciprocal-lattice points;

(ii) $f'_{even}=4(-2f_{Na}+f_{Cd})$ for even-order reciprocal-lattice points (including both super-reciprocal-lattice points and main reciprocal-lattice points).

Then, we have the relation $f'_{odd} \gg f'_{even}$. The shape function S, which is mainly responsible for the rod-like intensity weight of the diffuse reflexions, is common to all the reciprocal-lattice points, while the intensities of these reflexions near reciprocal-lattice points are mainly determined by the value of f'. Then, by the relation $f'_{odd} \gg f'_{even}$, the observed relative intensities of the $\langle 100 \rangle_r$ rods at reciprocal-

Table IV. Comparison of characteristic features of rods for the mixed crystals NaCl-CdCl$_2$ and NaCl-CaCl$_2$.

Mixed crystals	Types of rods	Reciprocal-lattice points about which rods appear	Symmetry about reciprocal-lattice points
NaCl-CdCl$_2$	$<100>_r$	Superlattice points	Symmetric
NaCl-CaCl$_2$	$<111>_r$ $<310>_r$	Matrix points	Asymmetric

lattice points of odd and even indices can be understood well.

It is interesting to compare the present results concerning the diffuse reflexions with the case of the mixed crystals $NaCl_2$-$CaCl_2$, for which $\langle 111 \rangle_r$ and $\langle 310 \rangle_r$ rods were observed in reciprocal space at an early stage of precipitation. Main features of the rods for these two kinds of mixed crystals are listed in Table IV.

1) From the mixed crystals NaCl-$CdCl_2$, the rods appeared only at super-reciprocal-lattice points and not at the matrix points, while, from NaCl-$CaCl_2$ the rods appeared only at reciprocal-lattice points for the matrix and not at super-reciprocal-lattice points. As has been shown above, the former case is readily explained by the unit cell structure of $CdCl_2 \cdot 6NaCl$. On the other hand, the latter could not be explained by unit cell structure only, and it was necessary to assume the formation of anti-phased platelets in thin regions called the plate-zones[5),6)].

2) The rods in reciprocal space are extended symmetrically about each reciprocal-lattice point in the case of NaCl-$CdCl_2$, and asymmetrically in the case of NaCl-$CaCl_2$. As the asymmetry of rods may be caused by the modulation of lattice spacings in the regions of platelets, the modulation of the spacings in the directions perpendicular to the platelets seems to be more conspicuous in the case of NaCl-$CaCl_2$ than in NaCl-$CdCl_2$. Such a difference may be explained in the following way. In the case of NaCl-$CdCl_2$, the platelets are the products in the initial stage of precipitation of the compound $CdCl_2 \cdot 6NaCl$ which have accidentally the same lattice spacings as NaCl. On the other hand, in the case of NaCl-$CaCl_2$,—especially for the $\langle 310 \rangle_r$ rods,—the platelets are the intermediate products which have grown up in the process of the precipitation of $CaCl_2$ crystal having different crystal structure, and therefore different lattice spacings from the NaCl matrix.

In conclusion, the author wishes to express his sincere thanks to Prof. S. Miyake for his kind guidance and encouragement throughout this work.

Theory of Ferro- and Antiferromagnetic Resonance Absorption

By Takehiko OGUCHI and Akio HONMA
Department of Physics, Tokyo University of Education
Otsuka-kubo-machi, Tokyo

(Received August 3, 1960)

The resonance conditions in ferro- and antiferromagnetic resonance absorptions are obtained by the spin-wave theory. According to the usual free spin-wave theory, the resonance frequency is independent of temperature and has only the value at 0°K. The spin-wave interactions give the correct temperature dependence for the resonance frequency. As the results of including these interactions, the ferromagnetic resonance condition taken account of the anisotropy energy agrees with the Kittel's formula. For the cases of the ferromagnetic resonance including the demagnetizing effect, and the antiferromagnetic resonance, however, the resonance conditions obtained at high temperatures agree with the formulae of Kittel and Nagamiya, Keffer-Kittel respectively, but at low temperatures our conditions show the different temperature dependence from their formulae. However, this new theoretical result is not in agreement with the experimental data in MnF_2 by Jaccarino-Shulman and Johnson-Nethercot.

§1. Introduction

Ferromagnetic resonance was discovered first in experiments by Griffiths[1]. In the experiments, however, it is found that the apparent g values are often very much larger than the free electron g value when the results are interpreted in terms of the paramagnetic resonance relation. It has been shown by Kittel[2], when all demagnetizing effects are included, resonance condition is modified and g factor obtained becomes reasonable value.

Kittel's theory is based on the equation of motion for the macroscopic magnetization vector consisting of the total spin of the entire saturated ferromagnet as quantized in the large magnetic field, which includes not only static magnetic field but also demagnetizing field and effective anisotropy field.

In antiferromagnetic resonance absorption, the situation is similar to ferromagnetic case, that is, the theory[3] is based on the equations of motion for the sublattice magnetization vector, although they are more complicated than the ferromagnetic one, because the former has interactions between sublattice magnetization.

So far as the magnetization vector M, the demagnetizing field (which related to M) and the anisotropy field (which related to the anisotropy constant K) are defined correctly, the theories mentioned above are valid. Therefore it has been believed that even at arbitrary temperatures the theories can be applied if M and K are replced by $M(T)$ and $K(T)$ at its temperature. In fact, basing upon this idea, a number of experimental data for the ferro- and antiferromagnetic resonance absorptions have been analysed.

From the theoretically rigorous point of view, however, $M(T)$ and $K(T)$ are not the quantities which are given from the the beginning, but they should be derived from the interactions in a system—in language of quantum mechanics, from the Hamiltonian—and also the resonance frequency itself must be obtained from the same Hamiltonian. When the resonance frequency at arbitrary temperatures is calculated by this way, it will become clear whether the naive idea stating the replacement of M and K by $M(T)$ and $K(T)$ is right.

In this paper we treat the magnetic system by the spin-wave theory. As is well known, the free spin-wave theory neglecting the spin-wave interactions was given first by Bloch[4]. The same result was obtained by the first approximation of the Holstein-Primakoff's theory[5] which uses the creation and annihilation operators of spin waves. According to the selection rule, the microwave field absorbs or emits the spin waves with wave number

$k=0$, so that the resonance frequency ω is equal to the energy of spin wave of $k=0$. Since the spin-wave energy of $k=0$ in the free spin-wave theory is constant, the resonance frequency obtained is independent of temperature. If the spin-wave interactions are taken into account, the spin wave of $k=0$ feels the Hartree field made by the other spin waves, therefore, its energy depends upon the occupation number of spin waves. As the occupation number obeys the Bose distribution and hence depends on temperature, the resonance frequency obtained shows consequently the temperature dependence. Following such an idea, the resonance frequency in the case of free spin-wave theory corresponds to no occupation of spin waves, so that it has only the value at 0°K, $\omega(0)$. If the spin-wave interactions are treated carelessly in the Holstein-Primakoff's method, there arises the discrepancy[6] with the result by Dyson[7] who has studied rigorously these interactions. Recently one of the authors[8] has shown that the perturbational method to treat the spin-wave interactions in the Holstein-Primakoff theory is essentially in agreement with the Dyson's theory. His method is very favourable, because it can be applied easily to the Kubo's theory[9] which is antiferromagnetic analog of the Holstein-Primakoff's theory.

Though the problem of the width in ferromagnetic resonance absorption line had been thought to be one of the difficult problems, and a clue of the solution was given by Clogston et al.[10] In our theory it seems also to be capable to treat the problems of absorption line width. They will be discussed in the subsequent paper.

§ 2. Ferromagnetic Resonance Absorption, Anisotropy Energy Effect

A portion of the energy in ferromagnetic single crystals depends on the direction of the magnetization relative to the crystalline axis. This part of energy is called the anisotropy energy. In this section we confine ourselves to a spherical specimen, so that the effect of the demagnetizing field (dipolar interaction) on the resonance frequency may be neglected.

We consider first the ferromagnetic crystal with the uniaxial anisotropy energy. The principal axis is taken as the z axis and the x and y axes are taken to the prependicular to it. The nearest neighbour exchange interaction model of the ferromagnet, with the static magnetic field $\boldsymbol{H}$ along the z axis, is described by the following Hamiltonian,

$$\mathscr{H}=-2J\sum_{\langle j,l\rangle}\boldsymbol{S}_j\cdot\boldsymbol{S}_l + g\mu\boldsymbol{H}\sum_{j=1}^{N}\boldsymbol{S}_j^z-\kappa\sum_{j=1}^{N}S_j^{z2}\ . \tag{2.1}$$

Here J is the exchange integral, $\boldsymbol{S}_j$ the spin operator at the j-th atom, g the spectroscopic splitting factor, μ the Bohr magneton, the summation $\sum_{\langle j,l\rangle}$ is taken over all nearest neighbour pairs, N the total number of atoms and κ is a constant proportional to the anisotropy energy at 0°K. The last term in (2.1) is the simplest Hamiltonian representing the uniaxial anisotropy energy and the spin quantum number S of each atom must be greater than unity. We take the ζ axis as the axis of quantization of spins, perpendicular to which the ξ and η axes are defined. In the present case the static magnetic field is along the z axis, so that the ζ axis agrees with the $-z$ one and the ξ and η axes are equal to the $-x$ and $+y$ ones respectively.

Following Holstein-Primakoff we express the spin operators in the forms;

$$\begin{aligned} S_j^+&=S_j^\xi+iS_j^\eta=\sqrt{2S}\,f_j(S)a_j\ ,\\ S_j^-&=S_j^\xi-iS_j^\eta=\sqrt{2S}\,a_j^*f_j(S)\ ,\\ S_j^\zeta&=S-n_j\ . \end{aligned} \tag{2.2}$$

where

$$f_j(S)=\left(1-\frac{n_j}{2S}\right)^{1/2}\doteqdot 1-\frac{n_j}{4S}+\cdots \tag{2.3}$$

and the operator $a_j^*a_j=n_j$ is called the spin deviation operator, and a_j^* and a_j are to be regarded as the creation and annihilation operators of the spin deviation and they satisfy the commutation rule

$$a_ja_l^*-a_j^*a_l=\delta_{jl}\ . \tag{2.4}$$

Using these operators the Hamiltonian (2.1) can be written as follows;

$$\begin{aligned} \mathscr{H}=&-N(zJS^2+g\mu SH+\kappa S^2)\\ &-2J\sum_{\langle j,l\rangle}[2Sa_j^*f_j(S)f_l(S)a_l-2Sa_j^*a_j+a_j^*a_ja_l^*a_l]\\ &+Hg\mu\sum_j a_j^*a_j+\kappa\sum_j(2Sa_j^*a_j-a_j^*a_ja_j^*a_j) \end{aligned} \tag{2.5}$$

We introduce the Fourier transforms of a_j and a_j^*,

$$a_k=\frac{1}{\sqrt{N}}\sum_j e^{-ikj}a_j\,,\qquad a_k^*=\frac{1}{\sqrt{N}}\sum_j e^{ikj}a_j^*\,,\tag{2.6}$$

which satisfy the commutation relation

$$a_k a_{k'}^*-a_{k'}^*a_k=\delta_{kk'}\,,\tag{2.7}$$

and $a_k^*a_k=n_k$ is the number of spin wave with wave number k. Then using (2.3), we obtain

$$\begin{aligned}\mathscr{H}=&-N(zJS^2+g\mu SH+\kappa S^2)\\&+\sum_k\left\{2SzJ(1-\gamma_k)+g\mu H+2S\kappa\left(1-\frac{1}{2S}\right)\right\}n_k\\&+\sum_{k_1,\cdots,k_4}\delta(k_1+k_2-k_3-k_4)\frac{1}{N}\left\{\frac{zJ}{2}(\gamma_1+\gamma_4-2\gamma_{2-4})-\kappa\right\}a_1^*a_2^*a_3a_4\,,\end{aligned}\tag{2.8}$$

where we have picked up all terms proportional to S^0, S and S^2, and we have defined

$$\gamma_k=\sum_\rho e^{ik\rho}/z\tag{2.9}$$

with ρ denoting the vectors to the nearest neighbor atoms, and z the number of them. We have used the notation a_1, γ_1, etc. instead of a_{k1}, γ_{k1}, etc., and later we will use n_1 etc. instead of n_{k1}.

Though the last term in (2.8) contains the non-diagonal terms in the representation of diagonalizing n_k, we shall neglect them because they give a negligibly small contribution to the resonance frequency. Then (2.8) is written in the following form.

$$\mathscr{H}=A+\sum_k B_k n_k+\frac{1}{2}\sum_{k,k'}C_{kk'}n_k n_{k'}\,,\tag{2.10}$$

where

$$A=-N(zJS^2+g\mu SH+\kappa S^2)\,,\tag{2.11}$$

$$B_k=2SzJ(1-\gamma_k)+g\mu H+2S\kappa\left(1-\frac{1}{2S}\right),\tag{2.12}$$

$$C_{kk'}=C_{k'k}=\frac{4}{N}\left\{\frac{zJ}{2}(\gamma_1+\gamma_2-1-\gamma_{1-2})-\kappa\right\}.\tag{2.13}$$

According to Kubo and Tomita[11], the imaginary part of the frequency dependent susceptibility $\chi''(\omega)$ is proportional to the following quantity,

$$\chi''(\omega)\propto\int_{-\infty}^{\infty}\langle e^{it\mathscr{H}/\hbar}M_\xi e^{-it\mathscr{H}/\hbar}M_\xi\rangle e^{i\omega t}dt\,,\tag{2.14}$$

where the average $\langle\ \rangle$ is defined by

$$\langle A\rangle=\mathrm{Tr}\,e^{-\mathscr{H}/k_0T}A/\mathrm{Tr}\,e^{-\mathscr{H}/k_0T}\,,\tag{2.15}$$

k_0 is the Boltzmann's constant and M_ξ is the magnetization component along the ξ axis,

$$M_\xi=\sqrt{\frac{SN}{2}}(a_0+a_0^*)-\frac{1}{4S}\sqrt{\frac{S}{2N}}\sum_{k,k'}(a_k^*a_{k'}a_{k-k'}+\mathrm{c.c})+\cdots.\tag{2.16}$$

Inserting only the first term of the right hand side in (2.16) into (2.14), (2.14) becomes

$$\frac{SN}{2}\int_{-\infty}^{\infty}\langle e^{it\mathscr{H}/\hbar}(a_0+a_0^*)e^{-it\mathscr{H}/\hbar}(a_0+a_0^*)\rangle e^{i\omega t}dt$$

$$=\frac{SN}{2}\int_{-\infty}^{\infty}\langle(n_0+1)e^{-it(B_0+\Sigma C_{0k}n_k)/\hbar}+n_0e^{it(B_0+\Sigma C_{0k}n_k)/\hbar}\rangle e^{i\omega t}\,dt\,. \tag{2.17}$$

The integral in (2.17) can be calculated as follows:

$$\int_{-\infty}^{\infty}\langle e^{-it(B_0+\Sigma C_{0k}n_k)/\hbar}\rangle e^{i\omega t}\,dt$$

$$\doteqdot\int_{-\infty}^{\infty}e^{i(\omega-B_0/\hbar)t}e^{-it\sum_k C_{0k}\langle n_k\rangle/\hbar-t^2\{\langle(\Sigma C_{0k}n_k)^2\rangle-\langle\Sigma C_{0k}n_k\rangle^2\}/2\hbar^2}\,dt$$

$$=\left\{\frac{2\hbar^2\pi}{\sum C_{0k}^2(\langle n_k^2\rangle-\langle n_k\rangle^2)}\right\}^{1/2}\exp\left\{-\frac{\hbar^2}{2}\frac{\left(\omega-\dfrac{B_0+\sum C_{0k}\langle n_k\rangle}{\hbar}\right)^2}{\sum C_{0k}^2(\langle n_k^2\rangle-\langle n_k\rangle^2)}\right\}. \tag{2.18}$$

According to (2.14), (2.17) and (2.18), $\chi''(\omega)$ has a maximum value at

$$\hbar\omega=B_0+\sum C_{0k}\langle n_k\rangle \tag{2.19}$$

and has the following line width

$$\hbar\Delta\omega=\{\sum C_{0k}^2(\langle n_k^2\rangle-\langle n_k\rangle^2)\}^{1/2}\,. \tag{2.20}$$

This width arises from the fluctuation of spin waves with wave number k, depends strongly on temperature and vanishes at 0°K. Since this width, however, suffers the narrowing by the motion of spin waves, it is not the true origin of the width in ferromagnetic resonance curve. The discussions about the width will be performed in the subsequent paper. For the present we neglect this width, i.e. fluctuation. Then the effective Hamiltonian for the spin wave of $\boldsymbol{k}=0$ is given from (2.10) by

$$\mathscr{H}_0=B_0n_0+\sum_k C_{0k}n_0\langle n_k\rangle\,. \tag{2.21}$$

Using the selection rule of microwave $\Delta n_0=\pm1$, Eq. (2.19) as the resonance frequency can be obtained directly, that is, $\chi''(\omega)$ is represented by the δ function which has a center at (2.19).

The second term in (2.16) leads the smaller term than (2.18) by the factor $\sum\langle n_k\rangle/N$. Therefore, we leave them out of consideration.

Eq. (2.19) is the resonance frequency at the temperature T. Using (2.12) and (2.13), and omitting the terms of order $1/S$, we have

$$\omega=\frac{g\gamma}{2}\left[H+\frac{2S\kappa\left(1-\dfrac{1}{2S}\right)\left(1-\dfrac{2}{NS}\sum_k\langle n_k\rangle\right)}{g\mu}\right]. \tag{2.22}$$

When the axis of quantization of spins ζ is inclined by angle θ from the $-z$ axis (the magnetization vector being inclined by θ from the z axis), the anisotropy energy is given by the following canonical average,

$$\langle\mathscr{H}_{an}\rangle=-\kappa\sum_j\left\langle\frac{1}{2}(S^2-S_{j\zeta}^2)-\frac{1}{2}(S^2-3S_{j\zeta}^2)\cos^2\theta\right\rangle. \tag{2.23}$$

In (2.23), the portion proportional to $\cos^2\theta$ is the anisotropy constant $K(T)$, that is

$$K(T)=K(0)\left\{1-\frac{3}{NS}\sum_k\langle n_k\rangle\right\}, \tag{2.24}$$

$$K(0)=\kappa NS^2\left(1-\frac{1}{2S}\right). \tag{2.25}$$

On the other hand, the magnetization is written as

$$M(T)=g\mu\sum_j S_j{}^{\zeta}=M(0)\left(1-\frac{1}{NS}\sum_k\langle n_k\rangle\right), \tag{2.26}$$

$$M(0)=g\mu NS. \tag{2.27}$$

Using (2.22), (2.24) and (2.26), we have as the resonance frequency at temperature T

$$\omega(T)=\frac{g\gamma}{2}\left[H+\frac{2K(T)}{M(T)}\right], \tag{2.28}$$

which is perfectly in agreement with the Kittel's formula.

Next we shall consider the case of ferromagnetic specimen with the cubic anisotropy energy. The Hamiltonian of the anisotropy energy in this case is written as, provided that the non-commutative relations of spin operators are disregarded;

$$\mathcal{H}_{an}=\frac{\kappa}{S^2}\sum_j(S_j{}^{x^2}S_j{}^{y^2}+S_j{}^{y^2}S_j{}^{z^2}+S_j{}^{z^2}S_j{}^{x^2}). \tag{2.29}$$

We take the axis of quantization of spins as ζ and define S_ξ, S_η, S_ζ as follows:

$$\begin{aligned}
S_x&=\cos\theta\cos\varphi S_\xi-\sin\varphi S_\eta+\sin\theta\cos\varphi S_\zeta,\\
S_y&=\cos\theta\sin\varphi S_\xi+\cos\varphi S_\eta+\sin\theta\sin\varphi S_\zeta,\\
S_z&=-\sin\theta\, S_\xi+\cos\theta\, S_\zeta.
\end{aligned} \tag{2.30}$$

Inserting (2.30) to (2.29), we have

$$\begin{aligned}
\mathcal{H}_{an}=\frac{\kappa}{S^2}\sum_j[&S_j{}^{\xi^2}S_j{}^{\eta^2}+S_j{}^{\eta^2}S_j{}^{\zeta^2}+S_j{}^{\zeta^2}S_j{}^{\xi^2}\\
&+(\sin^4\theta\sin^2\varphi\cos^2\varphi+\sin^2\theta\cos^2\theta)(S_j{}^{\xi^4}+S_j{}^{\zeta^4}-6S_j{}^{\xi^2}S_j{}^{\zeta^2})\\
&+\sin^2\varphi\cos^2\varphi\{(1-2\sin^2\theta)S_j{}^{\xi^4}+S_j{}^{\eta^4}-6\cos^2\theta S_j{}^{\xi^2}S_j{}^{\eta^2}\\
&\qquad+6\sin^2\theta(S_j{}^{\xi^2}S_j{}^{\zeta^2}-S_j{}^{\eta^2}S_j{}^{\zeta^2})\}].
\end{aligned} \tag{2.31}$$

When the static magnetic field $\boldsymbol{H}$ is strong enough, the magnetization points parallel to $\boldsymbol{H}$[12]. In the case of the magnetic field $\boldsymbol{H}$ along the [001] direction, we can put $\theta=\pi$ and $\varphi=0$. Then (2.31) becomes

$$\begin{aligned}
\mathcal{H}_{an}&=\frac{\kappa}{S^2}\sum_j(S_j{}^{\xi^2}S_j{}^{\eta^2}+S_j{}^{\eta^2}S_j{}^{\zeta^2}+S_j{}^{\zeta^2}S_j{}^{\xi^2})\\
&=\kappa\left\{2S\sum_k n_k-\frac{9}{N}\sum_{k,k'}n_k n_{k'}\right\}.
\end{aligned} \tag{2.32}$$

By the similar method as previous one, we obtain the resonance frequency as follows;

$$\omega(T)=\frac{g}{2}\gamma\left[H+\frac{2\kappa S\left(1-\dfrac{9}{NS}\sum_k\langle n_k\rangle\right)}{g\mu}\right]. \tag{2.33}$$

Next we consider the magnetic field along the $[\bar{1}\bar{1}\bar{1}]$ direction. In this case $\cos\theta$ and $\cos\varphi$ are equal to $1/\sqrt{3}$ and $1/\sqrt{2}$ respectively, so that (2.31) can be written as

$$\begin{aligned}
\mathcal{H}_{an}&=\frac{\kappa}{S^2}\sum_j\left[\frac{1}{4}S_j{}^{\xi^4}+\frac{1}{4}S_j{}^{\eta^4}+\frac{1}{3}S_j{}^{\zeta^4}+\frac{1}{2}S_j{}^{\xi^2}S_j{}^{\eta^2}\right]\\
&=\frac{1}{3}\kappa NS^2-\frac{4}{3}\kappa S\sum_k n_k+\frac{6}{N}\kappa\sum_{k,k'}n_k n_{k'}.
\end{aligned} \tag{2.34}$$

Therefore the resonance frequency is given by

$$\omega(T)=\frac{g\gamma}{2}\left[H-\frac{\frac{4}{3}\kappa S\left(1-\frac{9}{NS}\sum_k\langle n_k\rangle\right)}{g\mu}\right]. \tag{2.35}$$

Now we take the average of (2.31) by multiplying the density matrix, considering the following relations from the symmetry;

$$\begin{gathered}\langle S_\xi{}^4\rangle=\langle S_\eta{}^4\rangle=\frac{1}{3}\langle S_\xi{}^2S_\eta{}^2\rangle\,,\\ \langle S_\xi{}^2S_\zeta{}^2\rangle=\langle S_\eta{}^2S_\zeta{}^2\rangle\,.\end{gathered} \tag{2.36}$$

Then, we have

$$\begin{aligned}\langle\mathscr{H}_{an}\rangle=\frac{\kappa}{S^2}\sum_j\langle&(S_{j\xi}{}^2S_{j\eta}{}^2+S_{j\eta}{}^2S_{j\zeta}{}^2+S_{j\zeta}{}^2S_{j\xi}{}^2)\\&+(\sin^4\theta\sin^2\varphi\cos^2\varphi+\sin^2\theta\cos^2\theta)(S_{j\xi}{}^4+S_{j\zeta}{}^4-6S_{j\xi}{}^2S_{j\zeta}{}^2)\rangle\,.\end{aligned} \tag{2.37}$$

Since the second term of Eq. (2.37) shows the angular dependence of cubic symmetry, its coefficient equals to the anisotropy constant $K_1(T)$, that is,

$$\begin{aligned}K_1(T)&=\frac{\kappa}{S^2}\sum_j\langle S_{j\xi}{}^4+S_{j\zeta}{}^4-6S_{j\xi}{}^2S_{j\zeta}{}^2\rangle\\&=K_1(0)\left(1-\frac{10}{SN}\sum_k\langle n_k\rangle\right).\end{aligned} \tag{2.38}$$

$$K_1(0)=\kappa NS^2\,. \tag{2.39}$$

From (2.26) and (2.38), we have the following relation[13)]

$$\frac{K_1(T)}{K_1(0)}=\left\{\frac{M(T)}{M(0)}\right\}^{10}. \tag{2.40}$$

Using (2.26) and (2.38), Eqs. (2.33) and (2.35) reduce to

$$\omega(T)=\frac{g\gamma}{2}\left[H+\frac{2K_1(T)}{M(T)}\right] \tag{2.41}$$

and

$$\omega(T)=\frac{g\gamma}{2}\left[H-\frac{4}{3}\frac{K_1(T)}{M(T)}\right] \tag{2.42}$$

respectively, which are perfectly in agreement with the Kittel's formulae.

§ 3. Ferromagnetic Resonance Absorption, Demagnetizing Effect

In this section we investigate the effect of the demagnetizing field on ferromagnetic resonance absorption. For this purpose we consider the non-spherical specimen and omit, for the sake of simplicity, the one atomic anisotropy energy treated in the preceding section. The Hamiltonian is

$$\mathscr{H}=\mathscr{H}_{ex}+\mathscr{H}_{f}+\mathscr{H}_{\rm dip} \tag{3.1}$$

where $\mathscr{H}_{ex}$ and $\mathscr{H}_{f}$ represent the first and second terms of (2.1) respectively and $\mathscr{H}_{\rm dip}$ is the magnetic dipolar interactions written as

$$\mathscr{H}_{\rm dip}=\sum_{j>l}D_{jl}[\boldsymbol{S}_j\cdot\boldsymbol{S}_l-3(\boldsymbol{r}_{jl}\cdot\boldsymbol{S}_j)(\boldsymbol{r}_{jl}\cdot\boldsymbol{S}_l)]\,, \tag{3.2}$$

$$D_{jl}=(g\mu)^2/R_{jl}{}^3\,. \tag{3.3}$$

Here R_{jl} and r_{jl} are the distance connecting the j-th atom and the l-th one, and the unit vector along its direction respectively. Taking the axis of quantization of spins as the z axis ($\xi=x$, $\eta=y$, $\zeta=z$, i.e., the static magnetic field is applied along the $-z$ direction), and using the procedures below (2.2), (3.2) is rewritten as

$$\begin{aligned}\mathscr{H}_{\mathrm{dip}}=\sum_h D_h\Big[&\frac{N}{2}S^2(1-3z_h^2)\\&-S\sum_k\left\{(1-3z_h^2)\left(1+\frac{1}{2}e^{iR_hk}\right)a_k^*a_k+\frac{3}{4}(r_h^{+2}e^{iR_hk}a_k^*a_{-k}^*+r_h^{-2}e^{-iR_hk}a_ka_{-k})\right\}\\&+\frac{3}{2}\sqrt{\frac{2S}{N}}\sum_{k_1,k_2,k_3}\delta(k_1+k_2-k_3)(z_hr_h^+e^{iR_hk_1}a_1^*a_2^*a_3+z_hr_h^-e^{-iR_hk_1}a_3^*a_2a_1)\\&+\frac{1}{2N}\sum_{k_1,\cdots,k_4}\Big\{\delta(k_1+k_2-k_3-k_4)\left[(1-3z_h^2)e^{i(k_1-k_3)R_h}+\frac{1}{4}(e^{iR_hk_1}+e^{-iR_hk_4})\right]a_1^*a_2^*a_3a_4\\&\qquad+\frac{3}{4}\delta(k_1+k_2+k_3-k_4)[r_h^{+2}e^{iR_hk_1}a_1^*a_2^*a_3^*a_4+r_h^{-2}e^{-iR_hk_1}a_4^*a_3a_2a_1]\Big\}\Big]\end{aligned}\tag{3.4}$$

where

$$r_h^{\pm}=x_h\pm iy_h\,,\tag{3.5}$$

with x_h, y_h and z_h describing the direction cosines of lattice vector R_h. In order to simplify the calculations without destroying the essence of the problem, let the ferromagnetic specimen be a spheroid of revolution about the z axis. Then taking account of the symmetry, (3.1) is written by

$$\mathscr{H}=\mathscr{H}_0+\mathscr{H}_2+\mathscr{H}_3+\mathscr{H}_4\,.\tag{3.6}$$

Here $\mathscr{H}_0$ is independent of operators and $\mathscr{H}_2$ is given by

$$\mathscr{H}_2=A_0a_0^*a_0+\sum_{k\neq0}\left\{A_ka_k^*a_k+\frac{1}{2}B_ka_ka_{-k}+\frac{1}{2}B_k^*a_k^*a_{-k}^*\right\},\tag{3.7}$$

where

$$A_0=g\mu\{H+(N_T-N_z)M(0)\}\,,\tag{3.8}$$

$$A_{\pm k}=2zJS(1-\gamma_k)+g\mu\{H-N_zM(0)+2\pi M(0)\sin^2\Theta_k\}\,,\tag{3.9}$$

$$B_{\pm k}=2\pi g\mu M(0)\sin^2\Theta_k\,e^{-2i\Phi_k}\,,\tag{3.10}$$

$$N_z=\frac{1}{N}\sum_h\frac{1}{R_h^3}(1-3z_h^2)+\frac{4\pi}{3}\,.\tag{3.11}$$

$$N_T=N_x=N_y=\frac{1}{N}\sum_h\frac{1}{R_h^3}(1-3x_h^2)+\frac{4\pi}{3}\,.\tag{3.12}$$

N_x, N_y and N_z are the demagnetization factors and Θ_k and Φ_k are the polar angles of $\boldsymbol{k}$. We have used the method by Cohen and Keffer[14] to evaluate A_0, $A_{\pm k}$ and $B_{\pm k}$.

In (3.6), $\mathscr{H}_3$ and $\mathscr{H}_4$ are the terms of 3rd and 4th orders of spin-wave operators respectively. These are very important in the relaxation problem[10),15)]. In our case, however, we need only terms which are diagonal and involve $a_0^*a_0$ in the final expression. Therefore $\mathscr{H}_3$ does not contribute* and $\mathscr{H}_4$ is

---

* By the 2nd order perturbation, it contributes to the terms like $\frac{1}{N}\sum_k\langle b_0^*b_0\rangle\langle b_k^*b_k\rangle$ and $\frac{1}{N}\sum_{k,k'}\langle b_0^*b_0\rangle\cdot\langle b_k^*b_k\rangle\langle b_{k'}^*b_{k'}\rangle$ using the transformation (3.15), but the former is negligible by the factor $1/N$ compared with the other terms and the latter can be neglected for it expresses three spin-wave interaction.

$$\mathscr{H}_4 = \sum_{k\neq 0} \frac{3}{2N} \sum_h D_h \Big[(1-3z_h^2)(1+e^{ikR_h}) a_k^* a_k a_0^* a_0 + \frac{1}{2}(r_h^{-2} e^{-ikR_h} a_k a_{-k} + r_h^{+2} e^{ikR_h} a_k^* a_{-k}^*) a_0^* a_0 \Big] \tag{3.13}$$

$$= \frac{g\mu}{NS} M(0) \sum_{k\neq 0} [\{(N_T - N_z) + 3(N_z - 2\pi \sin^2 \Theta_k)\} a_k^* a_k a_0^* a_0 - \pi \sin^2 \Theta_k (e^{-2i\Phi_k} a_k a_{-k} + e^{2i\Phi_k} a_k^* a_{-k}^*) a_0^* a_0] . \tag{3.14}$$

We first diagonalize (3.7) by means of the following transformation,

$$\begin{aligned} a_0 &= b_0 \\ a_k &= \frac{1}{\sqrt{2}} \{\cosh \theta_k (b_k + b_{-k}) + \sinh \theta_k (b_k^* - b_{-k}^*)\} e^{i\Phi_k} \qquad (k\neq 0) \\ a_{-k} &= \frac{1}{\sqrt{2}} \{\cosh \theta_k (b_k - b_{-k}) + \sinh \theta_k (b_k^* + b_{-k}^*)\} e^{i\Phi_k} \qquad (k\neq 0) \end{aligned} \tag{3.15}$$

and

$$\tanh 2\theta_k = -|B_k|/A_k . \tag{3.16}$$

Then we get

$$\langle \mathscr{H}_2 \rangle = \text{const.} + g\mu\{H + (N^T - N_z) M(0)\} \langle b_0^* b_0 \rangle + \sum_{k\neq 0} g\mu \Big[\Big\{ \frac{2zJS}{g\mu}(1-\gamma_k) + H - N_z M(0) + 4\pi M(0) \sin^2 \Theta_k \Big\} \times \Big\{ \frac{2zJS}{g\mu}(1-\gamma_k) + H - N_z M(0) \Big\} \Big]^{1/2} \langle b_k^* b_k \rangle . \tag{3.17}$$

This result was obtained already by the group in Bell Telephone Laboratories[10),15)]. The energy spectrum given in (3.17) is not correct in the region of $k < k_{\min}$ except $k=0$, where $k_{\min}$ is about equal to ten times the reciprocal sample dimensions. In this region, we must replace (3.17) by Walker's modes[16)] which are taken account of boundary condition at the sample-air interface. But Walker's mode is so complicated that we will use the spin-wave expression (3.17) even for $k < k_{\min}$. This assumption may be justified from the fact that Suhl's result[15)] based on the same assumption is in good agreement with the experiment. By means of the transformation (3.15), we obtain

$$\langle \mathscr{H}_4 \rangle = \frac{g\mu}{NS} M(0) \sum_{k\neq 0} \Big[\{(N_T - N_z) + 3(N_z - 2\pi \sin^2 \Theta_k)\} \times (\cosh 2\theta_k \langle b_k^* b_k \rangle + \sinh^2 \theta_k) - 2\pi \sin^2 \Theta_k \sinh 2\theta_k \Big(\langle b_k^* b_k \rangle + \frac{1}{2} \Big) \Big] \langle b_0^* b_0 \rangle . \tag{3.18}$$

The magnetization is given by

$$M(T) = M(0) \Big[1 - \frac{1}{NS} \{ b_0^* b_0 + \sum_{k\neq 0} (\cosh 2\theta_k \langle b_k^* b_k \rangle + \sinh^2 \theta_k) \} \Big] . \tag{3.19}$$

When the temperature is sufficiently low, an overwhelmingly numerous number of spin waves with small energy is excited. These spin waves are those which are $k \approx 0$ and $\Theta_{k\simeq 0} \approx 0$. (These are not important in the mechanism of subsidiary absorption treated by Suhl[15)]. However, it is the case of high signal power.) Thus we may be allowed to replace the coefficients of $\langle b_k^* b_k \rangle$ in (3.18) and (3.19) by their values at $k \approx 0$ and $\Theta_{k\simeq 0} = 0$. $\Theta_{k\simeq 0} = 0$ means $\theta_{k\simeq 0} = 0$ by (3.9), (3.10) and (3.16). Then from (3.18) and (3.19) we obtain

$$\langle \mathscr{H}_4 \rangle = \frac{g\mu}{NS} M(0) \sum_k (N_T + 2N_z) \langle b_k^* b_k \rangle \langle b_0^* b_0 \rangle , \tag{3.20}$$

$$M(T)=M(0)\left[1-\frac{1}{NS}\sum_k\langle b_k{}^*b_k\rangle\right]. \tag{3.21}$$

The resonance frequency is the coefficient of $\langle b_0{}^*b_0\rangle$ in (3.17) and (3.20), as follows,

$$\begin{aligned}\omega(T)&=\frac{g}{2}\gamma\left[H+(N_T-N_z)M(0)-M(0)\{2(N_T-N_z)-3N_T\}\frac{1}{NS}\sum_k\langle b_k{}^*b_k\rangle\right]\\&=\frac{g}{2}\gamma\left[H+(N_T-N_z)M(0)\left\{\frac{M(T)}{M(0)}\right\}^2+3N_T\{M(0)-M(T)\}\right].\end{aligned} \tag{3.22}$$

This result differs from the Kittel's formula.

On the other hand, when the temperature is considerably high and a number of spin waves with large k are uniformly excited, and hence $a_k{}^*a_k$ does not depend strongly on k, we may eliminate the terms involve $\exp(\pm i\boldsymbol{kR})$ in (3.13). In this case we have

$$\langle\mathscr{H}_4\rangle=-g\mu M(0)(N_T-N_z)\frac{1}{NS}\sum_k\langle a_k{}^*a_k\rangle\langle a_0{}^*a_0\rangle\,, \tag{3.23}$$

$$M(T)=M(0)\left\{1-\frac{1}{NS}\sum_k\langle a_k{}^*a_k\rangle\right\}. \tag{3.24}$$

By the same way, the resonance frequency is

$$\omega(T)=\frac{g}{2}\gamma\{H+(N_T-N_z)M(T)\}\,, \tag{3.25}$$

which is agreement with the Kittel's formula. It is concluded that the Kittel's formula in this case, is correct at 0°K, but at low temperatures it does not give the correct dependence of the temperature and at considerably high temperatures it has again the correct dependence. The fact that the temperature dependence changes as the temperature is increased is somewhat similar to the case of the anisotropy constant. In that case (2.40) holds at low temperatures, but the power changes to 6 instead of 10 as the temperature is increased[13].

Though a number of experimental data in ferromagnetic resonance absorption have entirely been analysed by the Kittel's formula, it is not proper at low temperatures. Thus the g-factor obtained by such an analysis, especially its temperature dependence, is not correct.

§ 4. Antiferromagnetic Resonance Absorption

The theories of antiferromagnetic resonance absorption were treated classically by Nagamiya and Keffer-Kittel (abbreviated as NKK)[3] in the same method as in ferromagnetic resonance absorption, while by Nakamura and Ziman by means of the spin-wave method (free spin-wave theory)[17]. We shall derive the correct temperature dependence of resonance absorption frequency, by including the interactions between spin waves as in the previous sections.

For the sake of simplicity let the antiferromagnetic crystal have the uniaxial anisotropy energy represented by the one atomic spin. Therefore the atomic spin S must be greater than unity. First in the case of the static magnetic field along the principal axis (taken as the $-z$ axis), the Hamiltonian can be written as

$$\mathscr{H}=2|J|\sum_{\langle l,m\rangle}\boldsymbol{S}_l\cdot\boldsymbol{S}_m-g\mu H\Big(\sum_l S_l{}^z+\sum_m S_m{}^z\Big)-\kappa\sum_l S_l{}^{z2}-\kappa\sum_m S_m{}^{z2}\,. \tag{4.1}$$

According to Kubo[9] we have to introduce two different definitions of creation and anninhilation operators of the spin deviation. These are

$$\begin{aligned}S_l{}^+&=\sqrt{2S}\,f_l(S)a_l\,,\\S_l{}^-&=\sqrt{2S}\,a_l{}^*f_l(S)\,,\\S_l{}^z&=S-a_l{}^*a_l\end{aligned} \tag{4.2}$$

for an "up" spin on the l sublattice, and

$$\begin{aligned} S_m^+ &= \sqrt{2S}\, b_m^* f_m(S)\,, \\ S_m^- &= \sqrt{2S}\, f_m(S) b_m\,, \\ S_m^z &= -S + b_m^* b_m \end{aligned} \tag{4.3}$$

for a "down" spin on the m sublattice. The operators b and b^* are defined in the same way as a and a^*, and satisfy the equations,

$$\begin{aligned} b_m^* b_m &= n_m'\,, \\ b_m b_{m'}^* - b_{m'}^* b_m &= \delta_{mm'}\,. \end{aligned} \tag{4.4}$$

We introduce the Fourier transforms of a_l, a_l^* and b_m, b_m^*:

$$\begin{aligned} a_k &= \sqrt{2/N} \sum_l e^{ikl} a_l\,, & a_k^* &= \sqrt{2/N} \sum_l e^{-ikl} a_l^*\,, \\ b_k &= \sqrt{2/N} \sum_m e^{-ikm} b_m\,, & b_k^* &= \sqrt{2/N} \sum_m e^{ikm} b_m^*\,, \end{aligned} \tag{4.5}$$

where N is the total number of atoms. Furthermore, we use the new operators α_k, α_k^* and β_k, β_k^* defined by

$$\begin{aligned} a_k &= \alpha_k \cosh\theta_k - \beta_k^* \sinh\theta_k\,, & a_k^* &= \alpha_k^* \cosh\theta_k - \beta_k \sinh\theta_k\,, \\ b_k &= -\alpha_k^* \sinh\theta_k + \beta_k \cosh\theta_k\,, & b_k^* &= -\alpha_k \sinh\theta_k + \beta_k^* \cosh\theta_k\,, \end{aligned} \tag{4.6}$$

where

$$\tanh 2\theta_k = \frac{\gamma_k}{1+\tilde{\kappa}}\,, \tag{4.7}$$

$$\tilde{\kappa} = \frac{2S\left(1-\dfrac{1}{2S}\right)\kappa}{2z|J|S}\,. \tag{4.8}$$

Then the Hamiltonian (4.1) can be written as (only the main terms)

$$\begin{aligned} \frac{\mathscr{H}}{2z|J|S} = \sum_k \big[&\{(1+\tilde{\kappa})\cosh 2\theta_k - \gamma_k \sinh 2\theta_k + \tilde{H}\} n_k + \{(1+\tilde{\kappa})\cosh 2\theta_k - \gamma_k \sinh 2\theta_k - \tilde{H}\} n_k'\big] \\ + \sum_{k,k'} \Big[&-\frac{2}{SN}\Big\{(1+2\tilde{\kappa})\cosh 2\theta_1 \sinh^2\theta_2 + \frac{1}{2}\sinh 2\theta_1 \sinh 2\theta_2\, \gamma_{1-2} \\ &\qquad -\frac{1}{2}\cosh 2\theta_1 \sinh 2\theta_2 \gamma_2 - \sinh 2\theta_1 \sinh^2\theta_2 \gamma_1\Big\}(n_1+n_1') \\ &-\frac{2}{SN}\Big\{\cosh^2\theta_1 \sinh^2\theta_2 + \frac{1}{4}\sinh 2\theta_1 \sinh 2\theta_2 \gamma_{1-2} - \frac{1}{2}\sinh 2\theta_1 \cosh 2\theta_2 \gamma_1 \\ &\qquad + \tilde{\kappa}(\cosh^2\theta_1 \cosh^2\theta_2 + \sinh^2\theta_1 \sinh^2\theta_2)\Big\}(n_1 n_2 + n_1' n_2') \\ &-\frac{2}{SN}\Big\{\cosh^2\theta_1 \cosh^2\theta_2 + \sinh^2\theta_1 \sinh^2\theta_2 + \frac{1}{2}\sinh 2\theta_1 \sinh 2\theta_2 \gamma_{1-2} - \frac{1}{2}\sinh 2\theta_1 \cosh 2\theta_2 \gamma_1 \\ &\qquad -\frac{1}{2}\cosh 2\theta_1 \sinh 2\theta_2 \gamma_2 + 2\tilde{\kappa}(\sinh^2\theta_1 \cosh^2\theta_2 + \cosh^2\theta_1 \sinh^2\theta_2)\Big\} n_1 n_2' \Big]\,. \end{aligned} \tag{4.9}$$

with

$$n_k = \alpha_k^* \alpha_k\,, \qquad n_k' = \beta_k^* \beta_k\,, \tag{4.10}$$

$$\tilde{H} = g\mu H / 2z|J|S \tag{4.11}$$

In (4.9) $\tilde{\kappa}$ which is included in the coefficients of the quadratic terms of spin deviation operators is that replaced by 1 instead of $1-1/2S$ in the definition (4.8). There are two modes in the antiferromagnetic spin wave and the selection rules of microwave for these modes are represented by $\varDelta n_0=\pm 1$ and $\varDelta n_0'=\pm 1$ respectively. Therefore the antiferromagnetic resonance absorption can be obtained by the canonical average of the coefficients of n_0 and n_0' in (4.9). Denoting the two resonance absorption frequencies by ω_+ and ω_- respectively, we have

$$\frac{\hbar\omega_\pm}{2z|J|S}=\sqrt{2\tilde{\kappa}}\pm\tilde{H}-\frac{2}{SN}\sum_k\frac{\sqrt{2\tilde{\kappa}}}{4}\left(\frac{3-\gamma_k^2}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}-3\right)$$
$$-\frac{2}{SN}\sum_k\frac{\sqrt{2\tilde{\kappa}}}{4}\frac{3-\gamma_k^2}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}\langle n_k+n_k'\rangle\mp\frac{1}{SN}\sum_k(1-2\tilde{\kappa})\langle n_k-n_k'\rangle\,. \tag{4.12}$$

The average magnetization along the z axis is

$$\sum_l M_l^z(T)+\sum_m M_m^z(T)=g\mu\langle\sum_l S_l^z+\sum_m S_m^z\rangle=-g\mu\sum_k\langle n_k-n_k'\rangle\,. \tag{4.13}$$

Eq. (4.13) is connected by the following relation with the parallel susceptibility

$$\sum_k\langle n_k'-n_k\rangle=\frac{\chi_{||}}{g\mu}H=\frac{1}{2}NS\,\tilde{H}\frac{\chi_{||}}{\chi_\perp}\,, \tag{4.14}$$

where

$$\chi_\perp=N(g\mu)^2/4z|J|\,. \tag{4.15}$$

Eq. (4.15) is the perpendicular susceptibility obtained by the molecular field theory. $\chi_\perp$ obtained by the spin-wave theory has small corrections of (4.15) and furthermore includes the temperature dependent terms, too. Using (4.14), (4.12) is written as

$$\omega_\pm(T)=\frac{g\gamma}{2}\left[\left\{\frac{8z|J|S^2\left(1-\frac{1}{2S}\right)\kappa}{(g\mu)^2}\right\}^{1/2}\left\{1-\frac{1}{2SN}\sum_k\left(\frac{3-\gamma_k^2}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}-3\right)\right.\right.$$
$$\left.\left.-\frac{1}{2SN}\sum_k\frac{3--\gamma_k^2}{\sqrt{(1+\kappa)^2-\gamma_k^2}}\langle n_k+\langle n_k'\rangle\right\}\pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right]. \tag{4.16}$$

The anisotropy constant $K(T)$ is given by, in the same form as (2.23),

$$K(T)=-\frac{1}{2}\kappa(\sum_l\langle S^2-3S_l^{z\,2}\rangle+\sum_m\langle S^2-3S_m^{z\,2}\rangle)$$
$$=K(0)\left[1-\frac{3}{NS}\sum_k\left(\frac{1}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}-1\right)-\frac{3}{NS}\sum_k\frac{1}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}\langle n_k+n_k'\rangle\right], \tag{4.17}$$

$$K(0)=\kappa NS^2\left(1-\frac{1}{2S}\right). \tag{4.18}$$

Let us now introduce two approximations; (1) in the terms which do not contain $\langle n_k+n_k'\rangle$ in (4.16) and (4.17), the corrections of order $1/S$ are omitted with S^0. (2) as in the ferromagnetic case at considerably high temperatures $\langle n_k+n_k'\rangle$ can be placed outside the summation over $\boldsymbol{k}$, because the spin waves with large $\boldsymbol{k}$ are also excited uniformly. Then $\sum_k\gamma_k^2$ can be neglected compared with unity. Accordingly (4.16) and (4.17) can be written as follows,

$$\omega_\pm(T)=\frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(0)}{N(g\mu)^2}\right\}^{1/2}\left\{1-\frac{1}{2NS}\frac{3}{1+\tilde{\kappa}}\sum_k\langle n_k+n_k'\rangle\right\}\pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right], \tag{4.19}$$

$$K(T)=K(0)\left[1-\frac{3}{NS}\frac{1}{1+\tilde{\kappa}}\sum_k\langle n_k+n_k'\rangle\right]. \tag{4.20}$$

Using (4.19) and (4.20), we have

$$\omega_\pm = \frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(0)}{N(g\mu)^2}\right\}^{1/2}\left\{\frac{K(T)}{K(0)}\right\}^{1/2} \pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right]$$
$$= \frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(T)}{N(g\mu)^2}\right\}^{1/2} \pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right]. \tag{4.21}$$

On the other hand the antiferromagnetic resonance absorption frequency obtained by NKK is expressed by

$$\omega_\pm = \frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(T)}{N(g\mu)^2} + \left(\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}H\right)^2\right\}^{1/2} \pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right]. \tag{4.22}$$

We take up MnF_2 as the numerical example. Since at low temperatures $8z|J|K(T)/N(g\mu)^2 \simeq 10^{10}\ (\mathrm{Oe})^2$ and $(1/2\cdot\chi_{||}/\chi_\perp\cdot H)^2 < 10^5\ (\mathrm{Oe})^2$ for $H=5000$ Oe, the latter in (4.22) can be entirely omitted. Therefore (4.21) agrees with the NKK's formula. In order to obtain the omitted term $(1/2\cdot\chi_{||}/\chi_\perp\cdot H)^2$ in our theory, it is necessary to calculate the 6-th order terms of annihilation and creation operators.

Next we leave alone the first approximation mentioned above and discard the second approximation in order to consider the case of low temperature. As at low temperatures there are an overwhelming number of spin waves with small $\boldsymbol{k}$, the coefficients of n_k and n_k' may be replaced by their values at $\boldsymbol{k}=0$. In this case, therefore, γ_k is equal to unity. Accordingly (4.16) and (4.17) are written as

$$\omega_\pm(T) = \frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(0)}{N(g\mu)^2}\right\}^{1/2}\left\{1-\frac{1}{SN}\frac{1}{\sqrt{2\tilde{\kappa}}}\sum_k\langle n_k+n_k'\rangle\right\} \pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right], \tag{4.23}$$

$$K(T) = K(0)\left[1-\frac{3}{NS}\frac{1}{\sqrt{2\tilde{\kappa}}}\sum_k\langle n_k+n_k'\rangle\right]. \tag{4.24}$$

respectively and combining (4.23) with (4.24) we have

$$\omega_\pm(T) = \frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(0)}{N(g\mu)^2}\right\}^{1/2}\left\{\frac{K(T)}{K(0)}\right\}^{1/3} \pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right]. \tag{4.25}$$

On the one hand the sublattice magnetization $M(T)$ at low temperatures is given by

$$M(T) = g\mu\sum_m S_m{}^z = M(0)\left\{1-\frac{1}{NS}\frac{1}{\sqrt{2\tilde{\kappa}}}\sum_k\langle n_k+n_k'\rangle\right], \tag{4.26}$$

$$M(0) = g\mu NS/2\ , \tag{4.27}$$

so that we have another form of (4.25) as follows

$$\omega_\pm(T) = \frac{g\gamma}{2}\left[\left\{\frac{8z|J|K(T)}{N(g\mu)^2}\right\}^{1/2}\left\{\frac{M(0)}{M(T)}\right\}^{1/2} \pm H\left(1-\frac{1}{2}\frac{\chi_{||}}{\chi_\perp}\right)\right]. \tag{4.28}$$

Thus at low temperatures it is concluded that the NKK's formula gives the incorrect temperature dependence.

Furthermore we attempt to calculate accurately the resonance frequency without the approximations stated above. Using the numerical evaluations of Anderson[18] and Kubo[9], the correction terms in (4.16) and (4.17) are given by

$$-\frac{1}{2SN}\sum_k\left(\frac{3-\gamma_k^2}{\sqrt{1-\gamma_k^2}}-3\right) = \begin{cases}-0.054/S & \text{for NaCl type}\\ -0.057/S & \text{for CsCl type}\end{cases} \tag{4.29}$$

and

$$-\frac{3}{NS}\sum_k\left(\frac{1}{\sqrt{1-\gamma_k^2}}-1\right) = \begin{cases}-0.234/S & \text{for NaCl type}\\ -0.225/S & \text{for CsCl type}\end{cases} \tag{4.30}$$

respectively. $\tilde{\kappa}$ in the denominator of the left hand side of (4.29) or (4.30) was neglected, since it is much smaller than 1 and the term $k=0$ does not contribute to the summation. The factors proportional to $\langle n_k+n_k'\rangle$ in (4.16) and (4.17) can be calculated by applying the Eisele-Keffer's method[19] as follows;

$$\frac{1}{2SN}\sum_{k}\frac{3-\gamma_k^2}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}\langle n_k+n_k'\rangle=\frac{4}{S\pi^2}\sum_{n=1}^{\infty}\cosh\left(n\frac{2z|J|S}{k_0T}\tilde{H}\right)\left\{\varDelta\frac{K_1(x)}{x}+\frac{3}{2}\varDelta^2\frac{K_2(x)}{x^2}\right\}, \tag{4.31}$$

where

$$\varDelta=\tilde{\kappa}(2+\tilde{\kappa}), \tag{4.32}$$

$$x=nT_{AB}/T, \tag{4.33}$$

$$k_0T_{AB}=2z|J|S\sqrt{\varDelta}. \tag{4.34}$$

Here K_1 and K_2 are the real Hankel functions of degree one and two respectively. In the same way, we have

$$\frac{3}{NS}\sum_{k}\frac{\langle n_k+n_k'\rangle}{\sqrt{(1+\tilde{\kappa})^2-\gamma_k^2}}=\frac{12}{S\pi^2}\sum_{n=1}^{\infty}\cosh\left(n\frac{2z|J|S}{k_0T}\tilde{H}\right)\varDelta\frac{K_1(x)}{x}. \tag{4.35}$$

Let us carry out the numerical evaluations of (4.31) and (4.35), by assuming $T_{AB}=15$°K, $S=5/2$ (values of MnF_2) and $H=0$. Using these values we have from (4.16), (4.17), (4.31) and (4.35)

$$\frac{\omega(T)}{\omega(0)}=0.98\left\{\frac{K(T)}{0.91K(0)}\right\}^{A}. \tag{4.36}$$

Values of A are shown in the following table.

T°K	5	10	15	20	25	30
A	1/3.14	1/3.00	1/2.82	1/2.61	1/2.42	1/2.22

According to this table, as was anticipated in the beginning, at low temperatures A lies near 1/3 and approaches to 1/2 as the temperature increases. The facts that A at low temperatures differs from 1/3 and the numerical coefficient in (4.36) is different from unity are due to the $1/S$ correction.

Finally we consider the case where the static magnetic field is applied along the direction perpendicular to the preferred axis. This situation is more complicated than the previous one, so that we shall not describe the detailed calculations. The essential point is that we include the terms of 3rd and 4th orders of spin-wave operators. If we neglect the $1/S$ corrections, the resonance frequencies at 0°K are

$$\omega_1(0)=\frac{g\gamma}{2}\left\{\frac{8z|J|K(0)}{N(g\mu)^2}\right\}^{1/2}, \tag{4.37}$$

$$\omega_2(0)=\frac{g\gamma}{2}\left\{\frac{8z|J|K(0)}{N(g\mu)^2}+H^2\right\}^{1/2} \tag{4.38}$$

which are in agreement with the NKK's formulae. In the spin-wave calculations by Nakamura[17], the terms of 3rd and 4th orders of operators were not included and he could not obtain the field dependence of resonance frequency (4.38). On the other hand, Kanamori and Yosida[20] have obtained the same results as NKK's, in consideration of the deviation of spin equilibrium directions from the z axis due to the external magnetic field. As was already pointed out in their paper, our treatment in the case of perpendicular field is equivalent to theirs.

§ 5. Considerations on Experiments of Antiferromagnetic Resonance Absorption in MnF_2

Though there are observations of antiferromagnetic resonance absorptions for several substances, we consider here the experimental results of antiferromagnetic resonance absorption in MnF_2 especially.

The antiferromagnetic resonance absorption of MnF_2 was observed first by Johnson and Nethercot[21]. Afterwards Foner[22] observed it in the temperature range from low temperatures to the Néel point, by means of pulsed field and millimeter waves (wave length being 8 mm and 4 mm). Furthermore Johnson and Nethercot[23] had the very accurate measurements of antiferromagnetic resonance absorption over the wide range of temperature making use of the oscillating field with shorter wave length (3 mm and 1 mm). When their experimental data were analysed, they used the NKK's formula. Accordingly in the case of zero static field, the resonance frequency is expressed by (4.22), that is,

$$\frac{\omega(T)}{\omega(0)}=\left\{\frac{K(T)}{K(0)}\right\}^{1/2}. \tag{5.1}$$

As easily seen from (4.24) and (4.26), we have

$$\frac{K(T)}{K(0)}=\left\{\frac{M(T)}{M(0)}\right\}^{3}. \tag{5.2}$$

The more detailed calculation including the $1/S$ correction and the anisotropy energy coming from the dipolar interaction states that the power of the right hand side of (5.2) become 2.9[24].

On the other hand Jaccarino and Shulman[25] observed the nuclear magnetic resonance of F^{19} in MnF_2 in the antiferromagnetic range. The resonance frequency shifts considerably from the predicted nuclear resonance frequency. According to the theory by Shulman and Jaccarino[26] its shift $\Delta\omega$ is given by

$$\Delta\omega(T)=\frac{1}{\hbar}(2A_z^{I}-A_z^{II})\left(\frac{5}{2}-\alpha\right)\frac{M(T)}{M(0)}, \tag{5.3}$$

where A_z^I and A_z^{II} are the elements of effective hyperfine coupling tensor regarded as constants here and α is the deviation of the expectation value of Mn spin at 0°K (5/2). (5.3) means

$$\frac{\Delta\omega(T)}{\Delta\omega(0)}=\frac{M(T)}{M(0)}. \tag{5.4}$$

From (5.1), (5.2) and (5.4)

$$\frac{\omega(T)}{\omega(0)}=\left\{\frac{\Delta\omega(T)}{\Delta\omega(0)}\right\}^{1.45} \tag{5.5}$$

should be satisfied. In fact Johnson and Nethercot, by using their observed values and Jaccarino and Shulman's, showed that (5.5) is satisfied very well at low temperatures.

At low temperatures, however, we pointed out the replacement of NKK's formula (4.22) by (4.25). Accordingly

$$\frac{\omega(T)}{\omega(0)}=\frac{M(T)}{M(0)}=\frac{\Delta\omega(T)}{\Delta\omega(0)}, \tag{5.6}$$

must be held due to (5.2). According to Johnson and Nethercot, (5.6) is, however, rather valid at high temperatures and deviates at low temperatures. One question arises about the cause of the temperature variation in ω or $\Delta\omega$, because we assumed it came chiefly through the temperature dependence of $K(T)$ and $M(T)$ and regarded the exchange integral J and effective hyperfine coupling constant independent of temperature. In reality these quantities have the temperature dependence through the thermal expansion, so that we shall attempt to estimate these indirect effect on the temperature dependence of ω or $\Delta\omega$. We examine here the hyperfine coupling constant on which we have a number of data. The data obtained by Benedek and Kushida[27] are used, but the following method of estimation is different from theirs. (5.3) is written as

$$\Delta\omega(T)=AM(T) \tag{5.7}$$

or

$$\log \Delta\omega=\log A+\log M \tag{5.8}$$

where we call temporarily A "the hyperfine coupling constant". Differentiating (5.8) with respect to temperature under the constant pressure p, we have

$$\frac{1}{\Delta\omega}\left(\frac{\partial\Delta\omega}{\partial T}\right)_p=\left(\frac{\partial\log A}{\partial V}+\frac{\partial\log M}{\partial V}\right)_T\left(\frac{\partial V}{\partial T}\right)_p+\left(\frac{\partial\log M}{\partial T}\right)_V . \tag{5.9}$$

Here the first term of (5.9) is the correction due to the temperature variation of A and M (being the functions of distance between nearest neighbours) through the thermal expansion of specimen, that is, A arises chiefly from the overlaps of electrons belonging to the nearest neighbour ions[28] and M is the quantity determined by the exchange integral. Next we differentiate (5.8) with respect to p under constant T, resulting in

$$\frac{1}{\Delta\omega}\left(\frac{\partial\Delta\omega}{\partial p}\right)_T=\left(\frac{\partial\log A}{\partial V}+\frac{\partial\log M}{\partial V}\right)_T\left(\frac{\partial V}{\partial p}\right)_T . \tag{5.10}$$

According to Benedeck and Kushida, the observed values of the left hand side of (5.10) are 1.9×10^{-6}, 2.2×10^{-6} and 3.2×10^{-6} $(\mathrm{kg/cm^2})^{-1}$ at 4.2°, 20.4° and 35.7° respectively. For the sake of simple estimation we adopt the average value of them, 2×10^{-6} $(\mathrm{kg/cm^2})^{-1}$. Denoting the lattice constants of $\mathrm{MnF_2}$ perpendicular and parallel to the antiferromagnetic axis by a and c respectively, we have

$$\left(\frac{\partial V}{\partial p}\right)_T=\left(\frac{\partial(a^2c)}{\partial p}\right)_T=V\left\{\frac{2}{a}\left(\frac{\partial a}{\partial p}\right)_T+\frac{1}{c}\left(\frac{\partial c}{\partial p}\right)_T\right\} . \tag{5.11}$$

The measured values of the right hand side of (5.11) compressibility, at 20°C are $1/a\cdot(\partial a/\partial p)_T=-0.45\times10^{-6}$ $(\mathrm{kg/cm^2})^{-1}$, $1/c\cdot(\partial c/\partial p)_T=-0.31\times10^{-6}$ $(\mathrm{kg/cm})^{-1}$. We do not have low temperature values, but assume them to be valid even at low temperatures. Then $1/V\cdot(\partial V/\partial p)_T=-1.2\times10^{-6}$ $(\mathrm{kg/cm^2})^{-1}$ and from (5.10) we obtain

$$\left(\frac{\partial\log A}{\partial V}+\frac{\partial\log M}{\partial V}\right)_T=\frac{\dfrac{1}{\Delta\omega}\left(\dfrac{\partial\Delta\omega}{\partial p}\right)_T}{\left(\dfrac{\partial V}{\partial p}\right)_T}=-\frac{1.7}{V} . \tag{5.12}$$

Inserting (5.12) into (5.9)

$$\frac{1}{\Delta\omega}\left(\frac{\partial\Delta\omega}{\partial T}\right)_p=-\frac{1.7}{V}\left(\frac{\partial V}{\partial T}\right)_p+\left(\frac{\partial\log M}{\partial T}\right)_V . \tag{5.13}$$

The coefficient of linear expansion was measured by Gibbons.[29] Since the coefficient of linear expansion along the a axis is negligibly small at low temperatures, we may put

$$\frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_p=\frac{1}{c}\left(\frac{\partial c}{\partial T}\right)_p . \tag{5.14}$$

The values of $1/c\cdot(\partial c/\partial T)_p$ at 15°, 20° and 30°K are 3.25, 6.40 and 10.33×10^{-6} $(\mathrm{deg})^{-1}$ respectively and at 4°K smaller than 10^{-6}. According to Benedeck and Kushida, on the other hand, the values of the left hand side of (5.13) are -0.075, -3.2 and -8.5×10^{-3}

(deg)$^{-1}$ at 4.2°, 20.4° and 35.7°K respectively. Therefore the first term of the right hand side of (5.13) is negligible. As a result of this estimation we must conclude that the temperature dependence of $\Delta\omega$ is chiefly determined from the explicit temperature dependence of M, and that A can be regarded as a constant. It could be also said that the exchange integral is constant.

Our result (5.6) seems to be theoretically correct. As both the experiments of Jaccarino and Shulman, and Johnson and Nethercot are very accurate, there is no room to doubt about their experimental results. It looks as though we are between Scylla and Charybdis.

The authors wish to express their sincere thanks to Professor R. Kubo for his kind discussions, and also their sincere appreciations to Professor M. Toda for his encouragements and advices.

A Method for Measuring High Electron Densities in Plasmas

By Susumu TAKEDA and Michel ROUX

Nagoya University, Nagoya, Japan University of Illinois,
Urbana, Illinois, U.S.A.

(Received September 21, 1960)

It is proposed that high electron densities in plasmas can be determined from the complex reflection coefficient of a plane microwave at the plasma boundary. The coefficient which is related to the electron density and the collision frequency in plasmas is measured from the standing wave pattern produced by the incident and reflected wave at the boundary. As a result of the calculation, for a microwave frequency of 9000 MC, electron densities of 10^{14} and 10^{16} cm^{-3} are determinable respectively from the measurement of 11 and 1.1 degree in the phase angle of the complex reflection coefficient.

§1. Introduction

Recently, the measurement of high electron densities in plasmas has become increasingly important for researches in high temperature plasma physics. An approach to this problem, using microwave techniques, has been reported,[1] in which a TE_{011} mode cavity has been used; but such cavity techniques are not adapted to plasmas contained in large discharge chambers. When probing techniques in such plasmas are based on microwaves, usually the transmitted waves through the plasma have been considered; however, the reflection of an electromagnetic wave by the plasma limits the measurable density to its upper value of 10^{14} cm^{-3}, even in the case of 4 mm wave length. Thus, the measurement of densities higher than 10^{15} cm^{-3}, requires other techniques, such as spectroscopy.

This article proposes a new microwave method, able to extend the measurable density range by a factor of 10^4 above that by the propagation method previously used. This means that densities up to 10^{16} and 10^{18} cm^{-3} can be measured by waves of 9 KMC and 75 KMC respectively.

The well known method for measuring the electron density by means of an electromagnetic wave is based on the fact that the complex conductivity of the medium to be measured depends on the electron density and the collision frequency. When the frequency of the electromagnetic wave is much lower than the plasma frequency, most of the energy of the incident wave is reflected at the discontinuity surface and does not penetrate deeply into the plasma. However, the reflection at the surface of a high electron density plasma is a little different from that at the perfect conductor.

In the complex reflection coefficient given by $|R|e^{j\theta}$, a perfect conductor gives $|R|=1$ and $\theta=180°$. Therefore, in principle the measurement of the small deviations, $1-|R|$ and $180°-\theta=\phi$ should allow the determination of electron densities corresponding to plasma frequencies much higher than the wave frequency.

§2. Formulas for the reflection coefficient

A plane electromagnetic wave, propagating through a plasma with a complex conductivity σ, takes the form $\exp j(\omega t-kz)$ where k, the propagation constant in the medium, is given by the expression

$$k=\alpha-j\beta=k_0\left(1-j\frac{\sigma}{\omega\mathcal{E}}\right)^{1/2} \tag{1}$$

k_0 is the phase constant in vacuum; the complex conductivity of the plasma is, as well known,

$$\sigma=\frac{ne^2}{m}\,\frac{1}{\nu+j\omega} \tag{2}$$

From Eqs. (1) and (2), and making use of the relation $ne^2/m\mathcal{E}=\omega_p{}^2$, one obtains

$$\alpha^2=\frac{k_0{}^2}{2}\left[\left\{1-\frac{(\omega_p/\omega)^2}{1+(\nu/\omega)^2}\right\}+\left\{\left(1-\frac{(\omega_p/\omega)^2}{1+(\nu/\omega)^2}\right)^2+(\nu/\omega)^2\,\frac{(\omega_p/\omega)^4}{(1+(\nu/\omega)^2)^2}\right\}^{1/2}\right] \tag{3a}$$

$$\beta^2=\frac{k_0{}^2}{2}\left[-\left\{1-\frac{(\omega_p/\omega)^2}{1+(\nu/\omega)^2}\right\}+\left\{\left(1-\frac{(\omega_p/\omega)^2}{1+(\nu/\omega)^2}\right)^2+(\nu/\omega)^2\,\frac{(\omega_p/\omega)^4}{(1+(\nu/\omega)^2)^2}\right\}^{1/2}\right] \tag{3b}$$

The absolute value of the reflection coefficient $|R|$ and its phase angle θ are given as

$$|R| = \left|\frac{k_0-k}{k_0+k}\right| = \frac{\{(k_0-\alpha^2-\beta^2)^2+4k_0^2\beta^2\}^{1/2}}{(k_0+\alpha)^2+\beta^2} \qquad (4a)$$

$$\tan\theta \equiv -\tan\phi = \frac{2k_0\beta}{k_0^2-\alpha^2-\beta^2} \qquad (4b)$$

When $\nu/\omega=0$ and $\omega_p^2/\omega^2>1$,

$$\tan\phi = \frac{2\sqrt{(\omega_p/\omega)^2-1}}{(\omega_p/\omega)^2-2}, \qquad |R|=1 \qquad (4b)'$$

When $(\omega_p/\omega)^2/1+(\nu/\omega)^2 \gg 1$, α and β in (3a) and (3b) simplify to:

$$\alpha^2 = \frac{k_0^2}{2}\frac{(\omega_p/\omega)^2}{1+(\nu/\omega)^2}[\{1+(\nu/\omega)^2\}^{1/2}-1] \qquad (3c)$$

$$\beta^2 = \frac{k_0^2}{2}\frac{(\omega_p/\omega)^2}{1+(\nu/\omega)^2}[\{1+(\nu/\omega)^2\}^{1/2}+1] \qquad (3d)$$

Eqs. (4a) and (4b) can be rewritten as

$$1-|R| = 1-\frac{\{(1-C)^2+B^2\}^{1/2}}{1+A+C} \doteqdot A-\frac{B^2}{2}+2C \qquad (4c)$$

$$\tan\phi = \frac{B}{1-C} \qquad (4d)$$

where

$$A = \frac{2\alpha k_0}{\alpha^2+\beta^2} = \frac{\sqrt{2}\,[\{1+(\nu/\omega)^2\}^{1/2}-1]^{1/2}}{\omega_p\omega}$$

$$B = \frac{2\beta k_0}{\alpha^2+\beta^2} = \frac{\sqrt{2}\,[\{1+(\nu/\omega)^2\}^{1/2}+1]^{1/2}}{\omega_p/\omega}$$

$$C = \frac{k_0^2}{\alpha^2+\beta^2} = \frac{\{1+(\nu/\omega)^2\}^{1/2}}{\omega_p/\omega}$$

Again, when $(\omega_p/\omega)^2/1+(\nu/\omega)^2 \gg 1$, (4c) and (4d) simplify to

$$1-|R| \doteqdot A = \frac{\sqrt{2}}{\omega_p/\omega}[\{1+(\nu/\omega)^2\}^{1/2}-1]^{1/2} \qquad (4e)$$

$$\tan\phi \doteqdot B = \frac{\sqrt{2}}{\omega_p/\omega}[\{1+(\nu/\omega)^2\}^{1/2}+1]^{1/2} \qquad (4f)$$

The values of $\tan\phi$, and $1-|R|$ versus $(\omega_p/\omega)^2$ are shown in Figs. 1 and 2 for different parameters of ν/ω. For $\omega_p^2/\omega^2 \gg 2$ the value of $\tan\phi$ for $\nu/\omega<1$ does not differ too much from its value for $\nu/\omega=0$.

Solving Eqs. (4e) and (4f) for ω_p^2/ω^2 and $(\nu/\omega)^2$

$$(\omega_p/\omega)^2 = \frac{4}{\tan^2\phi-(1-|R|)^2} \qquad (5a)$$

$$(\nu/\omega)^2 = \left[\frac{1+\dfrac{\{1-|R|\}^2}{\tan^2\phi}}{1-\dfrac{\{1-|R|\}^2}{\tan^2\phi}}\right]^2-1 \qquad (5b)$$

When ν/ω is small,

$$1-|R| \doteqdot 0 \qquad (5c)$$

and

$$(\omega_p/\omega)^2 = \frac{4}{\tan^2\phi} \qquad (5d)$$

It may be worthwhile to note that $\phi=11°$ at $(\omega_p/\omega)^2=10^2$ for $\nu/\omega=0$. This means that $n=10^{14}\,\text{cm}^{-3}$ will be very easily measured by using a wave of 9000 MC.

The electromagnetic wave is very rapidly attenuated in plasmas, where ω_p^2/ω^2 is greater than one. The attenuation distant d is defined[2] by

$$d=1/\beta \qquad (6)$$

The ratio of the attenuation distance to the free space wave length d/λ is shown in Fig. 3 for different ν/ω. From (3b) it is simplified for $\nu/\omega=0$, as

$$\frac{d}{\lambda} = \frac{1}{2\pi}\frac{1}{\{(\omega_p/\omega)^2-1\}^{1/2}} \qquad (7)$$

Except at the low value of ω_p/ω, the ratio is very small. A plasma which has a thickness larger than this value is considered to be infinite. In other words, the effect of another surface can be neglected. The electron density in the vicinity of the wall is not uniform, but changes rapidly within a distance which is the order of the Debye length. The latter is much smaller than the attenuation

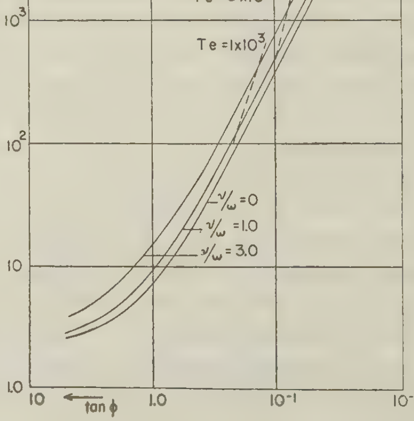

Fig. 1. Normalized electron density versus phase angle of the complex reflection coefficient for different values of ν/ω and T_e.

distance. Therefore, this non-uniformity close to the wall may be neglected.

If the gas is perfectly ionized, ν is a function of the electron temperature T_e and the electron density n as

$$\nu=3.6nT_e^{-3/2}\log\left(1.25\times10^4\frac{T_e^{3/2}}{n^{1/2}}\right) \qquad (8)$$

This equation is obtained from the collision characteristic time[3] between ions and electrons. In Figs. 1, and 2, the dotted lines correspond to the constant electron temperature for 9300 MC.

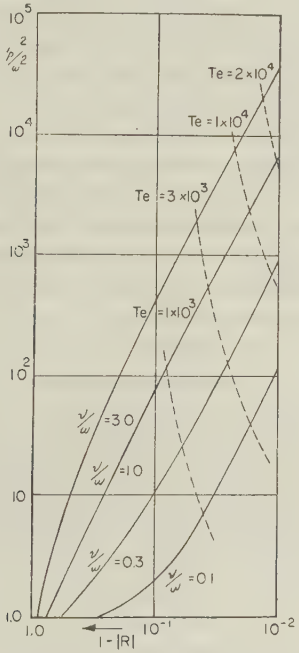

Fig. 2. Normalized electron density versus absolute value of the complex reflection coefficient for different values of ν/ω and T_e.

Thus, the electron density can be found from $1-|R|$ or $\tan\phi$, if the electron temperature is known, or both of the electron density and the collision frequency can be calculated from Eqs. (5a) and (5b) for $\omega_p^2/\omega^2\gg1$. Then the electron temperature can also be estimated from these values and Eq. (8).

§ 3. Principle of the measurement

The next problem is the measurement of the small values of $1-|R|$ and $\tan\phi$. If the plasma is a steady state or repeated one, the standard techniques of the impedance measurement (standing wave or interferometer method) can determine the complex reflection coefficient. However, for non-reproducible and transcient plasmas, the following improvement is here developed.

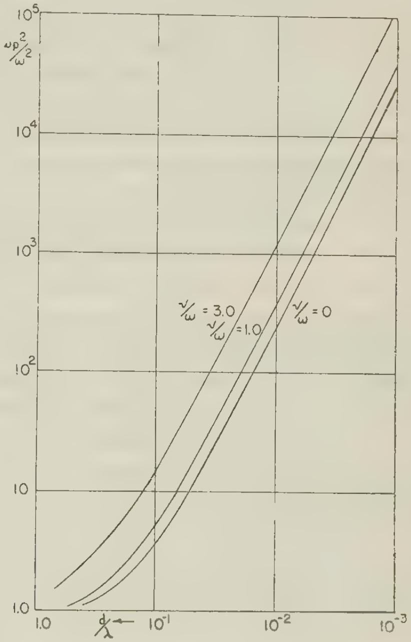

Fig. 3. Normalized electron density versus ratio of attenuation constant in plasmas to the free space wave length.

The standing wave pattern due to the reflection at a plane plasma surface and at a metal surface are shown by solid and dotted lines in Fig. 4. The signal heights h_1 and h_2, which are functions of the electric field at these points are related to $|R|$ and ϕ by means of the equations,

$$h_1=\frac{1}{4}\left|1-|R|e^{j\phi}\right|^2=\frac{1}{4}\{(1-|R|\cos\phi)^2+|R|^2\sin^2\phi\} \qquad (9a)$$

$$h_2=\frac{1}{4}\left|1+|R|e^{i\phi}\right|^2=\frac{1}{4}\{(1+|R|\cos\phi)^2+|R|^2\sin^2\phi\} \qquad (9b)$$

where a square characteristic of the crystal detectors is assumed, and h_1 and h_2 are normalized to have their maximum value 1. By solving Eqs. (9a) and (9b),

$$|R|=\frac{h_2-h_1}{\cos\phi}=\{2(h_1+h_2)-1\}^{1/2} \qquad (10a)$$

$$\sin\phi=\left\{1-\frac{(h_2-h_1)^2}{2(h_1+h_2)-1}\right\}^{1/2} \qquad (10b)$$

The small changes ΔR and $\Delta\phi$ in $|R|$ and ϕ cause the small deviation Δh_1 and Δh_2 in h_1

and h_2; they are deduced from (10a).

$$\Delta R=\frac{\Delta h_2-h_1\Delta}{|R|}=\frac{\Delta h_1+\Delta h_2-|R|\sin\phi\Delta\phi}{\cos\phi} \tag{11a}$$

$$\Delta\phi=\frac{\Delta h_1+\Delta h_2-\cos\phi\cdot\Delta R}{|R\ \sin\phi} \tag{11b}$$

The two time varying signals of h_1 and h_2 are displayed simaltaneously on a dual trace oscilloscope, where the continuous microwave is used. Two probe detectors, movable along the slotted sections of the wave-guide pick up the signals h_1 and h_2 and are fixed at such positions that one is at the minimum, and the other is at the maximum amplitude of a perfect standing wave pattern built by a metal plate, which shorts the open end of the waveguide. The correction of the formulas in the wave guide propagation is not serious except small ω_p^2/ω^2. The movable shorting plate slipped between the end of the waveguide and the plasma acts to show a standing wave as a reference. A thin mica plate is used to minimanize the wall effect between the plasma and the space in the waveguide. The maximum value of the detector signals, h_m, which is necessary to normalize h_1 and h_2 can be known from the maximum height of h_2, where a pulse modulated microwave should be used

As is seen in Fig. 4, better sensibility in h_1 and h_2 with respect to the small change of ϕ is expected at some value of ϕ other than $\phi=0$. Therefore, the probe detectors are better to be shifted out of their initial minimum or maximum amplitude positions to new positions to have a bigger slope, $\Delta h_1/\Delta\phi$. The normalized value, $\Delta h_1=0.01$ (1 mm for $h_m=100$ mm) yields a 1° change in the phase angle for $\phi=90°$, if ΔR is neglected. (refer (11b)), This phase angle change corresponds to $n=1\times10^{16}\,\mathrm{cm}^{-3}$ at a frequency of 9000 MC.

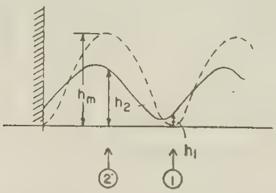

Fig. 4. Standing wave patterns due to the reflection at the plasma surface and the perfect conductor.

The application of this method to shock wave produced plasmas is now undertaken and the results will be reported with the experimental procedures. The measurement method here developed is also useful in other time varying complex values, such as impedances or propagation constants.

Although the calculation of the complex reflection coefficient described here assumes a free space propagation of the wave, a sharp discontinuity in the electron density at the plane boundary, and plasmas without magnetic field, the idea could be extended to more complicate conditions.

Acknowledgment

The authors greatly appreciate Professor L. Goldstein who gave us the opportunity to start the experiment. They also thank to Prof. R. John who kindly send them an unofficial report on the wave propagation.

Energy Spectrum of Mn^{++} Ion in Calcium Fluorophosphate I

By Koziro NARITA

Hitachi Central Research Laboratory, Kokubunji, Tokyo

(Received July 6, 1960)

In order to find the effect of the change in the lattice constants of the host crystal upon the energy levels of the activator ion, calculations were performed for the particular case of calcium fluorophosphate activated by Mn^{++}. The wave functions of the d^5 configuration in excited states are formed by the method of Condon and Shortley, and the matrix elements of the crystalline field potential at the Mn^{++} ion were calculated. The Hamiltonian matrix thus obtained was diagonalized by a computer to derive the eigenvalues. On the assumption that the emission of this fluorescent body is due to the transition of Mn^{++} ions from the lowest excited state to the ground state, the calculation leads to a shift of the emission peak by about 200Å to the longer wave length side caused by 1% decrease in the lattice constant.

§ 1. Introduction

The position of the emission peak varies when the composition of the basic compound is changed, even under activation by the same element. For example, in the system of MVO_3 activated by manganese, where M stands for alkaline metals Na, K, Rb or Cs, the position of the emission peak moves to the shorter wave length side with increasing order of ionic radii of the alkaline metal ions involved.[1] But in the case of barium strontium orthophosphate phosphors the emission peak shifts toward the shorter wave length side, when a part of barium ions is replaced by strontium ions having smaller ionic radii than barium.[2]

These emissions are considered to be due to the transition of the activator ion from an excited state to the ground state. The excited state from which the transition takes place is the lowest state among those arising from the 1st excited state of the free ion by the crystal field splitting. When we replace a part of ions by the ions of smaller ionic radii, the crystal field at the position of the activator ion is strengthened due to the contraction of the crystal lattice. Therefore the experimental results mentioned above for the system of MVO_3 can be reasonably understood with this view point.

From these consideration G.R. Fonda[3] speculated that the main cause of these variation of the position of spectral emission would be the variation of crystal field strength due to the change in lattice constant, and that in the case of alkaline earth orthophosphate phosphors other factor such as polarization of ions might become important.

Recently, M. Emoto[4] found the similar phenomena. Namely, when a part of the calcium ions in $\beta-Ca_3(PO_4)_2$ is replaced by magnesium or barium, the emission peak shifts towards the shorter wave length side, while a similar replacement by strontium causes the shift toward the longer wave length side. He also found that in the case of calcium fluorophospate, the emission peak shifts towards the longer wave length side when a part of the calcium ions is replaced by cadmium. The change in lattice constant resulting from the replacement of ions in these crystals is measured by T. Mitsuishi[5] using X-ray method.

In investigating the causes of such emission peak shift, one of the most important points is to examine the effect of the change in lattice constant of the host crystals upon the energy levels of the activator ion.

Systematic calculation of the crystal field for the case of $\beta-Ca_3(PO_4)_2$ and MVO_3 would be very interesting to compare with the experimental results. Unfortunately we have no information about the crystal structure or the change in lattice constant due to the replacement of ions.

In this report, therefore, the author decided to calculate the energy levels of the activating Mn^{++} ion in calcium fluorophosphate, and compare with the available experimental results.

The energy levels of the d^5 configuration have been calculated by Orgel[6] for the case of cubic crystalline field, and the result is given against the parameter Dq corresponding to the cubic field strength. Calcium fluorophosphate, however, has more complex crystal structure and one of the sites of the activating manganese ions possesses a 3-fold symmetry axis parallel to the z-axis, and it needs four parameters to describe the crystalline field potential at this point.

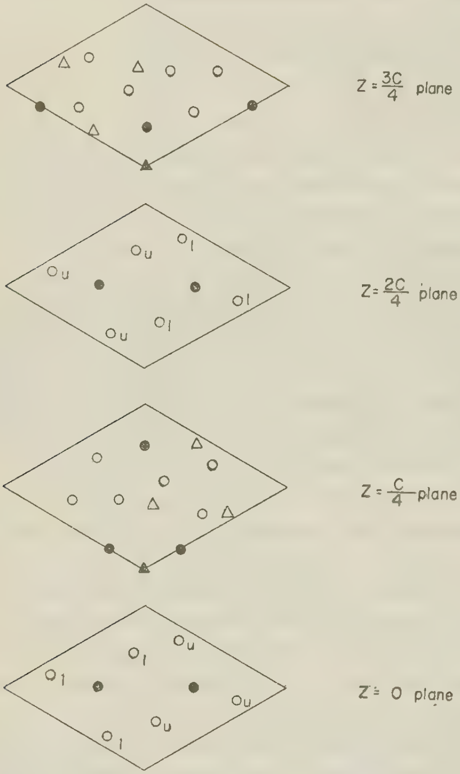

Fig. 1. Crystal Structure of Calcium Fluorophosphate.

lattice constant $a = 9.37$ Å and $c = 6.88$ Å

○ Oxygen ion, ● Calcium ion

△ Phosphorus ion, ▲ Fluorin ion

The suffix u or l indicates whether so-indicated oxygen is $c/16$ above or below the plane

We, therefore, calculate these parameters, regarding the ions surrounding the activator ion as point charges, and investigate the order of magnitude of the shift of these energy levels caused by the change in lattice constant.

§ 2. Crystal Structure[7]

A unit cell of the calcium fluorophosphate crystal comprises 4 layers and possesses 42 ions as illustrated in Fig. 1. The suffices u and l on O (oxygen) in Fig. 1 indicate that the relevant oxygen are located at $c/16$ above or below the plane respectively.

Each of the Ca^{++} ions lying in the $z=0$ and $z=2c/4$ planes possesses a 3-fold symmetry axis parallel to the z axis, but those in the $z=c/4$ and $z=3c/4$ planes have no such symmetry axis. It is not known which of these sites are occupied by the Ca^{++} ions replaced by Mn^{++}, but it is believed that, when considering only the dependence of the energy level on the change in lattice constant, there would be no great variance due to the difference in site. Therefore we shall carry out the calculation on the assumption that the Ca^{++} ions in the $z=0$ plane are replaced by Mn^{++}. The Mn^{++} ion in this case is in a crystalline field having a 3-fold symmetry axis.

§ 3. Wave Function

The ground state of Mn^{++} ion is ${}^6S$. The excited state of $3d^5$ configuration are ${}^4G$, ${}^4P$, ${}^4D$ and ${}^4F$[8]. The wave functions of these excited states can be derived by the method of Condon and Shortley[9]. Namely, the wave function of ${}^4G$ state having maximum M_L is given by

$$({}^4G4) = (2^+2^-1^+0^+-1^+)$$

where the last index on the left side of above equation gives the values of M_L and notation such as $(2^+\ 2^-\ 1^+\ 0^+-1^+)$ stands for a determinantal wave function in which one electron has $m_l=2$ and spin up, while the 2nd has $m_l=1$ and spin down, and so on.

Operation of $L^- \equiv L_x - iL_y$ upon the state (${}^4G$ 4) gives (${}^4G$ 3) as a linear combination of certain determinantal functions. The state (${}^4F$ 3) can be expressed as the linear combination of the same component functions orthogonalized to (${}^4G$ 3). In this way, we can obtain the whole wave functions of $3d^5$ configuration.

§ 4. Matrix Elements of Crystalline Field

The potential of the crystalline fields possessing a 3-fold symmetry around the z-axis can generally be given by the following expression.[10)]

$$V=\sum_i \{C_2{}^0 r_i{}^2 P_2{}^0(\cos\theta_i)+C_4{}^0 r_i{}^4 P_4{}^0(\cos\theta_i)+C_4{}^3 r_i{}^4 P_4{}^3(\cos\theta_i)\cos 3\varphi_i+d_4{}^3 r^4{}_i P_4{}^3(\cos\theta_i)\times\sin 3\varphi_i\}, \tag{1}$$

and if we regard the ions surrounding to the activator ion as point charges,[11)]

$$\begin{aligned} C_l{}^0&=\sum_j \frac{e\ e_j}{R_j{}^{l+1}}\quad P_l(\cos\Theta_j)\\ C_l{}^m&=2\frac{(l-m)!}{(l+m)!}\sum_j \frac{e\ e_j}{R_j{}^{l+1}}\quad P_l{}^m(\cos\Theta_j)\cos m\Phi_j\\ d_l{}^m&=2\frac{(l-m)!}{(l+m)!}\sum_j \frac{e\ e_j}{R_j{}^{l+1}}\quad P_l{}^m(\cos\Theta_j)\sin m\Phi_j, \end{aligned} \tag{2}$$

where r_i, θ_i and φ_i are the coordinates of the ith electron in the activator ion under consideration, while R_j, Θ_j and Φ_j give the coordinates of the jth ion measured from the center of this ion. The charge of the electron and of the jth ion are denoted by e and e_j respectively. Since the potential of the crystalline field is of the form of $\sum v_i$, its matrix elements $(L, M\,|V|\,L', M')$ can be expressed in terms of the matrix elements $(m\ |v|\ m')$ of a single electron. Also, on account of the fact that the matrix element $(L, M\,|V|\,L', M')$ has a non-zero element only when $M'=M$ and $M'=M\pm3$, total 24×24 matrix can be factorized into three 8×8 matrices. In the rest of this article we shall use symbols ***A***, ***B***, and ***C*** to represent these matrices. The states involved in these matrices are listed in Table I.

Table I. The states involved in matrices ***A***, ***B*** and ***C***.

Matrix	States contained in the Matrix							
A	$(^4G4)$,	$(^4G1)$,	$(^4G{-2})$,	$(^4F1)$,	$(^4F{-2})$,	$(^4D1)$,	$(^4D{-2})$,	$(^4P1)$
B	$(^4G3)$,	$(^4G0)$,	$(^4G{-3})$,	$(^4F3)$,	$(^4F\ 0)$,	$(^4F{-3})$,	$(^4D\ 0)$,	$(^4P0)$
C	$(^4G2)$,	$(^4G{-1})$,	$(^4G{-4})$,	$(^4F2)$,	$(^4F{-1})$,	$(^4D2)$,	$(^4D{-1})$,	$(^4P{-1})$

Of the matrix elements of the crystal field potential thus obtained only the following elements have non-zero values. (Owing to the Hermitian character of these matrices, it is only necessary to write half of the off-diagonal elements above the diagonal.)

Matrix ***A***

$$(4, 4\,|V|\,3, 1)=-2\frac{\sqrt{3}}{\sqrt{10}}(2\,|v|-1)$$

$$(4, 4\,|V|\,1, 1)=-2\frac{\sqrt{2}}{\sqrt{10}}(2\,|v|-1)$$

$$(4, 1\,|V|\,3, 1)=\frac{\sqrt{3}}{\sqrt{140}}\times[2(2|v|2)+2(1|v|1)-4(0|v|0)]$$

$$(4, 1\,|V|\,3, -2)=\frac{2\sqrt{6}}{\sqrt{28}}(2\,|v|-1)$$

$$(4, 1\,|V|\,1, 1)=\frac{2\sqrt{2}}{\sqrt{140}}\times[(2|v|2)-4(1|v|1)+3(0|v|0)]$$

$$(4,-2\,|V|\,3,1)=\frac{4\sqrt{3}}{\sqrt{280}}(-1|v|2)$$

$$(4,-2\,|V|\,3,-2)\frac{-2\sqrt{6}}{\sqrt{56}}[(2|v|2)-(0|v|0)]$$

$$(4,-2\,|V|\,1, 1)=\frac{14\sqrt{2}}{\sqrt{280}}(-1|v|2)$$

$$(3, 1\,|V|\,2, 1)=\frac{2\sqrt{2}}{\sqrt{140}}\times[3(2|v|2)-4(1|v|1)+(0|v|0)]$$

$$(3, 1\,|V|\,2,-2)=-\frac{10\sqrt{2}}{\sqrt{140}}(2|v|-1)$$

$$(3,-2\,|V|\,2, 1)=-\frac{2}{\sqrt{28}}(-1|v|2)$$

$$(3,-2\,|V|\,2, -2)=-\frac{4}{\sqrt{28}}[(2|v|2)-(0|v|0)]$$

$$(2, 1\,|V|\,1, 1)=\frac{2\sqrt{3}}{\sqrt{140}}\times[2(2|v|2)-(1|v|1)-(0|v|0)].$$

Matrix ***B***

$$(4, 3\,|V|\,3, 3)=[(2|v|2)-(1|v|1)]$$

$$(4, 3\,|V|\,3, 0)=-\frac{2}{\sqrt{20}}(2|v|-1)$$

$$(4, 3\,|V|\,1, 0)=\frac{6}{\sqrt{20}}(2|v|-1)$$

$$(4, 0\,|V|\,3, 3)=\frac{10}{\sqrt{140}}(-1|v|2)$$

$$(4, 0\,|V|\,3, -3)=\frac{10}{\sqrt{140}}(2|v|-1)$$

$$(4,-3\,|V|\,3,0)=-\frac{2}{\sqrt{20}}(-1|v|2)$$

$$(4,-3\,|V|\,3,-3)=-[(2|v|2)-(1|v|1)] \tag{4}$$

$$(4,-3\,|V|\,1,0)=\frac{6}{\sqrt{20}}(-1|v|2)$$

$$(3,3\,|V|\,2,0)=\frac{6}{\sqrt{28}}(2|v|-1)$$

$$(3,-3\,|V|\,2,0)=\frac{6}{\sqrt{28}}(-1|v|2).$$

Matrix ***C***

$$(4,2\,|V|\,3,2)=\frac{2\sqrt{6}}{\sqrt{56}}[(2|v|2)-(0|v|0)]$$

$$(4,2\,|V|\,3,-1)=\frac{4\sqrt{3}}{\sqrt{280}}(2|v|-1)$$

$$(4,2\,|V|\,1,-1)=\frac{14\sqrt{2}}{\sqrt{280}}(2|v|-1)$$

$$(4,-1\,|V|\,3,2)=\frac{2\sqrt{6}}{\sqrt{28}}(-1|v|2)$$

$$(4,-1\,|V|\,3,-1)=-\frac{\sqrt{3}}{\sqrt{140}}\times[2(2|v|2)+2(1|v|1)-4(0|v|0)]$$

$$(4,-1\,|V|\,1,-1)=-\frac{2\sqrt{2}}{\sqrt{140}}[2(2|v|2)-4(1|v|1)+3(0|v|0)]$$

$$(4,-4\,|V|\,3,-1)=-\frac{2\sqrt{3}}{\sqrt{10}}(-1|v|2)$$

$$(4,-4\,|V|\,1,-1)=-\frac{2\sqrt{2}}{\sqrt{10}}(-1|v|2)$$

$$(3,2\,|V|\,2,2)=\frac{4}{\sqrt{28}}[(2|v|2)-(0|v|0)] \tag{5}$$

$$(3,2\,|V|\,2,-1)=-\frac{2}{\sqrt{28}}(2|v|-1)$$

$$(3,-1\,|V|\,2,2)=-\frac{10\sqrt{2}}{\sqrt{140}}(-1|v|2)$$

$$(3,-1\,|V|\,2,-1)=-\frac{2\sqrt{2}}{\sqrt{140}}\times[3(2|v|2)-4(1|v|1)+(0|v|0)]$$

$$(2,-1\,|V|\,1,-1)=-\frac{2\sqrt{3}}{\sqrt{140}}[2(2|v|2)-(1|v|1)-(0|v|0)].$$

One electron matrix element $(m|v|m')$ can be calculated by Stevens' method.[12]

$$\begin{aligned}(m|v|m')=&\frac{1}{2}C_2^0\alpha\overline{r^2}(3m^2-6)\delta_{mm'}\\&+\frac{1}{8}C_4^0\beta\overline{r^4}(35m^4-155m^2+72)\delta_{mm'}\\&+315(C_4^3+id_4^3)\beta\overline{r^4}(2m-3)\delta_{m,m'+3}\\&+315(C_4^3-id_4^3)\beta\overline{r^4}(2m+3)\delta_{m,m'-3}\end{aligned} \tag{6}$$

Here, α and β are constants and their values for the single d-electron are

$$\alpha=-\frac{2}{21} \qquad \beta=\frac{2}{63} \tag{7}$$

$\overline{r^2}$ and $\overline{r^4}$ are the average values of r^2 and r^4 respectively, and they can be estimated by assuming the wave function of d-electron in the following form with the value of Z_{eff} determined by Slater's rule[13].

$$\psi_m=N_m r^2\exp\left(-\frac{Z_{eff}}{3a_H}r\right)P_2^{|m|}(\cos\theta)\exp(im\varphi). \tag{8}$$

With $Z_{eff}=5.6$ for 3d-electron, we obtain

$$\overline{r^2}=8\cdot7\cdot\left(\frac{3a_H}{2Z_{eff}}\right)^2.$$

$$\text{and}\quad \overline{r^4}=10\cdot9\cdot8\cdot7\cdot\left(\frac{3a_H}{2Z_{eff}}\right)^4. \tag{9}$$

Here a_H is the Bohr radius.

In order to obtain the coefficients, C_2^0, C_4^0, C_4^3 and d_4^3, we calculate the sum of equation (2) for the eight unit cells around Mn^{++}. We use $+2e$ and $-e$ for the charges of Ca and F ion respectively. Considering the fact that a P ion is surrounded nearly tetrahedrally by four O ions, we assume the charges of P and O ions to be $+e$ and $-e$, although the bonding character between P and O ions in this crystal is not clear. The values of the coefficients for the ordinary lattice constant of calcium fluorophosphate in C.G.S. units are as follows

$$\begin{aligned}&C_2^0=0.4311\times10^4\\&C_4^0=-0.6450\times10^{20}\\&C_4^3=0{,}005543\times10^{20}\\&d_4^3=-0.005216\times10^{20}\end{aligned} \tag{10}$$

The change in lattice constant due to the replacement of ions is not always isotropic. For example, when the Ca^{++} ion in calcium fluorophosphate is replaced by Cd^{++}, the change in lattice constant has been found to be anisotropic as referred later. In this article, however, we shall carry out our calculation assuming, for simplicity, a uniform lattice contraction. Under this assumption, the crystalline field potential for the case of, say, 2% decrease of the lattice constant can be obtained by multiplying C_2^0 by 0.98^{-3} and C_4^0, C_4^3 and d_4^3 by 0.98^{-5} in equation (10).

By using equations (3)∼(10), we can obtain the numerical values of the matrix elements. Non-vanishing elements of the matrices $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ obtained in this manner are listed in Tables II∼IV. In these Tables, $R=R^0$ and $R=0.98R^0$ indicate, respectively, the case of normal lattice constant and the case where the lattice constant decreases by 2% from the normal values.

§ 5. Results and Discussion

The Hamiltonian matrix is completed by placing the following spectral values of the free Mn^{++} ion which come from the free ion part of the total Hamiltonian, in the diagonal part of the matrix obtained above.

$$^4G=26800 \qquad {}^4P=29200$$
$$^4D=32300 \qquad {}^4F=43600\ \mathrm{cm}^{-1}.$$

This matrix was then diagonalized by using I.B.M. 650 computer to obtain the energy levels of Mn^{++} in the calcium fluorophosphate crystal. By multiplying the perturbation matrix elements by $\mathcal{E}$ and taking the limit of $\mathcal{E}\to 0$, it is possible to find out the free ion state corresponding to each of the perturbed levels. Also, from the degeneracy of the free ion states and the fact that the trace of a matrix is invariant under the unitary transformation, we could derive the degeneracy of the perturbed energy levels obtained above.

The energy levels thus obtained are shown in Fig. 2. The symbols G, P, D, and F in Fig. 2 indicate the free ion state to which the levels converge at the limiting case of $\mathcal{E}\to 0$, while the numerals indicate the degeneracy of that level. Group theoretical consideration shows that the C_3 symmetry should remove all the degeneracies involved in this problem. However, two levels which are close enough to fall within the range of resolution of our machine computation can not be discriminated as such in our calculation. Therefore the degeneracies shown here are those of accidental type and not substantial.

According to these results, the lowest excited state appears near 24500 cm^{-1}. And a decrease by 2% in the lattice constant will cause a shift of approximately 300 cm^{-1} to the lower energy side. The magnitude of this shift corresponds to about 13% of the energy depression due to the perturbation of the crystalline field of the original lattice constant.

The absorption spectra of Mn^{++} ion in calcium fluorophosphate has not been measured yet. The emission spectrum has a peak near 17300 cm^{-1}. We have assumed that the Mn^{++} ion is imbedded in the crystalline field created by the surrounding ions and calculated its energy levels treating the crystalline field as a perturbation. It is not known how closely this crystal field model approximates our particular problem. Also, when Mn^{++} is excited, there should be a change in the configuration of the surrounding ions and hence a further decrease in the energy of the ion corresponding to the Stokes shift. Therefore, it may not be appropriate to use the results of the above calculation to determine quantitatively the shift of the emission peak near $17300\,cm^{-1}$ due to the change in lattice constant. We should, however, be able to deduce the order of magnitude of the shift from our calculation. Let us assume that even for the actual state giving the emission peak at $17300\,cm^{-1}$, 2% decrease in the lattice constant gives rise to a further shift of 13% of that due to the perturbation of the crystalline field at the original lattice constant. Then there should be a shift of about $1200\,cm^{-1}$ to the lower energy side when there is a lattice contraction by 2%.

Experimentally it has been found that the peak shifts by about $100\,cm^{-1}$ to the longer wave side when one Ca in each calcium fluorophosphate $Ca_{10}(PO_4)_6F_2$ is replaced by Cd. The changes in lattice constant for this particular case are anisotropic and are decrease by 0.042% and 0.35% along *a*-axis and *c*-axis respectively.5)

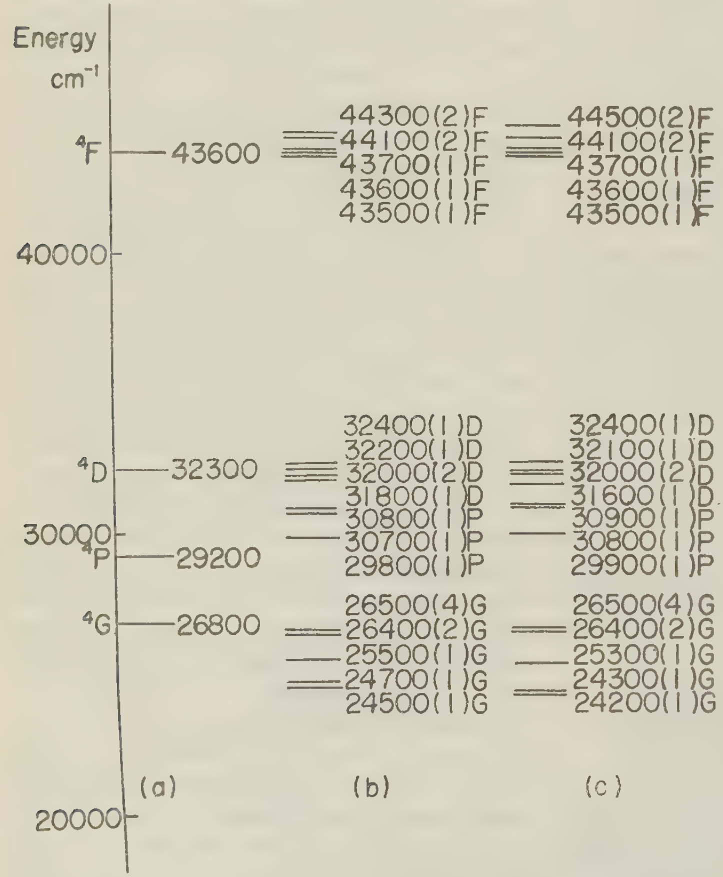

Fig. 2. Energy levels of Mn^{++} ion in free state and in the calcium fluorophosphate crystal. Energies are given in the unit of cm^{-1}

(a) Energy levels of free Mn^{++} ion from spectroscopic data.
(b) Calculated energy levels of Mn^{++} ion in the calcium fluorophosphate crystal having ordinary lattice oonstant.
(c) Calculated energy levels of Mn^{++} ion in the crystal of calcium fluorophosphate contracted by 2%.

Since our calculations are made on the assumption of isotropical decrease in the lattice constant, direct comparison can not be made. If, however, we were to replace the above mentioned anisotropic contraction with an isotropic contraction with the identical volume reduction, we would get a decrease by 0.14% in the lattice constant. Therefore, together with the above estimate of the energy shift per 2% decrease in the lattice constant, one would expect a shift by $85\,cm^{-1}$ to the longer wave side when one mole of Ca^{++} ions is replaced by Cd^{++} ions in each calcium fluorophosphate.

In calculating the crystalline potential around the Mn^{++} ion, we assume the charge $+e$ and $-e$ for P and O ion respectively. However, the validity of this assumption is not so clear, and ionicity of these ions will have considerable influence on the energy levels of Mn^{++} ion. Furthermore the oxygen ions near the Mn^{++} ion may be polarized, and if so, one must add the field from the electric dipole moments of the oxygen ions. These effect will be investigated in the forthcoming paper.

Because of the rough approximation employed in our calculation the value obtained here should not be taken too quantitatively but should be regarded as a measure of the order of the energy level shift due to the change in the crystalline field potential.

In regard to what other mechanism contribute to the energy level shift, the author is planning to carry on the similar study after obtaining the results of the experiments in which Ca is replaced by various divalent metals other than Cd in a systematic manner.

The Wavelength Dependence of Quantum Efficiency and Absorption Coefficient of ZnSiO₃/Mn Powder Phosphor

By Isoo MASUDA

Matsuda Research Laboratory,
Tokyo Shibaura Electric Co., Ltd.

(Received June 9, 1960)

In this paper, the relation between the wavelength dependence of the absorption coefficient of $ZnSiO_3$/Mn powder phosphor and that of the quantum efficiency of fluorescence as well as the relation between the latter and the activator concentration were studied. It was found out that the peak of the quantum efficiency was always at the longer wavelength side than that of the absorption coefficient, and that with decrease of manganese concentration, the quantum efficiency becomes larger, and its curve sharper. A simple theory was presented to explain these facts.

§1. Introduction

We have already reported on the measuring technique of the absorption coefficient of the powdered material following the theory of Kubelka.[1] According to our method, the absorption coefficient (α) can be estimated roughly from the following formula,

$$\alpha(cm^{-1})=210(1-R)^2/2R$$

under the resonable assumption that the scattering constant σ is always taken as 210 cm^{-1} irrespectively of wavelength. Here, R is the reflectivity of the powdered sample which has a sufficiently large thickness, and can be determined in comparison with the spectral reflectivity of the smoked magnesium oxide plate calibrated beforehand.

We have also reported the method of measuring the fluorescent intensity of these powdered material, and of obtaining the quantum efficiency of fluorescence. We found that the quantum efficiency in many cases was enormously varied with the wavelength of the exciting light. This fact was confirmed even when the absorption other than the characteristic absorption was eliminated and the emission was caused only by the characteristic absorption. Though the reason was briefly explained already,[2] it will be accounted for in detail in the present paper, taking $ZnSiO_3/Mn$ of low Mn concentration as an example and referring to the measured result of absorption coefficient.

The quantum efficiency η is defined as

$$\eta = \frac{\textit{number of emitted quanta}}{\textit{number of absorbed quanta}} = \frac{F \cdot \lambda_F}{J \cdot \lambda_J \cdot A_J}$$

where, A_J is the absorption factor for the exciting light, J the excitation intensity, λ_J the exciting wavelength, F the fluorescent intensity and λ_F the mean wavelength of the fluorescence. When the absorption of the host crystal became is of considerable amount, we subtracted it from the absorption of the sample containing the activator.

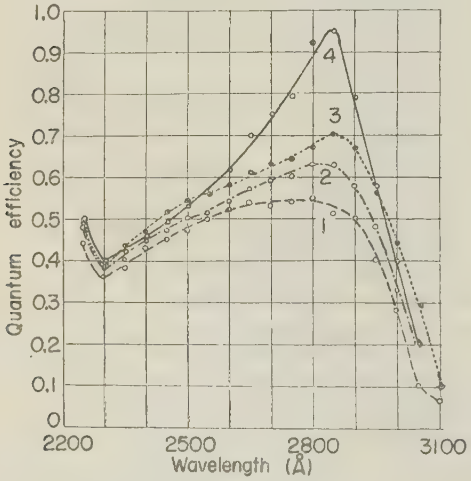

Fig. 1. Quantum efficiency curve of $ZnSiO_3/Mn$ Phosphor

① 10×10^{-2} mole Mn ② 4×10^{-2} mole Mn

③ $3\times10_{-}^{2}$ mole Mn ④ 2×10^{-2} mole Mn

§ 2. Experimental results

Fig. 1 shows curves of quantum efficiency of four kinds of $ZnSiO_3/Mn$ different in activator concentration. As activator concentration decreases, the quantum efficiency increases, especially at 2850Å. Consequently the curve shape becomes sharp with decrease of concentration. This effect will probably due to the fact that the concentration quenching effect becomes smaller with decrease of concentration.

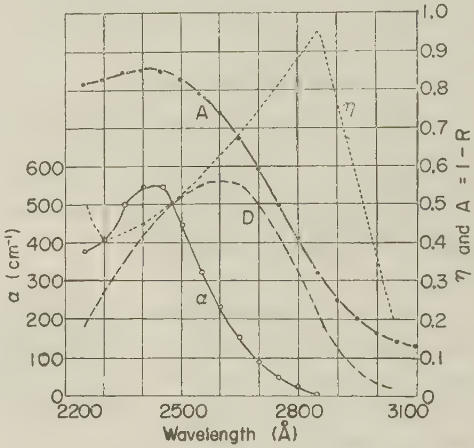

Fig. 2. Quantum efficiency (η), Absorption coefficient (α), Absorption (A) and Excitation (D–arbitraly unit) of $ZnSiO_3/Mn$ (2×10^{-2} mole) powder phosphor.

Fig. 2 shows the curve of absorption coefficient α, that of quantum efficiency η and excitation spectrum ($D=F/J$, in an arbitrary scale) of the material, in the case where manganese concentration is 2×10^{-2} mole. In this figure, it is observed that the quantum efficiency decreases with steep slant in the region shorter than 2300Å with increases wavelength, then begines to increase with gentle slant up to 2850Å, and after passing a maximum it decreases again with steep slant with increasing wavelength. There is a peak of absorption coefficient near 2450Å and its cauve is likely to be the bell shape. In the range shorter than 2300Å, there will probably be another characteristic absorption band. The absorption coefficient at 2850Å is about 10cm^{-1}. This value is the critical one which could be estimated by the mentioned method[1] and is about 1/60 times of the value at 2450Å.

§ 3. Discussion

Let us consider the relation between the curve of absorption coefficient and that of quantum efficiency shown in Fig. 2, in which the concentration quenching effect seems to be the smallest.

The absorption peak corresponding to the photon energy shown as AA′ in Fig. 3, lies at 2450Å in this material. This shown that most of the activation centers absorb photons of this energy and are excited, but the broad shape of the absorption band shows that an appreciable fraction of the activation centers are excited with photons of another energy. When the center absorbs minimum energy needed for excitation, the difference between the energy of the electron and the energy corresponding to the point *F* in the figure should be maximum, and the probability of radiative transition is to be maximum.[3] If the absorption curve is bell shape, this minimum energy will not be that which is equivalent to *AA′* in Fig. 3, but correspond to minimum energy component of bell shape distribution. So, in the characteristic absorption band, the quantum efficiency of fluorescence will increase monotonously from the shorter wavelength side towards the longer wavelength side. Indeed, Fig. 2 shows this tendency until 2850Å, which is the longest wavelength that we can distinguish the characteristic absorption from the background. Perhaps, the fact that the steep slant decrease in the longer wavelength region than 2850Å will be explained by the appearance of the weak absorption, the large part of which are the inactive absorption caused by other kinds of defects.

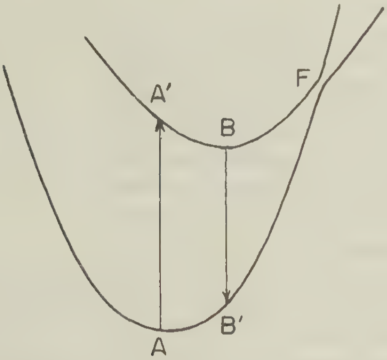

Fig. 3. Configrational coordinate Model of luminescent center.

C. K. Lui stated that the speak of characteristic absorption ought to correspond to that of excitation spectrum,[4] but, because quantum efficiency is not constant, D-curve is displaced to the longer wavelength side as shown in Fig. 2.

Pringsheim[5)] predicted that "So called specific excitation spectra are, in general, nothing but the characteristic absorption spectra of the photoluminescent substance", but at least in the case of inorganic crystal phosphor, D-curve does not correspond to the curve of characteristic absorption.

If we assume the specific excitation spectrum to be equal to the K-curve defined by Vavilov[6)], the following formula can be obtained by neglecting the quantum energy difference of exciting radiation;

$$K=D/A_J=\eta\cdot A_J/A_J=\eta.$$

Accordingly the specific excitation spectrum corresponds to the quantum efficiency spectrum, but not to the characteristic absorption spectrum. It has been reported that for solutions such as eosin, rhodamin or fluorescein, the quantum efficiency of fluorescence does not depend upon exciting wavelength. In the case of inorganic crystal phosphor, however, it is likely that the quantum efficiency of fluorescence depends upon the exciting wavelength and is similar to the excitation function of gaseous discharge.

Radiation Induced Optical Absorptions in Crystalline Quartz and Fused Silica

By Kazuko KUBO

Japan Atomic Energy Research Institute
Tokai Research Establishment
Tokai-mura, Ibaraki-ken, Japan

(Received September 8, 1960)

The optical absorption of γ- and fast neutron-irradiated crystalline quartz and fused silica was measured from 186 mμ to 2.6 μ. Dichroism of the A-band was confirmed. The phenomenon of radiation bleaching of the B_1-band and a remarkable movement of the C-band were found. The irradiation and optical bleaching experiments showed that only the C-band is essential due to radiation, and this was considered to be caused by an absorption center similar to the F-center which changes F′- or colloidal-center with subsequent irradiation.

§ 1. Introduction

Physical property changes in quartz and fused silica exposed to various radiations have been studied for many years, and reports published in this connection have been listed in a bibliography by Bechman.[1] Above all, optical absorption has been actively investigated by many authors who placed the absorption peaks in positions differing fairly markedly from author to author. The present author tabulated the hitherto reported data on the absorption bands according to the kind of radiation, that is, X-rays, γ-rays and neutrons, and found that (1) the principal absorption bands in the region from about 200 mμ to 2.6 μ are A-, B- and C-bands, so named by Mitchell and Paige, while the remaining bands are not important, and result from particular chemical impurities; and (2) except for the C-band, little discrepancy is found between the results obtained by irradiation with different sources. The disagreement of data mentioned above can be the result of differences in the conditions of irradiation and of measurement, and this has been partly proved by the present experiment: Firstly, the A-band of irradiated crystalline quartz shows anisotropy which caused peak deviation when measured from absorption with unpolarized light. It should be noted that there is a difference between the spectral polarizability curves of the A-band induced by γ-rays and those induced by neutrons. Secondly, there was found the most interesting fact that the C-band of irradiated fused silica moves from around 200 mμ to 215 mμ with increase of absorption coefficient after subsequent irradiation, and this displacement is reversed by annealing: This effect spread the peak of the C-band within a range whose upper limit varied from 200 mμ to 215 mμ depending on the exposure dose. The absorption bands are nearly stable and scarcely fade even at room temperature with the return of the C-band to shorter wavelength.

The experiments on optical bleaching with a 2536Å light revealed discrepancies between the bleaching behavior of A-, B- and C-bands. A- and B-band behavior appears to be attributable to defects existing in the crystal lattice of quartz or in the network of the fused silica existing before irradiation, while on the other hand the effect on the C-band appears to be essentially due to radiation, as affected by radiation-induced defects. The E-band observed by Mitchell and Paige in the vacuum ultraviolet region is considered very probably to be a complementary of the C-band to be the result of electron-trapping by an anion vacancy or corresponding broken bond in the fused silica network, similarly to the case of the *F*-center in alkali halides. This model of the absorption center is more apt to explain the C-band behavior.

§ 2. Irradiations and Measurements

The specimens were prepared as thin plates of fused silica and crystalline quartz with planparallel optically polished surfaces on both faces. The crystalline plates were cut from a natural Brazilian single crystal of optical grade and from synthetic quartz made at the Yamanashi University, which kindly donated the material to the author. Several kinds of fused silica were used.

The specimens were placed in some instances in the vertical beam hole of the JRR–1 (water boiler type reactor), where fast neutron irradiation of 2×10^{15} n/cm^2 is performed in a day, and in other instances in the 10000 Curie Co^{60} γ-irradiation facility, in a rotating cylinder 3 cm from the source.

The measurements of optical absorption, from 186 mμ to 2.6 μ, were made with a Cary spectrophotometer Model 14.

All irradiations and measurements were made at the ambient temperature (<50°C) since it was believed by many authors that radiation-induced absorption in this material was very stable at the room temperature.

§ 3. Radiation-Induced Absorption Bands

The absorption bands were induced by radiation in the vicinity of the following wavelengths:

Table I (in mμ)

Crystalline quartz	A$_1$(600)	A$_2$(⊥ to c-axis 440 ∥ to c-axis 380)		C(215)
Fused silica	A (540)	B$_1$(300)	B$_2$(240)	C(215)

where the designation of the absorption bands A, B and C corresponds to that of Mitchell and Paige. The above results represent the mean positions determined by averaging the values obtained from many measurements. The A$_1$–, A$_2$–, and A–bands spread over a wide range, since these bands are very broad; the A$_2$–band in particular had an anisotropy resulting in a broadening into the absorption spectrum when measured with unpolarized light, and which caused the peak position to spread over a rather wide ranges.

Absorption bands induced by radiations of different kinds generally have a bell-shaped appearance of very similar form and position. It is not wise, however, to conclude from appearances that the absorption center is analogous to the typical color center in alkali halides. Some specimens cut from natural crystal showed a striped pattern which appeared to have some relation to crystal growth, while some fused silica showed colored speckles after irradiation. Both examples indicate that the visible coloring has close connection with chemical impurities. Spectroscopic analysis indicated that all the specimens contained more or less Al and Mg, while the natural and synthetic crystal contained Cu and Fe respectively. The relation between chemical impurities and radiation-induced absorption bands is however not clear.

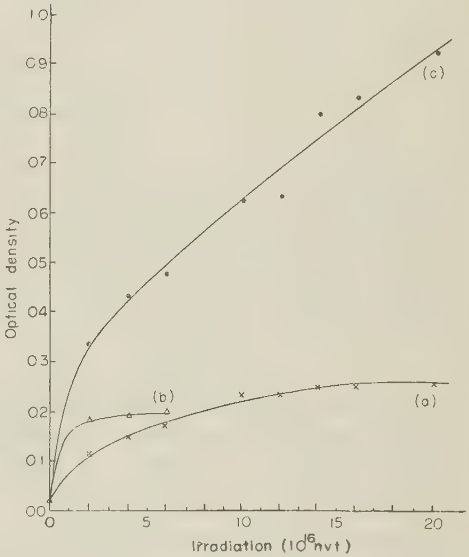

Fig. 1. Growth of optical absorption bands in fused silica of 3 mm thickness upon successive irradiations.
(a) A-band (b) B$_1$-band (C) C-band

The increase of absorption in the 2 mm thick plates of fused silica and crystalline quartz after successive irradiation in the reactor is shown in Figs. 1 and 2 respectively. The letters X, Y and Z in Fig. 2 indicate the directions of cut of the quartz plate. The B$_1$–band saturates first followed by that in the A–band, but the C–band continues to increase almost linearly after the change of growth rate. The difference in the characteristic forms of A–, B– and C–bands are clearly discernible. Further details of each band are as follows.

1) A-band. Ditchburn et al[2] have concluded that the A$_1$– and A$_2$–bands were caused by a hole trapped in the Al^{3+}-ion substituted for the Si^{4+}-ion in the crystal lattice with the optical and e.s.r. methods. Cohen and Smith[3] have also reported the anisotropy of the A$_1$–

and A_2–bands. This is confirmed by the present author with the neutron- and γ-irradiated specimens. The A_2–band measured with light polarized in a plane perpendicular to the *c*-axis forms a fine bell shape in contrast to the flat curve with ambiguous maximum point when measured with light polarized in the plane parallel to the *c*-axis.

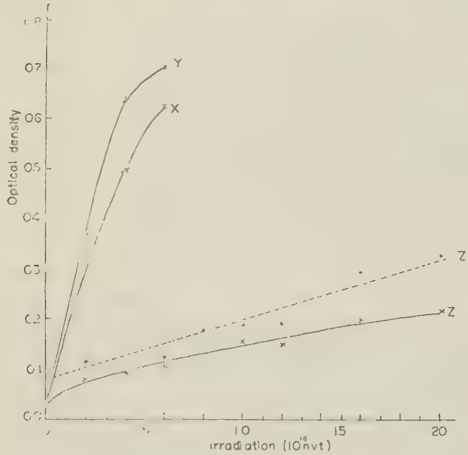

Fig. 2. Growth of optical absorption bands in crystalline quartz of 2 mm thickness upon successive irradiations. X, Y and Z indicate cut direction of crystal.

On the whole, scattering of the A–band position in crystalline quartz is due to the above-described dichroism, and Ditchburn's model of the A–center agrees with respect to the chemical impurity Al found in the present specimens and the saturation tendency of the A–band growth curve.

(2) B–band. This band is observed solely in irradiated fused silica. The B_1–band appears at rather low irradiation levels and rises to a maximum, after which the effect of bleaching by radiation makes itself felt. This behavior is shown in Fig. 3. The second increase after 5×10^{16} nvt represents masking by another absorption band. The present experiment has yielded little data about the B_1–band. Many authors have thought the B_2–band to be the result of various chemical impurities, but disagreement between the authors on the impurities suggested to be the cause would appear to indicate that the B_2–band is not due to any particular impurity other than the simple excess of Si or O. Yokota[4] found the B_2–band in a specimen prepared in a reducing environment and he concluded that it was due to interstitial Si or SiO. The data of Arnold and Compton[5] appear to support the idea of excess Si. They observed a 257 mμ band in an OH^--free specimen irradiated with electrons at 77°K, but did not discern this band in the OH^--bearing specimen under similar treatment. It can thus be inferred that OH^--ions fill the excess bonds of Si or SiO in the SiO_2 network, which correspond to the cation interstitial or to the anion vacancy in the ionic crystal if the 257 mμ band and the B_2–band are one and the same. The B–band is probably due to defects in fused silica network, broken bonds etc.

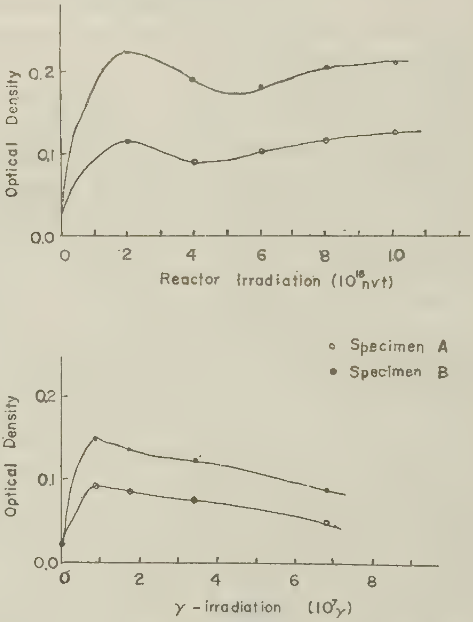

Fig. 3. Radiation bleaching effect on B_1–band.

(3) C–band. Nelson and Crawford[6] have reported that the C–band appeared in crystalline quartz only after a heavy neutron irradiation that could produce local disordered regions in the crystal, and they have suggested the C–center to be the resulting broken bonds or local strains with trapped electrons or holes.

In the present experiment, a prominent C–band was observed in every irradiated specimen of fused silica, as well as in some of the neutron-irradiated crystalline quartz, including the synthetic quartz in which the optical density of the A–band was very low, after irradiation with fast neutrons of an integrated flux of 8×10^{16} nvt.

The C-bank in fused silica has the remarkable behavior of moving towards the longer wavelengths with increasing exposure. This is shown in Fig. 4 in which the abscissa represents the exposure to γ-rays in log scale while the ordinate represents the wavelengths of the C-band maxima. The peak maximum moves from below 200 mμ to 215 mμ and it does not appear to move further. While Nelson and Crawford consider the C-center to be analogous to a center like the F-center in the alkali halides, the author judges that the behavior can be better explained if it is represented as the formation with radiation of an F′-band or a colloidal band at 215 mμ.

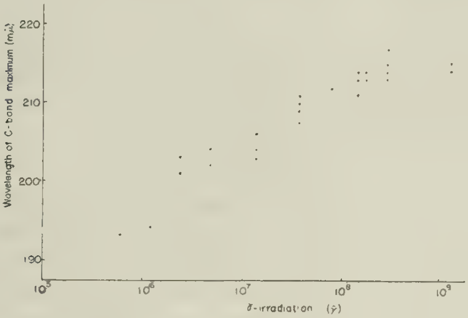

Fig. 4. Movement of C-band towards longer wavelength with increasing irradiation.

The C-band is positively due to radiation and not to chemical impurities because the absorption band is observed even with the most purified fused silica (Corning 7940 and 7943).

It might be said that the irradiation dose of 10^{17} nvt was too low to produce the C-band in the crystalline quartz, assuming the crystal to be perfect and the disorder to be the result only of radiation. Actually however, an as-grown crystal is never absolutely free of local disordered regions, and it may therefore be considered quite natural to find the C-band even after such slight irradiation.

§4. Optical Bleaching

The bleaching experiment was made with 2536 Å light from a high pressure mercury lamp with glass filter by Toshiba (UV-D 25). The absorption spectrum bleaches evenly under exposure to 2536 Å light as is shown in Fig. 5. The bleaching rate of each band is shown in Fig. 6. The B_1-band, unsubjected to radiation bleaching, rapidly bleaches, followed by the A-band. The A-band does not bleach with visible A-light, evidencing that the A-band is not due to an absorption center such as the F-center. The C-band is fairly stable but is bleached by C-light, and the peak moves back towards the shorter wavelength during bleaching. The bleaching is the reverse of that of ionizing radiation. The electrons must be released from the C-center by exposure to light and should recombine with the holes released from the A-center (or E-center).

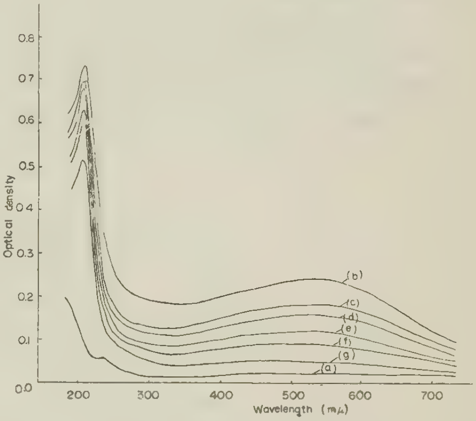

Fig. 5. Optical bleaching of γ-irradiated fused silica under illumination of 2536 A light.

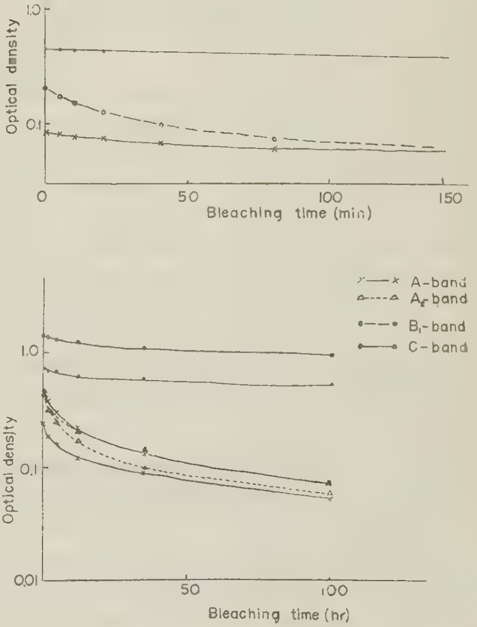

Fig. 6. Optical bleaching behavior of each absorption band in irradiated crystallide quartz and fused silica.

It is an interesting fact that the electron trapping cross section of the absorption center increased after bleaching, as is seen in Figs. 7 and 8. These figures respectively show the absorption behavior of a neutron-irradiated crystalline quartz and a γ-irradiated fused silica after bleaching and re-irradiation. After bleaching, much lighter irradiation than that previously received by specimen before bleaching is enough to restore the absorption to the previous value. In other words, the amount of absorption bleached by the light is recovered by slight radiation.

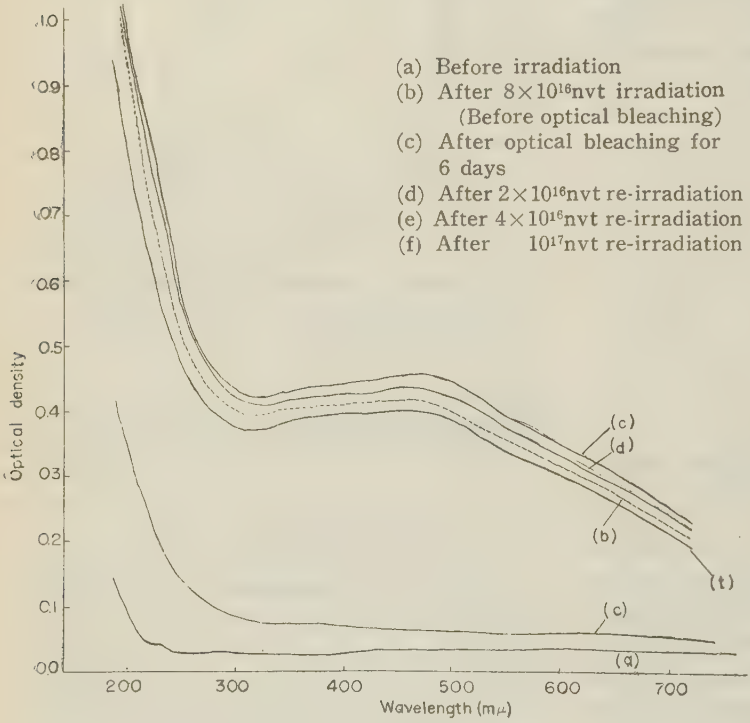

Fig. 7. Effect of optical bleaching on restoring of optical absorption in crystalline quartz upon re-irradiation.

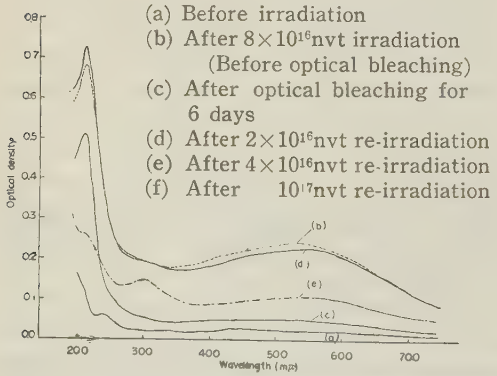

Fig. 8. Effect of optical bleaching on restoring of optical absorption in fused silica upon re-irradiation.

§ 5. Summary

The absorption spectrum of crystalline quartz and fused silica irradiated in reactor or with γ-rays was measured from 186 mμ to 2.6 μ.

The behavior of the absorption band during irradiation and during optical bleaching was investigated. Dichroism of the A–band in the crystalline quartz reported by Cohen and Smith was confirmed, and radiation bleaching of the B_1–band was found. These occurrences are clearly the cause of displacement of the absorption peak, and result in the disagreement found between the data reported hitherto.

The experimental results would lead us to conclude that the A–band and B–band are not important, and that it is the C–band that is essential from the point of view of radiation effect. The C–band is the result of a center like the F–center changing to F′–center or colloidal center with subsequent radiation. This explanation however does not for the moment represent more than a supposition. More effective measurements are required before conclusive confirmation can be offered.

The author wishes to express her gratitude to the JRR–1 Operations Section and Co⁶⁰ Irradiation Laboratory for their help in the irradiating work. Appreciation is also due to Mr. S. Taki of the Yamanashi University for his generous offer of the synthetic quartz crystal prepared by him.

Propagation of Ultrasonics in Triethylamine-water Mixture

By Seiken Shimakawa

Department of Precision Mechanics Eng., Faculty of Eng., University of Tokyo

(Received April 5, 1960)

Velocity and attenuation of ultrasonic waves in a binary mixture of Triethylamine-water were measured at different temperatures by using a pulse method at 1.5 and 2.5 Mc/s.

Assuming a Gaussian distribution of relaxation times centering on the main relaxation frequency, calculation showed that this main·frequency lies in a range of approximately 1 to 6 Mc/s and diminishes with increasing liquid temperature below the critical solution point. Tne prominent change of sound attenuation near the critical solution temperature depends mainly on the main relaxation frequency which varies with the liquid temperature.

§1. Introduction

The object of this work was to study the propagation of ultrasonic pulses in a mixture of triethylamine and water at different temperatures.

§2. Experimental Apparatus

The apparatus used in this work was similar to that which Brown⁽¹⁾ used for the measurement of ultrasonic propagation in an aniline-cyclohexane system in this laboratory.

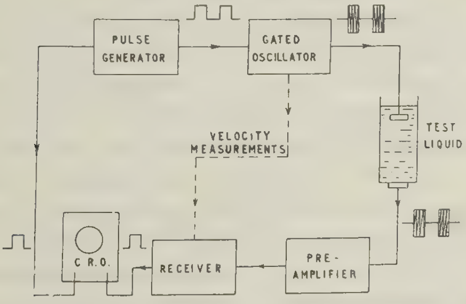

Fig. 1. Block diagram of the apparatus.

A block diagram of the mechanical and electrical apparatus is given in Fig. 1. The pulse generator gives 250 volt pulses of any width from 10 to 200 microseconds. In the present experiment an electrical pulse of some 40 microseconds was applied to the gating valve of the gated oscillator and switched on the oscillator at a repetition frequency of 200 per second. The resulting signal gave rise to a series of short pulses of R.F. voltage, which were amplified and fed to a piezoelectric transducer. The generated sound travelled through a liquid, triethylamine-water system, and was picked up by the second transducer, the receiver. The electrical pulses of R.F. oscillation, having an amplitude proportional to that of the incident sound, were amplified and detected, and the resulting signal was exhibited on a cathode-ray oscillograph, the time base of which was triggered by the pulse generator.

The transmitting crystal parallel to the receiving crystal was carried on a movable piston. As the distance between the crystals was increased, the attenuation due to the passage of the sound through the liquid became larger and the displayed signal decreased in amplitude. The amplitude absorption coefficient α' (db/cm) or α (neper/cm) can be obtained from the following relations,

---

* Present address: Dept. of Physics, King's College, University of Durham, Newcastle upon Tyne, England.

$$\alpha' = 20 \log_{10} \frac{A_0}{A} \Big/ x = 8{\cdot}686\alpha$$

where A_0 and A are the amplitudes of the received signal when the separation of the transmitting and received crystals are d and $d+x$ cms. respectively.

A cross-sectional view of the mechanical apparatus is given in Fig. 2. The receiving crystal was fixed and held in the upper crystal holder attached to the piston. This piston could be moved up and down by a micrometer screw of 20 threads per inch, and was prevented from rotating by three steel guiderods sliding in bushes in the upper plate, which carried a revolution counter and index mark for the micrometer head. The vessel containing the experimental liquid was of glass, 2″ in diameter and some 6½″ long.

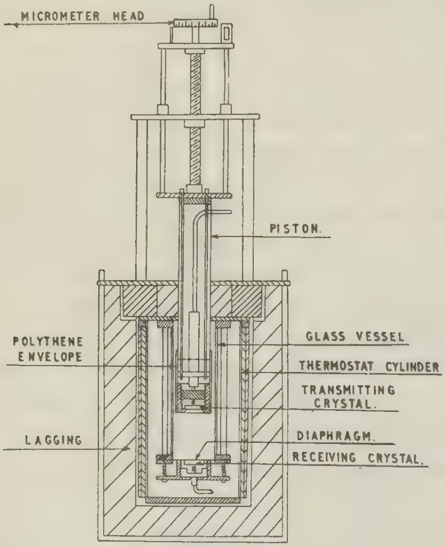

Fig 2. Cross-sectional view of the mechanical apparatus.

The transducers were conventional X-cut quartz of 1″ diameter and fundamental frequency 500 kc/s. A pair of these crystals was employed for work at 1.5 and 2.5 Mc/s., working at their 3rd and 5th harmonics respectively. One face of each crystal was exposed to air so that more energy could be radiated into the liquid from the transmitting crystal and that a larger amplitude of signal could be received by the receiving crystal. Both faces of the crystals were silver-plated. A thin aluminium foil was inserted between the near face of each transducer and a wire spring connected to the coaxial lead. This was to prevent the plating of the crystals from coming off which may have caused poor electrical contact.

Special care was taken to align the crystals parallel to one another so that unnecessary errors were not introduced into the results. As it was observed that the triethylamine-water mixture quickly attacked brass and aluminium, the bottom of the vessel which contained the experimental liquid was closed by a 0.005″ thick "Fluon" diaphram against which the lower crystal, the receiver, was pressed, acoustic contact being secured by a film of castor oil. A polythene envelope was used to insulate the upper crystal, the transmitter, in order to avoid any trouble caused by an electric current which could flow as a result of the electrolytic property of the triethylamine-water system.

In order to keep the liquid temperature below room temperature, say to about 5°C, double cylinders made of brass having 1.5 cm. clearance surrounded by felt lagging and glass wool in a wooden box were used. The glass vessel containing the test liquid was inserted inside the inner cylinder, a mixture of ice and calcium chloride being packed into the clearance between the cylinders. A thermostatically controlled heating coil was used to keep the test liquid above room temperature. A brass cylinder 8″ long and 4″ in diameter was used to enclose the glass vessel containing the test liquid. A pair of temperature control coils, one of copper and the other of constantan, were wound on the outside of the cylinder and formed two arms of a Wheatstone bridge circuit. Since the temperature coefficient of resistance of copper is 43×10^{-4} per degree C. whilst that of constantan is some 100 times smaller, the bridge is balanced at a certain temperature, the value of which is decided by the setting of the balance arms. The heating coil was wound on the outside of the control coils and connected to a relay mechanism. The relay was operated by the amplified voltage from the Wheatstone bridge circuit when the latter was out of balance. The temperature was kept constant to within 0.01°C between 20°C and 30°C. To measure the liquid temperature a copper constantan thermocouple was immersed in the liquid in the experimental vessel, the cold junction being maintained at 0°C in melting ice. The current flowing in the circuit was indicated by a Tinsley galvanometer with lamp and scale, and the temperature could be read significantly to 0.01°C. To enable the thermal equilibrium to be attained quickly, a manual stirrer formed of a loop of nichrome wire was also contained in the liquid vessel. A series of velocity and attenuation readings could be taken, the temperature remaining sufficiently steady during the short time required—perhaps 5 minutes.

In the measurement of velocity, the continuous electrical oscillation was fed directly into the receiving system. As the acoustic path changed, the phase difference between the received pulse, which had passed through the liquid, and the original oscillation varied. This was exhibited on an oscilloscope as the fluctuation of the received pulse every wavelength. In this experiment, the micrometer reading was taken every five or ten fluctuations. The velocity was then calculated from this wavelength and the frequency measured using a wave-meter.

The triethylamine-water system was used in the present work, because the sound absorption near the critical solution temperature is extremely large and also this temperature is close to room temperature, enabling the experiment to be carried out easily and with good accuracy. Commercially pure triethylamine and distilled water were used. When a series of experiments was finished, the triethylamine and water used were replaced by a new sample and the two crystals were carefully aligned before starting the next work. The test liquid was composed of 33.5 c.c. of triethylamine and 74.5 c.c. of water, i.e., 25% by weight of amine.

§ 3. Experimental Results

Previous experiments showed that the critical solution temperature for the triethylamine-water system occurred at 17.9°C(2) for a 44.6% mixture by weight of amine and 19.5°C(3) for a 34% mixture respectively. In the present test this temperature was 18.2°C for a mixture 25% by weight of amine. The measurements of velocity and absorption as a function of temperature for the above concentration at frequencies of 1.5 Mc/s. and 2.5 Mc/s. are given in Figs. 3 6.

The measurements of both absorption and velocity were first made while the temperature decreased from room temperature down

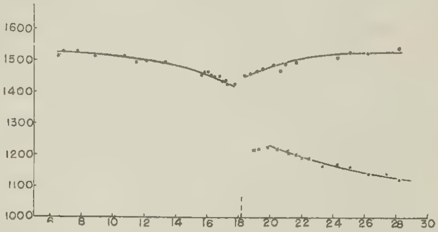

Fig. 3. Velocity vs temperature in Triethylamine-water system at 1.5 Mc/s.

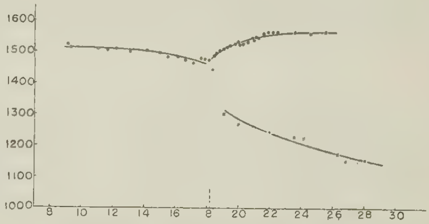

Fig. 4 Velocity vs temperature in Triethylamine-water system at 2.5 Mc/s.

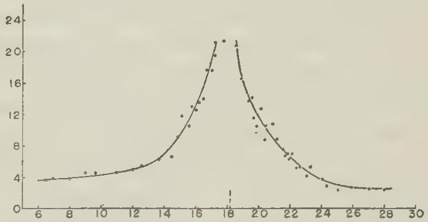

Fig. 5. Absorption vs temperature in Triethylamine-water system at 1.5 Mc/s.

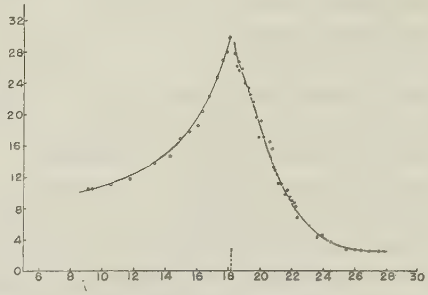

Fig. 6. Absorption vs temperature in Triethylamine-water system at 2.5 Mc/s.

to about 5°C and then the same measurements were carried out while the temperature increased. No effects of hysteresis were observed between these two series of measurements within the accuracy of experiment. The measurements in the temperature range from room temperature (about 20°C) up to about 28°C were made only as the temperature increased. The same measurements were checked three or four times keeping the temperature constant within the accuracy of ±0.05°C and the mean values of the absorption and velocity were plotted against the temperature.

For the "triethylamine-rich" layer, the received signal slightly above the critical temperature was so small because much of the sound energy was absorbed during the transmission through the "water-rich" layer that the measurement of absorption in it was made difficult, especially at 2.5 Mc/s.

§ 4. Discussion

The thermodynamic behaviour of triethylamine-water systems has been investigated by earlier workers[4) 5)], and it was noticed that the system has a minimum critical temperature of 18.4°C. By the Schlieren method used in the present work, it was observed that the liquid was not homogeneous especially above 13°C, and the density fluctuation of part of the liquid was evident. This phenomenon was very clear near the critical temperature and large clusters of greater density were observed to precipitate in various string-like shapes. Figs. 5 and 6 show the curves of absorption in db/cm. plotted against the temperature. These results give similar values of the velocity and absorption to those of previous workers[2) 3) 6)] and it is evident that the sound absorption increases rapidly with increasing temperature below the critical solution temperature.

In order to make clear the actual mechanism of absorption in binary liquid systems, some calculations have been done in terms of clusters associated with two components.

It can be assumed that the molecules of the two components combine to form clusters of various sizes and of various compositions in the critical region and they are in equilibrium giving rise to inhomogeneous density in the system. Lucas[7)] developed Stokes' theory of viscosity loss due to the inhomogeneity of the liquid, and then Sette calculated its value with certain assumptions. According to his estimate, it is found that the viscosity absorption as a consequence of heterogeneity of the liquid in the critical region can have a certain importance at low frequencies, but is far too small to explain the observed absorption, at least at frequencies higher than a few megacycles.

The scattering loss α_{sc} due to the inhomogeneity of density in the liquid can be calculated from the difference between the compressibilities of the clusters and the mother phase. An approximate calculation indicated that α_{sc}/f^2 should increase in proportion to f^2. The experiments, however, show α_{sc}/f^2 decreasing with the increasing of frequency and hence a large absorption due to scattering appears improbable. Therefore, it is most plausible to ascribe the anomalous high absorption to the relaxation phenomena predicted by earlier workers.

In a relaxation phenomenon occurring with only two equilibrium states, the amplitude absorption coefficient α is given by the following expression,[8)]

$$\alpha = Af^2 \frac{1}{1+(f/f_m)^2}\ , \tag{1}$$

where f and f_m are the frequencies of the ultrasonic waves and the relaxation phenomenon respectively. A is a parameter which depends on the temperature of the liquid but does not change with the ultrasonic frequency. Equation (1) can be written as follows,

$$\frac{\alpha}{f^2} = -\frac{1}{f_m^{\,2}}\alpha + A \tag{2}$$

which shows that the relationship between α/f^2 and α should give a straight line of slope $-1/f_m^2$. f_m can be estimated by this method. Sette estimated that the relaxation frequency in the triethylamine-water system lies in the range 2.5 to 30 Mc/s. at 15°C by this method.

Table I gives the relaxation frequencies calculated from curves in Figs. 5 and 6. These values are shown in Fig. 7 in relation to the liquid temperature. From this, although only two ultrasonic frequencies were used in the present work, the relaxation frequency in triethylamine-water was found to lie in the range 1 to 6 Mc/s. The relaxation frequency decreases with increasing liquid temperature

Table I.
Relaxation frequencies in triethylamine-water system.
(25% by weight of amine)

Temperature °C	$\alpha/f^2 \times 10^{14}$ (cm^{-1}sec^2) at 1.5 Mc/s.	$\alpha/f^2 \times 10^{14}$ (cm^{-1}sec^2) at 2.5 Mc/s.	f_m(Mc/s)

16	67.5	35.7	1.5
17	96.9	42.7	0.95

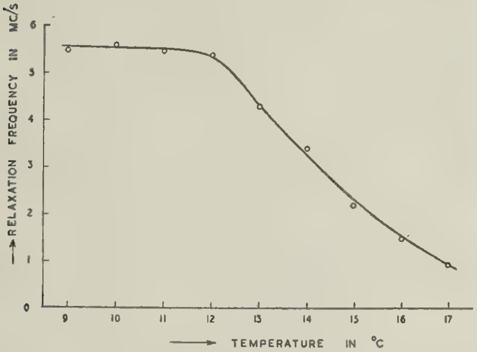

Fig. 7. The variation of the relaxation frequency with temperature in the Triethylamine-water system.

below the critical solution temperature.

The above result was obtained using the assumption that a single relaxation frequency exists for the liquid. In the present experiment, however, the relaxation phenomenon is unlikely to occur with a single relaxation time because of the existence of various associations of the components, or of clusters of various sizes and compositions. It may be that clusters of many different sizes co-exist and therefore the relaxation times are assumed to be distributed about the main relaxation time. In these mixtures, the total absorption by relaxation phenomena is given by summing up the absorptions over all relaxation frequencies. When the distribution band of relaxation times is narrow, a simple calculation assuming a Gaussian distribution of relaxation times shows that the value of α/f^2 is given by the same equation as equation (1) which involves only one single relaxation time. It may be considered that the distribution of relaxation times will change with changing liquid temperature and that the large absorption observed near the critical solution temperature depends mainly on the main relaxation frequency which depends on the liquid temperature.

The author wishes to thank the British Council for the award of a scholarship enabling him to carry out this research and Professor E. G. Richardson for suggesting the problem.

Paramagnetic Resonance Study in Some Copper Salts

By Hidetaro Abe and Hiroko Shirai
The Institute for Solid State Physics,
University of Tokyo,
Azabu, Minato-ku, Tokyo, Japan

(Received November 5, 1960)

As the continuation of the work on copper propionate monohydrate[1)], single crystals of copper-*n*-butyrate monohydrate, copper monochloroacetate monohydrate, and copper trichloroacetate monohydrate are examined by the method of electron paramagnetic resonance (EPR), at about 24 Gc/sec. and at room temperature.

It was checked by the chemical analysis of Cu and H_2O that these crystals have formulas $Cu(CH_3CH_2CH_2COO)_2 \cdot H_2O$, $Cu(CH_2ClCOO)_2 \cdot H_2O$, and $Cu(CCl_3COO)_2 \cdot H_2O$, respectively.

(a) *Copper-n-butyrate monohydrate*

This crystal grows in the monoclinic system and in a colour of dark green. The unit-cell dimensions were determined by Iball[2)] as $a=25.12\,kx$, $b=14.65\,kx$, $c=26.79\,kx$ and $\beta=109.7°$. Different crystals used for our investigation gave the same results within the experimental errors.

The EPR showed that there exist seven independent magnetic units in this crystal. Spectrum of each unit is described by a spin-Hamiltonian

$$\mathscr{H}=\tilde{g}\beta\vec{H}\vec{S}+D\{S_z^2-\tfrac{1}{3}S(S+1)\} \qquad (1)$$

with the effective spin $S=1$. The parameters for the seven units are almost the same and given by $g_{\parallel}=2.40$, $g_{\perp}=2.04\sim2.10$, and $D=0.34\,\mathrm{cm}^{-1}$. From this result of $S=1$, it is deduced that the magnetic unit in this crystal consists of a pair of Cu^{++} ions, namely of two formula units described as $Cu_2(CH_3CH_2CH_2COO)_4 \cdot 2H_2O$. Such constitution has been first discovered in copper acetate monohydrate[3)]. Afterwards, it was deduced in copper propionate monohydrate[1)]. It was found that one of the seven units has its principal axis within the *ac*-plane and other six units reduce to three independent units having three units in their mirror positions with the *ac*-plane. Therefore, it was concluded, so far as the EPR spectra are concerned, there exist 16 independent Cu^{++} ions per unit cell. On the other hand, Iball concluded from his data of unit-cell dimensions that the unit cell contains 32 formula units. These two results, however, are not contradictory, when it is taken into account that the crystallographically independent ions are not necessarily independent in magnetic behaviours. Similar situation occurs in copper acetate whose unit cell was determined by x-ray analysis to contain eight ions, while it was shown by EPR that only four of them are independent in magnetic behaviours.

(b) *Copper monochloroacetate monohydrate*

This crystal grows in shape of monoclinic system, though some possibilities of twinning are remained. Its colour is dark green. The examined crystals seem to have two independent Cu^{++} pairs, with other two in the mirror positions with the *ac*-plane. The EPR spectra are well explained by Eq. (1) with $g_{\parallel}=2.38$, $g_{\perp}=2.13$, and $D=0.35_0\,\mathrm{cm}^{-1}$.

(c) *Copper trichloroacetate monohydrate*

This crystal also grows in the monoclinic system and in a colour of light blue, as that of the copper sulfate pentahydrate. The dimensions of unit cell are $a=22.5\,\text{Å}$, $b=6.21\,\text{Å}$, $c=9.8\,\text{Å}$ and $\beta=90°\pm1°$ (C_s^4 or C_{2h}^6). The EPR spectrum shows only one resonance line at every direction of static magnetic field, which is well described by

$$\mathscr{H}=\tilde{g}\beta\vec{H}\vec{S} \qquad (2)$$

with $S=\frac{1}{2}$ and $g(2.44_1,\ 2.10$ and $2.05)$. The direction giving the maximum g-value coincides with the b-axis. The half width of the resonance line is about 60 oer. independently of direction. From the results of the paramagnetic resonance, it is deduced, in this crystal, that one copper ion has no other copper ions in its nearest neighbours but only diamagnetic ions such as O^{--} or Cl^-, as in the ordinary copper salts.

More detailed reports will appear in this Journal. We wish to thank Drs. H. Iwasaki and S. Tamura for the x-ray and chemical analysis.

Magnetic and Crystallographical Properties of Hexagonal Barium Mono-Ferrite, $BaO \cdot Fe_2O_3$

By Chisato OKAZAKI, Saburo MORI and
Research Department, Wireless Division,
Matsushita Electric Industrial Co.,
Ltd. Osaka, Japan
Fumikazu KANAMARU
Institute of Scientific and Industrial
Research, Osaka University

(Received October 10, 1960)

Among the mixed oxides belonging to the barium-iron oxide system, it was found that one new stable compound appeared as a single phase having the chemical composition of $BaO \cdot Fe_2O_3$, which had already been suggested in our previous report1). Here, we should like to report on the preliminary investigation on its magnetic and crystallographic properties.

Magnetic measurements of this compound were carried out using an automatic recording magnetic balance. The paramagnetic susceptibility of this crystal at room temperature was

$$\chi_{RT} = 7.6 \times 10^{-6} \text{ e.m.u./gr} .$$

where an aqueous solution of $NiCl_2$ was used as a reference. The results obtained from thermomagnetic measurements are shown in Fig. 1. In the high temperature range, the $1/\chi$-T curve is well described by the Curie-Weiss law, $\chi = C/(T+\theta)$, where $C = 3.75 \times 10^{-3}$ emu/gr-deg., $\theta = 200°$K. It may be concluded that this compound, $BaO \cdot Fe_2O_3$, is anti-ferromagnetic. To confirm it more definitely, it is desirable to consider the arrangement of the magnetic ions in this crystal.

It is reported that this compound may have a tetragonal lattice1),2) by means of the indexing for its Debye-Scherrer patterns: the lattice constants calculated are $a \sim 6.0$Å, $c \sim 9.4$Å. If each unit cell contains four chemical formula units, the calculated density of this crystal may be about 6.0 $\text{gr} \cdot \text{cm}^{-3}$. On the other hand, the measured density was estimated as 4.70 $\text{gr} \cdot \text{cm}^{-3}$. This disagreement is so large that, it is impossible to give a reasonable explanation. Therefore, more precise study is needed.

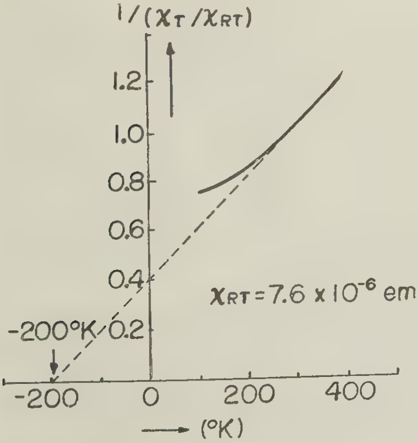

Fig. 1. Curve of inverse susceptibility versus temperature for $BaO \cdot Fe_2O_3$.

Fortunately, this compound has a rather low melting point (about 1450°C)2). So, we were able to prepare a small flake of single crystal by slow cooling from the molten phase. Laue photographs of this crystal did not show tetragonal symmetry but showed hexagonal holo-hedral symmetry, D_{6h}. Oscillation photographs and powder patterns were prepared using Fe-$K\alpha$ and Co-$K\alpha$ radiations. They indicated for the hexagonal sub-unit cell dimensions of this crystal,

$$a = 5.51\text{Å}(\times n) , \quad c = 8.44\text{Å} ,$$

where n is an integer and may be 2 in the real lattice. There are 2 formula units in each sub-unit. The calculated density is 4.78 $\text{gr} \cdot \text{cm}^{-3}$. If it is assumed that both barium and oxygen ions occupy the special positions in the lattice, the possible space group of this sub-unit cell is considered to be $D_{6h}^4 - P6_3/mmc$.

If the lattice has a usual hexagonal close-packed skeleton with respect to large barium and oxygen ions, the lattice dimension along the a axis must be about 5.88Å3), therefore, this crystal, $BaO \cdot Fe_2O_3$, may have a non close-packed Ba−O skeleton system and may be of a new type. It may be considered that this crystal has a modified type of $KFe_{11}O_{17}$ which is known already as a anti-ferromagnetic substance4), with respect to the ionic packing and magnetic coupling.

In order to confirm the above speculative consideration, further systematic investigations on the crystal structure are now in progress and the results will be published later.

Electron Linear Accelerator as a Source of Intense Secondary Particle Beams

By Kazuto OKAMOTO*

Department of Physics, Tohoku University, Sendai

(Received October 10, 1960)

An electron linear accelerator produces a very intense electron beam. If this electron beam is used to produce secondary particles, their intensities are expected to be very high. In this note we investigate the efficiency of π meson production. We assume $E_0=760$ MeV, $I_e=100\mu A$ (average).

The electron beam must be converted into γ rays. Therefore knowledge of the thickness dependence of the γ yield is necessary. Energy loss of electrons passing through the target can be calculated by Heitler's straggling theory[1]. One can then calculate the numbers of photons at varions thicknesses using Schiff's bermsstrahlung spectrum multiplied by the photon decay factor. The results for Pt are that the maximum appears at around 1.5 mm. Hence we assume this thickness.

Production of π mesons is calculated as follows. The yield produced in the π converter of thickness dx due to a certain energy interval of bremsstrahlung, $d\phi/dk$, is denoted as dY/dk. Then

$$dY/dk=N(d\phi/dk)\sigma dx\ , \qquad (1)$$

were N is the number of atoms per cm³ and σ is a (γ, π) cross section.

Assuming $\phi=\phi_0(k)\exp(-x/X)$ and intergrating eq. (1) we obtain

$$\begin{aligned} Y&=N\int_0^l \exp(-x/X)\,dx \int_{140}^{760} \frac{d\phi_0(k)}{dk}\,\sigma dk \\ &\simeq NX[1-\exp(-l/X)]\sum_{k=140}^{760} \frac{\Delta\phi_0(k)}{\Delta k}\,\sigma\Delta k\ . \qquad (2) \end{aligned}$$

In the last equation we replaced the integral by the sum for convenience of numerical calculation. Eq. (2) can easily be evaluated if one uses the table of bremsstrahlung spectrum[2]. We assume that a π converter is Be of thickness 2 cm. Assuming also that $\sigma(\gamma, \pi)$ for Be is about 2.5 times that for H and that $\pi^-/\pi^+=1.5$, and inserting necessary values, we get

$$Y(\pi^+)=2\sim3\times10^{10}\pi^+/\text{sec}\ , \qquad (3)$$

$$Y(\pi^-)=3\sim5\times10^{10}\pi^-/\text{sec}\ . \qquad (3')$$

If these mesons are analysed by a magnetic analyser which has a solid angle of 0.1%, we get differential π yields at the target for experiment.

$$6\times10^5\pi^+/\text{sec} \qquad (4)$$

$$1\times10^6\pi^-/\text{sec} \qquad (T_\pi=80\pm3\ \text{MeV})\ , \qquad (4')$$

They agree fairly well with the experimental data[3]. If the area of the target is several tens of cm², these values correspond to about $\gtrsim10^4$ mesons/sec/cm², which is an order of magnitude higher than the present meson beams from synchrocyclotrons.

If microwave of about 1300 MC is used for the electron linear accelerator, the average beam intensity could be increased up to 500μA$\sim$1 mA. Such an electron linear accelerator would produce π meson beams which are two orders of magnitude stronger than the strongest π meson beams at present.

Very recently the Stanford group carried out similar calculations for an electron linear accelerator of 25 Bev, 60μA[4],[5],[6]. Their conclusions are also that the linac can produce substantially high yields of π, K, μ and $\bar{p}$. Although the energies are quite different, that the two independent calculations agree very well shows that an electron linear accelerator will be a powerful machine for producing very intense beams of secondary particles.

The background of the beams thus obtained is probably not large at large angles, so that for slow pions it is not serious. For fast pions emitted at forward angles it is serious, but can be eliminated by an RF mass separator. It shoud be pointed out here that a beam from a linac is sharply bunched into small groups, which greatly facilitates mass separation[7] or time of flight technique[8].

The author expresses his gratitude to Prof. M. Kimura for his hospitality during his stay at Tohoku University. He is also indebted to Dr. Kitagaki and Dr. Torizuka for valuable discussions. He is especially grateful to Prof. W. K. H. Panofsky of Stanford University for kindness in sending him the results of recent calculations of Stanford. Finally he would like to thank the Japan Society for the Promotion of Science for the financial help.

A-Centers in Potassium Chloride Crystals

By Kazuko KOJIMA and Noriko NISHIMAKI
Osaka Women's University, Osaka

(Received October 24, 1960)

Recently, the *A*-center in alkali halide crystals, which has not been received much attention since the first discovery by Petroff[1], has become an object of active investigation[2,3,4]. We also report here some new experimental results on this center in KCl crystals. Single crystals used for experiments were grown out of reagent grade KCl by Kyropoulos method. Absorption measurements and optical bleaching were carried out with a Hitachi EPU-2 Spectrophotometer. The wavelength of *F*-light used for optical bleaching was chosen to be somewhat shorter than the peak wavelength of the *F*-band (520±5 mμ at −70°C, for example), because the *A*-band overlaps with the long-wavelength side of the *F*-band.

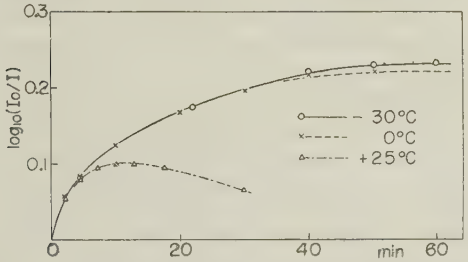

Fig. 1. Temperature dependency of the growth-rate of the *A*-band during irradiation with *F*-light.

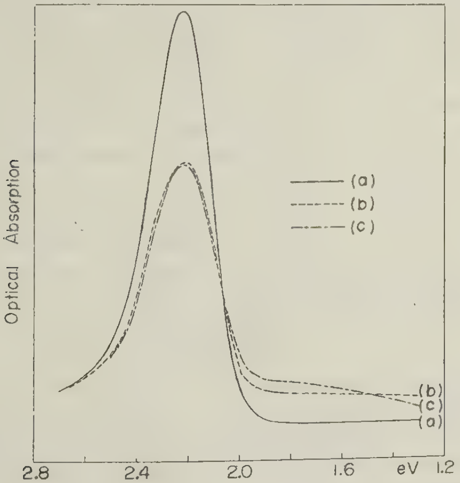

Fig. 2. Formation of the A'-band due to irradiation with *F*-light: (*a*) immediately after additive coloration, (*b*) after 10 min irradiation with λ=520 mμ at −70°C, (*c*) after additional 1.5 hrs irradiation. All measurements were made at −70°C.

Near room temperature, the *A*-band grows fairly rapidly with irradiation in the *F*-band. Its initial rate of growth, however, was almost the same at −30°C, 0°C, and +25°C (Fig. 1), and was about 1/10 as that for the typical $F \to F'$ conversion. This fact may be contrasted with the case of *M*-centers whose growth-rate is very sensitive to temperature[1]. Prolonged irradiation at +25°C causes the rise of the *M*-band and reduces again the *A*-band, while at −30°C the concentration of *A*-centers saturates and no *M*-centers appear at least within a time about three times as long as needed for the saturation of *A*-centers.

Near −70°C, at the beginning of irradiation with *F*-light, *F*-centers go over preferentially to F'-centers because the electron trapping cross section of an *F*-center is presumably larger than that of an *A*-center. Prolonged irradiation, however, seems to yield new centers which are supposed to be A'-centers from the following experiments: When a sample containing only *F*-centers is irradiated with *F*-light about 10 minutes at −70°C, no centers appear other than F'-centers (this can be confirmed by a recovery of the *F*-band upon warming to room temperature) (Fig. 2, curve *b*). However, further irradiation in the *F*-band more than 1.5 hours at −70°C changes the shape of the long-wavelength side of the F'-band as shown in curve *c* of Fig. 2, without any observable change in the peak-height of the *F*-band. The *A*-band appears on warming this sample to room temperature. When a crystal corresponding to curve *c* is irradiated with light in the vicinity of 850 mμ, it seems that the F'-band decreases and another broad band appears which is extensively superposed on the F'-band. We observed also that when a crystal in the state *c* is left in the dark at −70°C, the F'-band decreases gradually (whose half life time is about 1000 seconds at −70°C in accordance with Pick's data[5]), whereas the other centers are relatively stable and do not become unstable until −40°C. In addition, when a sample containing a large amount of *A*-centers is irradiated with *F*-light at −70°C, the F'-band develops only weakly and the new band grows within 5 minutes at the expense of the *A*-band. These experiments suggest that the new center may be an *A*-center captured another surplus electron, which we may term the A'-center. It should also be noted that *A*-centers decrease when the *M*-band is irradiated at room temperature in a sample containing a considerable amount of *M*-centers, and that scarcely no *A*-centers restore when we repeat irradiation in the *F*-band after most of the *M*-centers has been optically destroyed.

Judging from the above experimental facts, we may conclude that the A-center is a center produced by trapping an electron at a certain lattice defect existing originally without involving diffusion of ions, unlike the case of M-centers which is now commonly believed to accompany diffusion of vacancies in their formation. Moreover, if the existence of A'-centers is the truth, the assumptions would become irrelevant such that the A-center may be a paired vacancy carrying an electron[3], or a vacancy near a dislocation which has trapped an electron[6]. Thus it seems more reasonable to assume that a sort of impurities existing from the first in crystals is responsible for the A-centers.

Vibrational Effect on the Nuclear Quadrupole Coupling in ND_3

By Yoshifumi KATO

Osaka Municipal Technical Research Institute, Kita-ku, Osaka, Japan

(Received October 25, 1960)

The nuclear quadrupole coupling constant eQq ($=-4.10$ Mc/sec)[1] at the position of the nitrogen nucleus in ND_3 is nearly equal to the eQq ($=-4.0842$ Mc/sec)[2] in NH_3. When the electric field gradient q at the nitrogen nucleus is evaluated without respect to the effect of nuclear vibrations, field gradients in the two molecules have to take the same value. It may be obvious that the slight difference between the values of eQq is attributed to the effect of nuclear vibrations on the field gradient.

Now, the total field gradient q in ND_3 is divided into two parts, $q=q_n+q_e$, where q_n and q_e respectively mean the contributions to the field gradient from the nuclei and the electrons. However, it may be very difficult to take the effect of nuclear vibrations on q_e into account. Here the vibrational average has been evaluated only for q_n, on the assumption that the electron distribution near the nitrogen nucleus do not vary by small vibrations of the nuclei. In such a case, q_e in ND_3 would be equal to that in NH_3.

In the same way as the previous evaluation of the field gradient in NH_3[3], two approximate averages have been taken for q_n. One is the average over the simple harmonic oscillation by using the following normal coodinates on the symmetric bending mode $\nu_2(a_1)$ ($=749\,\mathrm{cm}^{-1}$),

$$Q_2=0.00402S_1+0.80996S_2\,,$$

where S_1 and S_2 respectively express normalized stretching and bending symmetry coordinates (assuming the anharmonicity factor $\chi=0.0867$, so that the harmonic frequency $\omega=814\,\mathrm{cm}^{-1}$). The other is the average over the inversion doubling by using the results of Manning on ND_3[4], as previously shown in NH_3[3] (assuming $\lambda=-0.26$).

Table I. Calculated values of the nuclear part q_n of the electric field gradient in ND_3 and the nuclear quadrupole moment $Q(N^{14})$.

	(I)*	(II)**
q_n (in au)	$-0.24492e$***	$-0.25173e$
$Q(N^{14})$ (in $10^{-26}\,\mathrm{cm}^2$)	0.941	0.938

* The value averaged over the simple harmonic oscillation.

** The value averaged over the inversion doubling.

*** e is the protonic charge ($=4.8022\times10^{-10}$ esu).

The results obtained are given in Table I. Here, for the value of q_e, the previous estimate by Kaplan's wave function with configuration interactions among 13 states has been used ($=-1.60973e$ au: e is the protonic charge)[3]. As seen in Table I, the value of the nuclear quadrupole moment $Q(N^{14})$ obtained from ND_3 is consistent with that obtained from NH_3 ($=0.94\times10^{-26}\,\mathrm{cm}^2$)[3]. This fact shows that the difference of eQq between ND_3 and NH_3 can be explained sufficiently by the above approximate calculation of the effect of nuclear vibrations. The value of $Q(N^{14})$ obtained above seems also to be supported by the value ($\sim1\times10^{-26}\,\mathrm{cm}^2$) calculated from nuclear shell model under the L-S coupling, while a recent direct experimental value gives $(1.6\pm0.7)\times10^{-26}\,\mathrm{cm}^2$[5].

The author wishes to express his appreciation to Prof. H. Narumi who suggested this problem and made helpful discussions.

Proton Resonance and Spin Quenching Effect in $NiSO_4\cdot 7H_2O$

By Hiroshi NAGASAWA and Yuzo TOMONO
Department of Physics, University of Tokyo

(Received November 18, 1960)

In some paramagnetic salts, all the degeneracies in the spin state of a paramagnetic ion, which has even number of unpaired electrons, are completely lifted by the combined action of spin orbit coupling and crystalline electric field. The static susceptibility of these salts above room temperature is well described by Curie-Weiss law. But as far as the line width of nuclear magnetic resonance is concerned, the polarization of the "quenched spin" plays an important role as a function of the applied magnetic field. Such an effect was generally studied by T. Moriya and Y. Obata[1]. According to their theory, the line width of the nuclear resonance is expected to be proportional to $H_0^2+H_i^2$ so long as the separation of initial splitting is larger than Zeeman energy, where H_0 and H_i mean the external magnetic field and the low frequency part of the spin-spin interaction respectively.

In this study the field dependence of second moment of proton resonance was observed on powdered $NiSO_4\cdot 7H_2O$ at room temperature. For a single crystal, paramagnetic resonance was observed by K. Ohno[2]. It has been found that the effect of paramagnetic ion on protons is comparatively smaller than that of the dipolar interaction between protons of the water molecules, which can be estimated by utilizing the line of $ZnSO_4\cdot 7H_2O$ as a reference substance, because it is nearly identical in structure to $NiSO_4\cdot 7H_2O$. Their lattice parameter are shown in Table I.

Table I.[3]

	a	b	c
$NiSO_4\cdot 7H_2O$	11.86 A	12.08	6.81
$ZnSO_4\cdot 7H_2O$	11.85	12.09	6.83

Here it is assumed that the effect of paramagnetic ions is a small perturbation and the unperturbed line shape is equal to that of zinc complex. According to this assumption, the absorption line of nickel complex is constructed from the line of zinc complex, of which each line element is broadened by the effect of the paramagnetic ions. So the shape function is written as follows,

$$G_{NiSO_4\cdot 7H_2O}(H-H_0)$$
$$=\int G_{ZnSO_4\cdot 7H_2O}(H'-H_0)\cdot f_{para}(H-H')dH' .$$

From this convolution, it is easily found that

$$\langle(\Delta H)^2_{NiSO_4\cdot 7H_2O}\rangle=\langle(\Delta H)^2_{ZnSO_4\cdot 7H_2O}\rangle+\langle(\Delta H)^2_{para}\rangle ,$$

where G_A is the shape function of A, f_{para} is the influence function of paramagnetic ion which, according to Moriya and Obata, is expected to be of Lorentzian type as a result of exchange narrowing. Strictly speaking the second moment is not affected by the exchange narrowing[4], and is not expected to have the field dependence of $(H_0^2+H_i^2)^2$, but it is impossible to know the exact second moment from the observed derivative curve because of the finite range of the magnetic field. Therefore it is estimated that the square root of the second moment should be proportional to $H_0^2+H_i^2$.

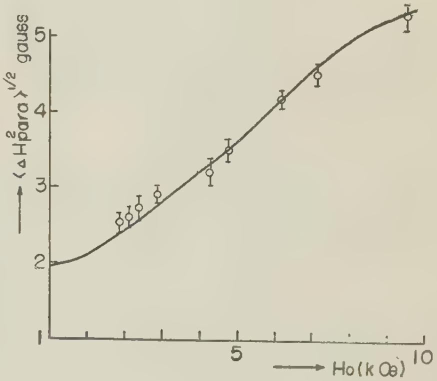

Fig. 1. The field dependence of the effective line width, which is obtained from the difference of the observed second moments of Ni and Zn complexes.

The experimental result is shown in Fig. 1. The field dependence of the effective line width shown in the figure does not always agree to $H_0^2+H_i^2$. But this discrepancy can be understood by taking into account that the Zeeman energy becomes comparable with the magnitude of initial splitting, and spin level separation varies appreciably from the initial value. This correction becomes important when external field is more than three thousands gauss. The solid curve shown in the figure is the result of the calculation considering this effect.

The unexpected result from experiment is the order of magnitude in the internal field H_i. The cause of the internal field discussed in the theory quoted above is the dipolar interaction between paramagnetic ions, but experimental result is about several ten times larger than the predicted value. The reason of this disagreement is not so certain, but it is expected that a sort of exchange interaction such as Moriya-Dzialoshinski term contributes to the internal field. The contribution can be evaluated, according to Moriya's mechanism[5], by utilising the value of isotropic exchange interaction which is estimated from the observed susceptibility by T. Watanabe[6]. The result seems to be consistent with the observed value.

Electrical Properties of Sb-Doped *n*-Type SnSe

By Jun-ichi UMEDA

Department of Physics, Faculty of Science, Kyushu University, Fukuoka, Japan

(Received November 4, 1960)

The electrical resistivity ρ and Hall coefficient R_H of Sb-doped n-type SnSe single crystals were measured in the temperature range between 100°K and 700°K, and the effects of some heat-treatments on them were also investigated.

Recently, Asanabe1) published a detailed report on the electrical properties of p-type SnSe single crystals, especially on the effects of heat-treatment on them. In his report the hole concentrations of those crystals at room temperature were increased by quenching from above 200°C and were decreased by annealing at below 200°C, whereas the Hall mobilities showed little change. He showed also that these behaviours could be explained if some acceptor levels were generated at high temperature and were frozen by the quenching, whereas they were annihilated at relatively low annealing temperature. It may be interesting to compare these behaviours with those of n-type SnSe.

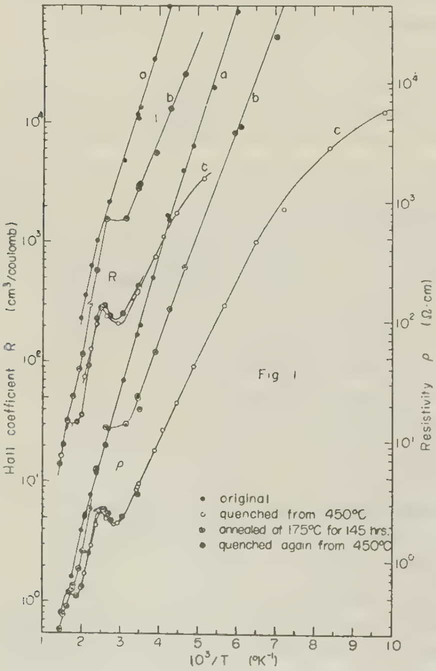

Fig. 1.

Single crystals of n-type specimens were obtained from the reaction $Sn_{0.98}+Se+Sb_{0.02}$* in an evacuated sealed quartz glass tube in the same method as described elsewhere1). The samples were cut in the rectangular form; their largest dimensions lay in c-plane.

The measured Hall coefficient and resistivity of one of these n-type specimens are shown in Fig. 1, in the three cases of heat treatment, i.e. a) original, b) annealed and c) quenched. Slopes of the curves of the Hall coefficient versus $1/T$ show the existence of two impurity levels below the conduction band by 0.16 eV and 0.20 eV. The effect of heat-treatment is found; that is, the carrier concentration increases by the quenching and decreases by the annealing. This behaviour is different from that expected from the results on p-type SnSe, and it is hardly understood on the model of the generation or annihilation of acceptors only. The similar behaviours have been reported on InAs, but they are different from those of SnSe, as the effect of the annealing on the carrier concentration of the InAs is reversed when n-type material is converted to p-type one2).

These electrical behaviours of SnSe suggest that donor levels made by Sb-doping are annihilated by the annealing and are generated by the quenching in the same way as the acceptor levels in p-type SnSe. But this is inconsistent with the fact that mobility of Sb-doped p-type SnSe is decreased by the annealing. No consistent explanation on this point has been obtained. It is conceivable, however, that some electrical properties of p- and n-type Sb-doped SnSe single crystals may be explained qualitatively by assuming simultaneous annihilation or generation of both acceptors and donors.

The author should like to express his sincere thanks to the late Prof. A. Okazaki for kind guidance. He is also indebted to Mr. K. Hashimoto for valuable advices.

Change of Surface state of Ge by Electron Bomberdment

By Kiichi KOMATSUBARA

Hitachi Central Reserch Laboratory, Tokyo

(Received November 16, 1960)

Change of surface state of germanium by electron bombardment has been studied by measuring the reverse current of a field effect change of *p-n* junction.

An alloy type *p-n* junction was prepared with 30 ohm. c.m. N type Ge. The change curves of ths reverse current, *Is*, by the application of an electric field, *E*, verfical to the opposide surface of the alloying surface has been pictured on the oscilloscope[1].

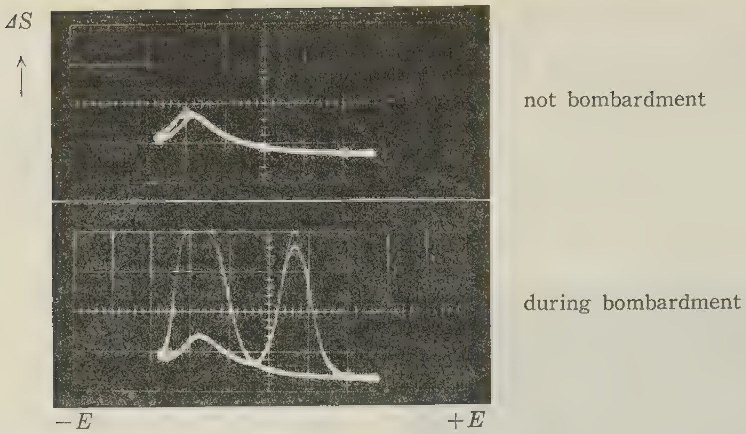
sample: about 30 ohm. c.m. N type Ge.
current density of irradiation.



V-scale 10 μA/div. H-scale 100 V/div.

Fig. 3. The variation of a S E curve during the electron bombardment.

The p-n junction was sealed in to a glass tube at 10^{-4} mm Hg vacuum, and the Ge surface on the other side of the p-n junction was mounted on a Ni electrode with a 0.1 mm mica spacer placed in between. The germanium was bombarded through the nickel electrode with an electron beam of energy about 0.8 MeV and current density 0.2 μA after passing through the electrode.

50 c/s A.C. voltage was applied on the nickel electrode for observing, then Is the changes in Is by the change of surface potential.

In this case the contributing factor to the reverse current here is the generation recombination mechanism of charged caraier on Ge surface[2]. With the dimension and the concentration of impurities of present sample, the following relationship exists between the variation of Is and that of surface recombination velocity, S:[3]

$$dS/S=1.3dIs/Is\ .$$

Therefore the variation in reverse current, Is, can be used as the measure of the variation in surface recombination velocity, s.

As the total dosage of electron was increased, the value of E corresponding to the maximum value of S shifted toward more negative direction as shown in Fig. 1.

From the value of E and of the capacity between the electrode and the Ge surface, the surface charge Qs was computed, and from this the surface potential, $\emptyset s$ have been obtained. The relation between the total dosage of bombarding electrons and the surface potential $\emptyset s$ in the absence of external electric field is shown in Fig. 2.

During the bombardment the S-E cvrve displayed curious phenomena which was shown in Fig. 3.

Antiferromagnetic Magnetostriction in CoO and NiO Single Crystals

By Takurô NAKAMICHI and Mikio YAMAMOTO

Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai

(Received September, 1960)

In connection with the origin of the lattice deformation accompanied with the magnetic transformation in antiferromagnets, it may be important to investigate the nature and behavior of magnetostriction in those substances. Recently, Belov and Levitin[1] reported briefly some magnetostrictive behavior of NiO polycrystals measured in magnetic field up to 14,000 Oe. We have made preliminary measurements on the antiferromagnetic magnetostriction of single crystals of CoO and NiO and obtained some interesting results.

The crystal specimens employed are rounded square plates, 3 mm thick and 13 mm wide, with plate surfaces coinciding with the (100) plane, which were cut out, making use of the cleavage, from large crystals grown by Mr. Y. Nakazumi of Fuji Titanium Industrial Co. using the Verneuil method. They were submitted to the measurements without any treatment. Magnetostriction measurements by the strain gauge technique[2] were performed at room and liquid air temperatures in magnetic field up to 11,000 Oe applied parallel to the (100) plate surface.

The results obtained are summarized as follows:

(1) The longitudinal and transverse magnetostrictions along the [100] and [110] directions vary monotonously with increasing field (Fig. 1). It seems that the measured magnetostrictions are proportinal to the square of the intensity of magnetic field, as contrasted to a linear increase of the magnetostriction beyond a distinct critical field as claimed by Belov and Levitin[1] with NiO polycrystals. (2) The magnitude of longitudinal magnetostriction is twice as large as that of the transverse one, and they have different signs, except the magnetostrictions along the [110] direction in CoO, for which the signs of longitudinal and transverse magnetostrictions are the same. (3) The magnetostriction along the [100] direction is larger than that along the [110] direction. (4) The dependency of the magnetostriction on the direction of an applied field is of the $\cos 2\phi$ type, where ϕ is the angle between the direction of the magnetostriction measurement and that of an applied field (Fig. 2). (5) The magnitude of the magnetostriction observed in the maximum applied field is of the order of 10^{-6} (Fig. 1 and 2). (6) For CoO single crystal, of which the Néel temperature is 279°K, the magnetostriction could not be observed at room temperature, showing that the magnetostriction observed here is certainly originated from antiferromagnetism. (7) The magnetostrictions along the [100] and [110] directions in CoO single crystal as well as those along the [100] direction in NiO single crystal are larger at the liquid air temperature than at room temperature, but the magnetostriction along the [110] direction in NiO single crystal is reverse in this respect. These are to be compared with Belov and Levitin's[1] finding that the magnetostriction in NiO polycrystal decreases monotonously with raising temperature. (8) Small hysteresis of magnetostriction was observed when an applied field was decreased in magnitude or reversed in direction, which seems to be originated from an accidental thermal expansion.

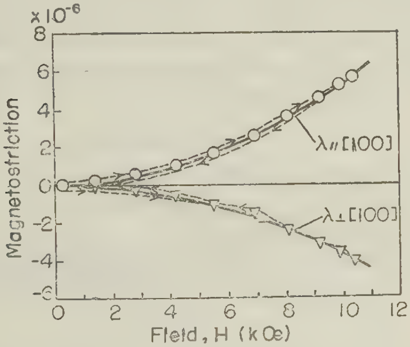

Fig. 1. Longitudinal and transverse magnetostrictions measured along the [100] direction in CoO single crystal at the liquid air temperature. Dashed lines follow the measured points in increasing and decreasing magnetic field and ○ and ▽ show the mean values of longitudinal and of transverse magnetostriction, respectively. Thick lines express the relation $\lambda \propto H^2$.

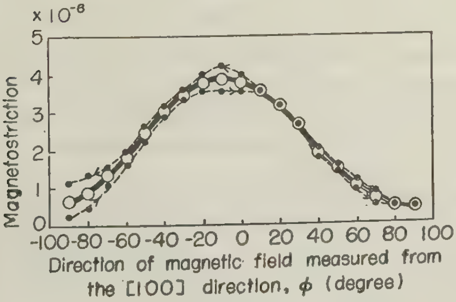

Fig. 2. Magnetostriction along the [100] direction as dependent on the direction, ϕ, of magnetic field of 10,200 Oe applied parallel to the (001) plane in NiO single crystal at the liquid air temperature. The measured points for the clockwise and anti-clockwise rotation of the field and their mean values are connected by dashed and thick lines, respectively.

We may conclude from these measured results that the magnetostriction observed here is originated from antiferromagnetism and make its appearance as a result of displacements of antiferromagnetic domain walls. Notably, the above mentioned experimental facts (1)～(4), can be interpreted in terms of the concept of the antiferromagnetic domain wall displacements proposed by Néel[3].

The Purification of KCl by the Zone Refining Method

By Morio INOUE and Hiroyuki MIZUNO
Matsushita Electronics Corporation, Takatsuki

(Received November 12, 1960)

The zone melting method has proved to be an effective technique for the purifying and growing of single crystals of non-polar semi-conductors.

Recently Gründig[1], by applying this method for the purification of alkali halides, could give an estimation of the binding energies of some divalent metal ions with positive ion vacancies in KCl and KBr. So far, however, the method has not been in common practice.

This report is the first of a series concerning the behaviour of impurities in KCl when the KCl is subjected to the purifying zone melting process.

The interior of the carbon boat containing KCl material was completely covered with thin platinum foil of 0.05 mm thickness in order to prevent adhesion of the KCl to the boat. The boat was moved with a speed of 1 to 100 mm/hour in the atmosphere of nitrogen through a furnace having a temperature distribution with a peak at its center.

In the zone refining method an impurity distribution is given by[2]

$$C_s=C_0\left[1-(1-K)\exp\left(-K\frac{x}{l}\right)\right], \qquad (1)$$

where C_0 is the initial concentration of an impurity, C_s is the concentration at a distance x from the starting point of the melting zone, K is the effective distribution coefficient and l is the zone length. Fig. 1 show the distributions of Br ions in a KCl crystal after zone refining is repeated n times. The moving speed of the zone is 42 mm/hour. The solid curve for $n=1$ in Fig. 1 is a theoretical curve given by Eq. (1). The value of K is chosen to be 0.75 to give the best fit to the experimental data for $n=2$ and $n=3$. Following the same procedures the effective distribution coefficient of Na ions in KCl was also measured and found to be 0.1 for the zone speed of 42 mm/hour. The concentration of Br ions was analysed[3] by the colorimetric method and that of Na ions by a spectroscopic method both with the probable error of ±5%. The distribution coefficient is expected to depend to a considerable extent on the speed of the zone and therefore closer examination of the relation between the distribution coefficient and the zone speed should be desirable. Moreover a similar study on the other impurities in a KCl single crystal is under investigation. The authors wish to thank the staff of the analysis section in their laboratory for the impurity analysis.

Heat Capacities of Two Manganese Salts*

H. FORSTAT and G. O. TAYLOR
Department of Physics and Astronomy Michigan State University, East Lansing, Michigan, U.S.A.

(Received August 31, 1960)

During the course of some work on the antiferromagnetic behavior of single crystals, heat capacity studies have been made on $MnSO_4 \cdot 4H_2O$ and $MnHPO_4 \cdot 3H_2O$. These single crystals were grown from aqueous solutions at room temperature and they weighed approximately 2 grams. The sulfate crystals were monoclinic while the phosphate crystals were rhombic. The heat capacity measurements were made in an adiabatic calorimeter using carbon resistance thermometry[1].

Fig. 1 shows the results of these experiments. The data for $MnHPO_4 \cdot 3H_2O$ shows no magnetic ordering process usually associated with an antiferromagnetic-paramagnetic transition. Proton resonance data[2] on this crystal did not indicate an antiferromagnetic state. These heat capacity measurements indicate a Debye temperature of 28°K. In the case of the manganese sulphate crystal, the heat capacity curve shows a slight rise at the lowest temperature. Whether this represents the beginning of a magnetic transition or a Schottky type anomaly is difficult to say, since our experiment could not be performed below 1.3°K. Preliminary proton resonance work²⁾ shows no evidence of a magnetic ordering process, but a more detailed examination in the low temperature region is in progress.

Excitation Function for the Reaction $O^{16}(\alpha, pn)F^{18}$

By Michiaki FURUKAWA and Shigeo TANAKA

Institute for Nuclear Study,
University of Tokyo,
Tanashi-Machi, Tokyo

(Received November 2, 1960)

The energy dependence of cross sections for the reaction $O^{16}(\alpha, pn)F^{18}$ has been determined for the alpha-particle energies up to 40 MeV. The bombardments were performed with the external alpha-particle beam from the 160 cm INSJ variable energy cyclotron by means of a stacked-foil technique. The values of energy loss in target and in aluminum absorber were taken from the compilation of Sternheimer (Phys. Rev. **115** (1959) 137). The beam was collected in a Faraday cup and the total charge of the beam was measured by a 100% feed-back type current integrator. In different experiments, the initial alpha-particle energies were 40.0 and 31.3 MeV. Sodium carbonate (about 4 mg/cm²) was used as an oxygen target. Sodium carbonate powder suspended in acetone containing a trace of polyvinylacetate (binder) was deposited onto a thin aluminum backing-foil by slow evaporation of acetone. And the target was dehydrated by heating in an oven before use. After the bombardment, the target foil was sandwiched by two brass plates of sufficient thickness to stop the positrons, and the two 0.51 MeV γ-rays were detected in coincidence with two ($1\frac{1}{2}$ in. dia. × 1 in. high) NaI scintillation counters positioned 180° from each other with respect to the source. After shorter-lived activities including C^{11} had decayed out, the decay was followed for about 12 hours. The half-life showed the literature value (112 min.) of F^{18}. The counting efficiency of the instrument was calibrated by an Na^{22} standard source.

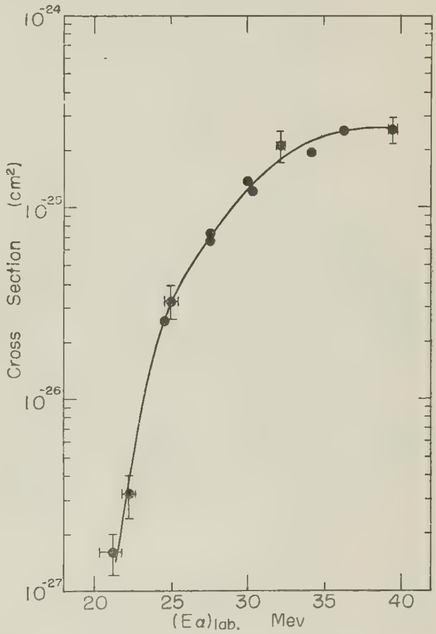

Fig. 1. Excitation function for the reaction $O^{16}(\alpha, pn)F^{18}$.

The result is shown in Fig. 1, together with the energy spread in target foil and with the estimated error of the magnitude of cross section for some experimental points. The error in the magnitude of cross section is mainly due to inhomogeneity of target foil. It can be seen that F^{18} is produced even below the threshould energy (23.2 MeV) of the (α, pn) reaction. This is not due to impuritie in target. It is thought that the deuteron emission is very important in this case. The threshold energy of the (α, d) reaction is 20.4 MeV. Further, the present result may give some informations about the interference of F^{18} towards the activation studies in which oxide targets are used.

Mass Spectra of Baryons

By Seitaro NAKAMURA and
Ken KAWARABAYASHI
Department of Physics, Facult of Science,
University of Tokyo, Tokyo, Japan

(Received December 3, 1960)

Recently, one of the present authors (S.N.)[1)-2)] constructed a Hamiltonian for the strong interaction between baryons and mesons with the spin 0. All baryons are here considered to represent different states of one particle, and among them a number of the Yukawa processes mediated by sixteen kinds of mesons (kaons, pions and D-mesons) are assumed. In order to specify baryons and mesons a new quantum number κ charge is introduced. ($Q_\kappa=+1$ for nucleons and Ξ-particles, $Q_\kappa=0$ for Σ and Λ-particles, $Q_\kappa=\pm1$ for kaons, and $Q_\kappa=0$ for pions and D-mesons.) The concept of strangeness and hypercharge are not used. We use two orthogonal Euclidian spaces; one is the three dimentional κ-charge space, and the other the three dimensional electric charge space, called N-space, which is identical with the M-space[3)] except its hypercharge assignment. The interaction Hamiltonian is assumed to be completely symmetric in these speculated charge spaces; $|\kappa|$, κ_3 and $|N|$, n_3 are conserved. In terms of such Hamiltonian (9)-12) in the reference 1)), we would expect the same number of the mass correction terms for all baryons. By means of a perturbation calculation to the lowest order, we obtain the following relations:

$$M_\Xi=M_0+g^2\left\{3I_{L\Sigma}+I_{L\Lambda}+I_{D^\pm}+\frac{1}{2}I_{D0}+\frac{1}{2}I_{D^{0\prime}}\right\}+\frac{g'^2}{2}\{3I_\pi+I_{\pi^{0\prime}}\}\,,$$
$$M_N=M_0+g^2\left\{3I_{K\Sigma}+I_{K\Lambda}+I_{D^\pm}+\frac{1}{2}I_{D^0}+\frac{1}{2}I_{D^{0\prime}}\right\}+\frac{g'^2}{2}\{3I_\pi+I_{\pi^{0\prime}}\}\,,$$
$$M_\Sigma=M_0+g^2\left\{2I_{KN}+2I_{L\Xi}+I_{\Sigma D}+\frac{1}{2}I_{\Lambda D}+\frac{1}{2}I_{D^{0\prime}}\right\}+\frac{g'^2}{2}\{2I_{\Sigma\pi}+I_{\Lambda\pi}+I_{\Sigma\pi^{0\prime}}\}\,,$$
$$M_\Lambda=M_0+g^2\left\{2I_{KN}+2I_{L\Xi}+\frac{3}{2}I_{\Sigma D}+\frac{1}{2}I_{D^{0\prime}}\right\}+\frac{g'^2}{2}\{3I_{\Sigma\pi}+I_{\Lambda\pi^{0\prime}}\}\,. \qquad (1)$$

Where $I_{L\Sigma}$ etc. in the expressions for M_Ξ etc. are the self energy terms of the lowest order derived from the respective channels $\Xi\rightarrow\Sigma+L\rightarrow\Xi$. (1) is independent of the cut-off which we resort to in order to get a finite result. It is clear that the sign of the integrals $I_{L\Sigma}$ etc. depends on their coupling types. To know their gross behaviors, however, we have only to make clear the sign of the leading terms in the finite self energy terms which are obtained by means of the Feynman cut (λ).

For scalar mesons,

$$\delta M=-f_1^2/4\pi\cdot3/8\pi\cdot M_0\log\lambda^2/M_0^2:\qquad(s-s)$$
$$\delta M=+f_2^2/4\pi\cdot M_0\cdot(M_0/\kappa)^2\cdot1/8\pi\cdot\lambda^2/M_0^2:\qquad(v-v)\,,\quad(2)$$

and for pseudoscalar mesons,

$$\delta M=g_1^2/4\pi\cdot M_0\cdot1/8\pi\log\lambda^2/M_0^2:\qquad(ps-ps)$$
$$\delta M=-g_2^2/4\pi\cdot M_0\cdot3/8\pi\cdot(M_0/\kappa)^2\cdot\lambda^2/M_0^2:\qquad(pv-pv)$$
$$\delta M=-g_1g_2^2/4\pi\cdot M_0\cdot(M_0/\kappa)\cdot1/2\pi\cdot\lambda^2/M_0^2:\qquad(ps-pv)\quad(3)$$

Here the interaction Lagrangians are taken as follows:

$$L_s=f_1\bar{\psi}\psi\varphi+i(f_2/\kappa)\bar{\psi}\gamma_\mu\partial_\mu\varphi$$
$$L_{ps}=ig_1\bar{\psi}\gamma_5\psi\varphi+i(g_2/\kappa)\bar{\psi}\gamma_5\gamma_\mu\psi\partial_\mu\varphi\,.$$

If we assume that the parity of K-kaons and that of L-kaons are of the opposite sign, we could predict the mass splitting for baryons into the three groups Ξ—$\Sigma\Lambda$—N. In fact, if we take $\Omega_{K\Sigma N.K\Lambda N}=i\gamma_5\gamma_\mu$ or 1, $\Omega_{L\Sigma\Xi.L\Lambda\Xi}=i\gamma_\mu$ or γ_5, then we obtain $M_\Xi>M_\Sigma=M_\Lambda>M_N$. In this case, the mass difference between the Σ and the Λ particles can not be explained.

If we take into account the hermiticity, either S or PS coupling will be cancelled in (12)-(13)[1)], so that only V–A couplings are preferred.

Lastly we mention that the mass splitting derived from the present considerations is of the right order of magnitude if we assume that $M_0\approx1000$ MeV, $g^2/4\pi\sim1$ and with the reasonable order of the cut-off.

Preferential Plastic Deformation in the Surface Region of Al and α-Fe Single Crystals

By Kôji SUMINO and Mikio YAMAMOTO

Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai

(Received November 11, 1960)

Although there are many evidences on the start of plastic deformation from the crystal surface[1)] and on the higher density of dislocations near the surface than that in the interior of deformed crystal[2)], very few evidences[1a)] are available on the difference in the proceeding of work-hardening in the surface region and in the interior, which has an important bearing on the theory of work-hardening of crystals.

We have pursued this problem with aluminium single crystals. As shown in Fig. 1, the value of flow stress at any stage of deformation is lowered by electrolytic polishing out of the surface region. It has been confirmed that the value of $(\sigma_2-\sigma_0)/(\sigma_1-\sigma_0)$ (σ_0 is the critical shear stress, and σ_1 and σ_2 are the flow stresses before and after the polishing out of the surface layer, respectively) decreases with an increase of the thickness of the polished-out surface layer, Δd, and attains to a smallest value of 0.5 at $\Delta d = 150-200\,\mu$ for a relatively small deformation, while the $(\sigma_2-\sigma_0)/(\sigma_1-\sigma_0)$ value shifts to a larger value for larger deformation (its orientation dependence is not yet clear). These results indicate the advance of work-hardening in the surface region more than in the interior. This effect seems to be interpreted in terms of the easiness of the operation of the dislocation sources in the surface region, although a part of the effect may be attributed to the hindrance action of the surface film against the escape of dislocations to the surface.

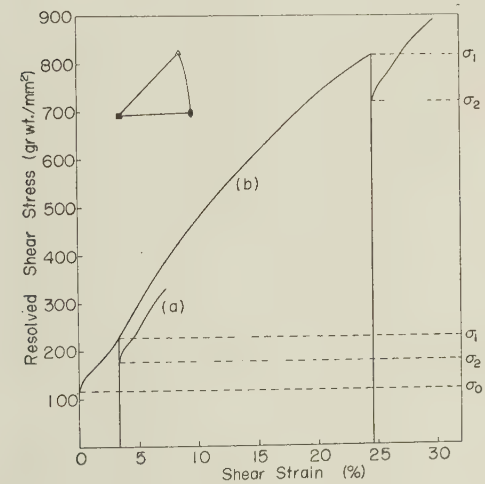

Fig. 1. Stress-strain curves of an aluminium single crystal. In curves (a) and (b) the surface layers of 190 μ and of 150 μ in thickness were removed after the deformation of 3.38% and of 24.6% shear strain, respectively.

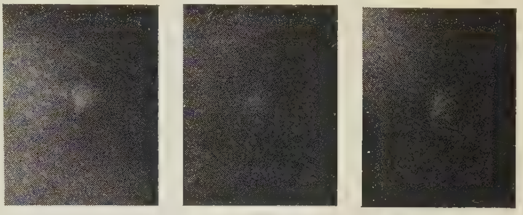

(a) (b) (c)

Photo. 1. (111) Laue back-reflection spots taken from the same portion of α-Fe single crystal (a) before and (b) after deformation of 7.6% elongation, and (c) on removing the surface layer of 260 μ in thickness after the deformation.

Furthermore, by observing the change in appearance of the back-reflection Laue spots with deformed α-iron single crystals (containing less than 0.01% C), we have obtained an evidence for the fact that the dislocation density is higher in the surface region more than in the interior upon the deformation. As is well known, in α-iron, there are strong interactions between dislocations and various impurity atoms resulting a high critical shear stress, so that the influence of surface oxide film may be very little. Photo. 1 shows that (111) back-reflection Laue spot of the same portion of a specimen changes from a spotty appearance to a very diffused one upon the deformation, but its spotty appearance comes back by removing the surface layer by electrolytic polishing.

A theoretical explanation of such a preferential plastic deformation in the surface region of crystals will be presented elsewhere in the near furture.

The authors thank to Prof. T. Suzuki for his suggestion of the present work and to Mr. K. Nakajima for his help in X-ray observations.

Seiji Nakamura

(1869—1960)

OBITUARY NOTICE OF PROFESSOR SEIJI NAKAMURA

Professor Seiji Nakamura, Honorary member of the Society, Emeritus Professor of the University of Tokyo and Member of the Japan Academy died in Tokyo on 18th July, 1960 at the age of ninety. By his death Japan has lost one of the great scholars who have made physics in Japan as it is today.

He was born at Sabae-machi in Fukui Prefecture on 24th September, 1869 as the fourth son of Masanori Nakamura and in his childhood he came up to Tokyo with his parents. In 1892, he was graduated from the College of Science of Tokyo Imperial University (now University of Tokyo) majoring in physics, after he had his preparatory education in the First Higher School. In 1895, he was appointed a Professor of the First Higher School, and in 1900 he was appointed an Assistant Professor in the College of Science of Tokyo Imperial University, his Alma Mater, where he conducted his researches under Professor Dr. Tanakadate.

In 1903, he visited Europe to study optics and crystallography, and made an intensive research under Professor Dr. Voigt at the University of Göttingen, Germany. In 1907, he was awarded a Doctor of Science by his thesis on Optics, and was promoted to professorship in Tokyo Imperial University in 1912. In 1925, he was elected a member of the Japan Academy, and also acted as Dean of the Faculty of Science of the University for three years beginning in 1926, contributing much to the administration of the institution. At his retirement in 1930, he was awarded an honorary title of Professor Emeritus. In the Academy, he also contributed to the promotion of science in Japan by issuing many papers at its regular meetings, and at the same time, he devoted his time to edit the History of Japanese Science before the Meiji Era which was one of the projects of the Academy.

He is an experimental physicist, especially excellent in experimental technique, obtained from his own abundant experiences. We can easily see his excellence in experiment by some of the remarks he made in his class at Tokyo Imperial University. Two examples of his hortative sayings are given here: "Don't carry a microscope as you swing a cat by the scruff of the neck." "In experiment an iron bank is not an iron bank; mind that it is like a jelly."

He had a special interest in the field of optical instruments, and endeavored to train the technical specialists in this field. It is not too much to say that all of the leading technicians of the optical instrument makers in Japan are educated by him directly or indirectly. His research fields extended also to geophysics in general, but specially in geomagnetism, geodesy and seiches of Japanese lakes. And he had a very deep interest in such curious phenomena related to optics and to acoustics known from the olden times in Japan as, for example, mysterious lights on the seas (Shiranuhi) in Kyushu, Singing Dragon in Toshogu Shrine in Nikko, Magic Mirror, and the musical scales in Japan and China.

His major achievements are his efforts in publishing great many books and articles and in promoting the education of physics in Japan. Furthermore, he was the foremost scholar who popularized the study of natural science for the younger people by devising new methods for it. Because of his contribution in education, he was awarded a national commendation as one of the Persons of Cultural Merits in 1953.

He was lucid and illumitable by his character, and he had not only a profound ability for scholarship in Japanese, Chinese and European languages, but also wide interest in most of all the fields of art and natural sciences. He was very fond of journey, and after his retirement, he especially enjoyed his trips which covered every nook and corner of Japan. He loved Japan as he loved his own family, and desired the advent of the eternal peace on this world.

He was survived by a son and a daughter.

Elastic and Inelastic Scattering of Protons from Carbon Nucleus from 6.5 to 16 Mev

By Yukio NAGAHARA

Physics Department, Yokohama National University, Minami-ku, Yokohama

(Received May 11, 1960)

Angular distributions and excitation functions of C^{12} (p, p) C^{12} $(Q=0)$ and C^{12} (p, p') C^{12*} $(Q=-4.43$ Mev) reactions were investigated with the bombarding energy from 6.5 to 16 Mev and from 9.5 to 16 Mev, respectively, by the INS variable energy cyclotron. Though the angular distributions were found to vary gradually with energy, several distinct anomalies were observed. Especially, at $T_p=9.1$ Mev, very sharp anomaly was found for the elastic scattering. Around $T_p=10.5$ Mev, large anomaly of composite nature was found (which had been reported by Braid and Yntema), where the angular distributions of the elastic and inelastic scattering varied violently. Rather strong correlations were observed between the elastic and inelastic $(Q=-4.43$ Mev) scattering. Observed anomalies were found to be closely related to the levels of the compound nucleus N^{13}.

§ 1. Introduction

Up to now, many investigations, both theoretical and experimental, have been performed with regard to the elastic and inelastic scattering of nucleons from various nuclei. We will hereafter restrict our subjects to 1) the medium low energy region, e.g., from several Mev to about 20 Mev, and 2) the elastic scattering and the inelastic scattering leaving the target nucleus to the well resolved excited states.

In the case of the medium weight nuclei, the elastic scattering shows the typical diffraction pattern and also shows the remarkably systematic transient change, in the absolute values and in the angular distribution, from nucleus to nucleus[1]. These are considered to be the very feature of the optical model. As to the inelastic scattering, at least for the even-even nucleus and in the higher energy region (say, higher than 10 Mev), the angular distributions are shown to be well-fitted with the simple Born approximation calculation based on the surface direct process[1,)2]. In several Mev region, the angular distributions are shown to become more flat and are believed to suggest the increase of the importance of the contribution via the compound process[3]. Also, the results of the angular correlation measurements are thought to be the support to these interpretation[3].

On the contrary to these comparatively clear situations, the scattering of nucleons from lighter nuclei have shown some complexity. At first, the elastic scattering showed the typical diffraction pattern, which would lead us to the understanding that the optical model had its validity. But, at the same time, it has been shown that the systematic regularities from nucleus to nucleus were not so distinct and also the energy dependence of the angular distribution was rather violent[4].

For the inelastic scattering, the situation is more complicated[4,5,5,7]. For example in Ne^{20} (p, p') Ne^{20*} $(Q=-1.63$ Mev), the experimental studies by K. Matsuda et al. have shown that the formerly obtained good fit of the theoretical result based on the surface direct process had to be thought as accidental. Here, it must be noted that for lighter nuclei, these energy regions may be the transient region from the resonance to the continum region and also the wave length of the incident nucleon is of the same order as the radius of the target nucleus.

Many refined direct precess theories have been presented about the inelastic scattering of nucleons from nuclei[8)-15]. The proton-carbon system is treated as their examples most frequently. But, we can say that the scarcity of the experimental materials[16)-23] is fatal in order to clarify the situation. The object of our experimental study is to make a " map ", though rather crude, on the elastic and the inelastic scattering of protons from carbon nuclei.

§ 2. Apparatus

The general feature of the experimental arrangement is shown in Fig. 1, schematically.

1) *Beam*

The 160 cm synchro- and variable energy ordinary cyclotron of the Institute for the Nuclear Study (University of Tokyo) was used in the latter operation condition. Detailes of the design, construction and operation have been published elsewhere[33], so they will not be repeated here.

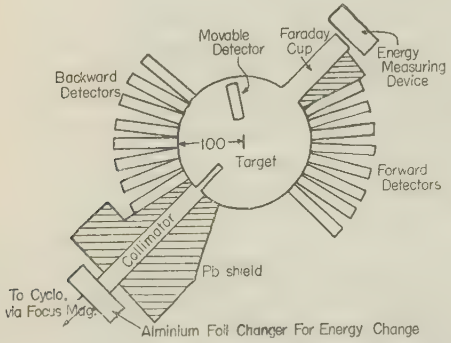

Fig. 1. Schematic view of the experimental arrangement.

Beam energy was varied with the interval of about 500 Kev by adjusting the machine parameters. Aluminium absorber foils were inserted between the focus magnet and the collimator, and then we could attain the fine variation of the beam energy.

After passing through the target, beam was collected in the Faraday cup and the collected charge was measured by the precision current integrator.

Beam energy was measured by the range measuring device outside the scattering chamber which comprised of an aluminium foil changer sandwitched between two ionization chambers.

2) *Scattering chamber*

The large scattering chamber, 100 cm in diameter and 40 cm in height, was used. As described in reference[24], this chamber has thirty-three ports on its side wall to which many detectors can be attached simultaneously.

3) *Target*

From 9.5 to 16 Mev, thin CH_2 foil was used. Its mean thickness was estimated to be 2.88 mg/cm^2 by weighing. Because of the degration of the foil caused by the proton irradiation, CH_4 gas target was used in the later stage (from 6.5 to 9.7 Mev and at two energy in the higher energy region for the calibration of the absolute value). CH_4 gas of 99.9% purity was filled in a gas target chamber, which was a brass cylinder of 90 mm in diameter and had two side slits of about 20 mm in breadth which were sealed by 20 micron aluminium foils.

4) *Detectors and Electronics*

The scattered protons were detected by NaI (Tl) crystals of about 20×20×1.5 mms, which were slightly thicker than the maximum range of protons, to minimize the gamma-ray background. As we have used so many detectors simultaneously, we were obliged to abandon to attach any gamma-ray removing devices (for example, proportional counters).

In the case of CH_2 foil target, sixteen detectors were mounted to the ports of the scattering chamber. The forward angle detectors (from 20° to 90°) were arranged with the interval of 10° on the beam transmitting side and the backward ones were arranged also with the interval of 10° (from 95° to 165°) on the beam reflecting side. One detector was mounted on the turntable of the scattering chamber and was able to be rotate around the target freely. Its aim was to make up for the defects which might be caused by the fixedness of the main detectors.

In the case of the gas target, fifteen detectors were mounted on one side of the scattering chamber with the interval of 10° ranging from 20° to 160°. The defining slits of rectangular shape (5 mm in width and 20 mm in height) spaced 34 cm apart were attached to the ports of the scattering chamber.

The signal pulses were fed to the plugboard in the counting room, where five of them were picked up and fed to five amplifier and pulse height analyzer systems, respectively. So, we could get the full angular distribution by changing the plug connection only four times, which economized the measuring time considerably and reduced the relative errors. All of these electronic equipments were designed and constructed in the Electronics Division of INS.

The diameters of the circular apertures of these detectors were 3 mm for 20° detector, 5 mm for 30° to 50° detectors and 10 mm for others. The aim of this design was to compensate the steep increase of the yields of the elastically scattered protons at forward angles and then to generally equalize the load to the succeeding stages.

§ 3. Experimental Procedures

The detectors were grouped into four sets, taking account of the yields and other measuring conditions. Each set included the 90° detector which served also as the monitor.

A particular set of 30°, 60°, 90, 125°, (120° for gas target) and 155° (150° for gas target) detectors was extensively used for the investigation of the excitation functions. By inspecting the obtained excitation functions, when some interesting features would be expected, then full observation for all angles was carried out. When the 90° detector's counts showed differences larger than the statistical error from those of the other run at the same energy, that run was deserted and repeated again. In fact, this has seldom occurerd.

The energy measurements were carried out when the coarse variation of beam energy had done. For the fine variation, only the thickness of the absorber foils used was recorded.

§ 4. Possible Errors and Corrections

1) *Energy*

The INS cyclotron has an excellent beam energy stability. Moreover, the measuring time required was rather short. So, the fluctuation of beam energy might be very small.

For the determination of the beam energy, the results of Bichsel, Mozley and Aron[25] were used. As we have used the same apparatus and the same procedure at each time, the relative value of T_p (the proton energy at the center of the target) was expected to be accurate within ±30 Kev. But, the absolute value of T_p was estimated to be accurate within about ±100 Kev. It has been reported that the energy spread at the half-maximum was about 0.5% at the outlet of the focus magnet[24]. So, at the center of the target, the energy spread might be 1% or less. (It is expected to be somewhat larger when the aluminium absorber foils are used to lower the beam energy).

2) *Angle*

Accuracy of the angular position of the port of the scattering chamber is very good[24], and the misalignment of the scattering chamber to the beam collimator is +0.01° or less. Considering the possible incorrectness in mounting the defining slit, the inaccuracy in angle was estimated to be at most ±0.1° for the foil target, and ±0.3° for the gas target. The other resposible factor to this inaccuracy was the one originated from the effectiveness of the collimator which was estimated to be ±0.05°.

3) *Current*

The accuracy of the current integrator used was estimated to be 1.5% or less, including both the zero-point drift and the relative fluctuation. But, when using the gas target, multiple scattering correction for the escape of the beam out of the Faraday cup was estimated by the theory of Bethe[26]. Aluminium foils which sealed the gas target chamber were most responsible. They were only appreciable in the energy region lower than 10 Mev and estimated to 8% at the lowest energy investigated. This correction might introduce about 2 to 3% error to the absolute value of the cross-section.

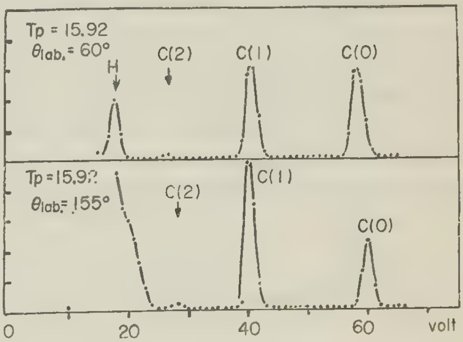

Fig. 2. Examples of the publse height spectrum of the emitted particles.

4) *Backround subtraction*

As is shown in Fig. 2, in almost all the cases, background subtraction did not introduce any disturbing errors. The maximum and minimum background spectrums were assumed by extraporating from both sides and subtraction was performed. When the subtraction error was larger than 15%, that data was deserted.

5) *Yield* (*CH_4 gas target*)

The gas pressure was pressure by Hg manometer and found to be substantially constant throughout (386 mm Hg). The temperature was also constant (20.0°C). The inaccuracy of the target density was estimated to be less than ±1%.

As for the G-factor, it was proved that all the higher order terms and also the effect of the finite beam width could be neglected[27]. Multiple scattering corrections on the G-factor were estimated and it was proved that they had some influences on the elastic scattering at forward angles for the lower energy region. Because of the difficulty in precise determination of this correction factor, estimated factors were treated as errors. (This correction should not be neglected in the sharp cusp of the elastic scattering angular distribution. But, we had no way of correction owing to the coarseness of the measuring angles).

6) *Yield (CH_2 foil target)*

In this case, the nonuniformity and the irradiation degradation of the target foil would have larger effects. So, to check the foil experiments, we measured the differential cross-sections of elastic and inelastic scattering by using CH_4 gas target at $T_p=15.50$ Mev, and 13.64 Mev, where both scatterings were expected to have the gradually varying features with energy. At both energies, it was found that the foil results would coincide to the gas results within at most ±5% by multiplying a factor of 1.06, the origin of which might be attributed to the nonuniformity and the possible inadequate mounting of the target foil.

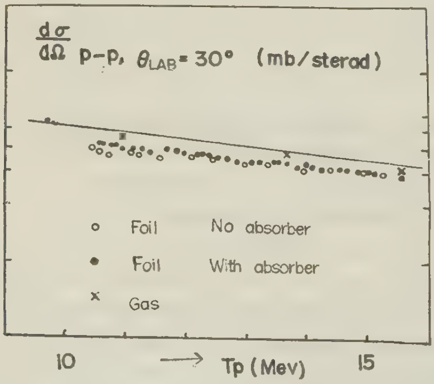

Fig. 3. Differential cross-sections of proton-hydrogen scattering at $\theta_{lab}=30°$.

On the other hand, the effects of the degradation of the target were of more complex nature. In Fig. 3, the proton-hydrogen differential cross-sections at $\theta_{Lab}=30°$ obtained by our experiments are plotted, which show small but regular bumps. (We have carried out our experiments from the higher energy side). It was found that these bumps corresponded to the presence of the absorber foils for lowering the beam energy. The origin of this phenomena might be attributed to the beam diverging effect of the absorber foils. By proton irradiation, the hydrogen atoms in the beam spot would be struck out or evaporated, the rate of which would be larger than for carbon atoms owing to their smaller mass. So, on the presence of the foils, diverged beam would strike the wider (that is, newer) region and then result in the formation of the abovestated bumps. On the other hand, we could not find any correlation between the proton-carbon scattering yields and the bumps of the proton-hydrogen scattering yields. So, we concluded that the degradation effects would have not introduced serious error.

Consequently, we have multiplied the results of the foil target experiment by a factor of 1.06 throughout. The accompanied error were assumed to be ±2% in the higher energy region, and ±3% in the lower energy region.

7) *Absolute value of the cross-section*

In Fig. 3, the full line shows the straight line interpolation curve joining between the proton-proton scattering data at $T_p=9.7$ Mev, 9.85 Mev[28] and 18.2 Mev[29] at $\theta_{Lab}=30°$. Our values obtained by gas target are slightly smaller, but it can be said that good agreement exsists.

8) *Grouping of the errors*

Above mentioned errors were grouped into two.

δ_1 is the error which may distort the shapes of the angular distribution. It is the combination of the statistical error, background subtraction error, errors from the inaccuracy in angle and G-factor.

δ_2 is the error which, after combined with δ_1, forms the error that may affects the shapes of the excitation function and the absolute value of the individual cross-section. It is the combination of the error in charge collection and its measurement and errors from the fluctuation in the properties of the target.

§ 5. Results

1) *Representation in tables and graphs*

Absolute values (in the center of mass system) of the differential cross-section of the elastic scattering are tabulated in Table I, and those of the inelastic scattering are tabulated in Table II.

Over-all view of the angular distributions are shown in Fig. 4a (elastic) and Fig. 4b (inelastic), where some of our results are omitted in order to make the figures clear-cut.

Excitation functions at five angles are shown in Fig. 5 to 9 and in Fig. 11, including other author's results.

The integrated partial cross-section of the inelastic scattering are plotted in Fig. 10.

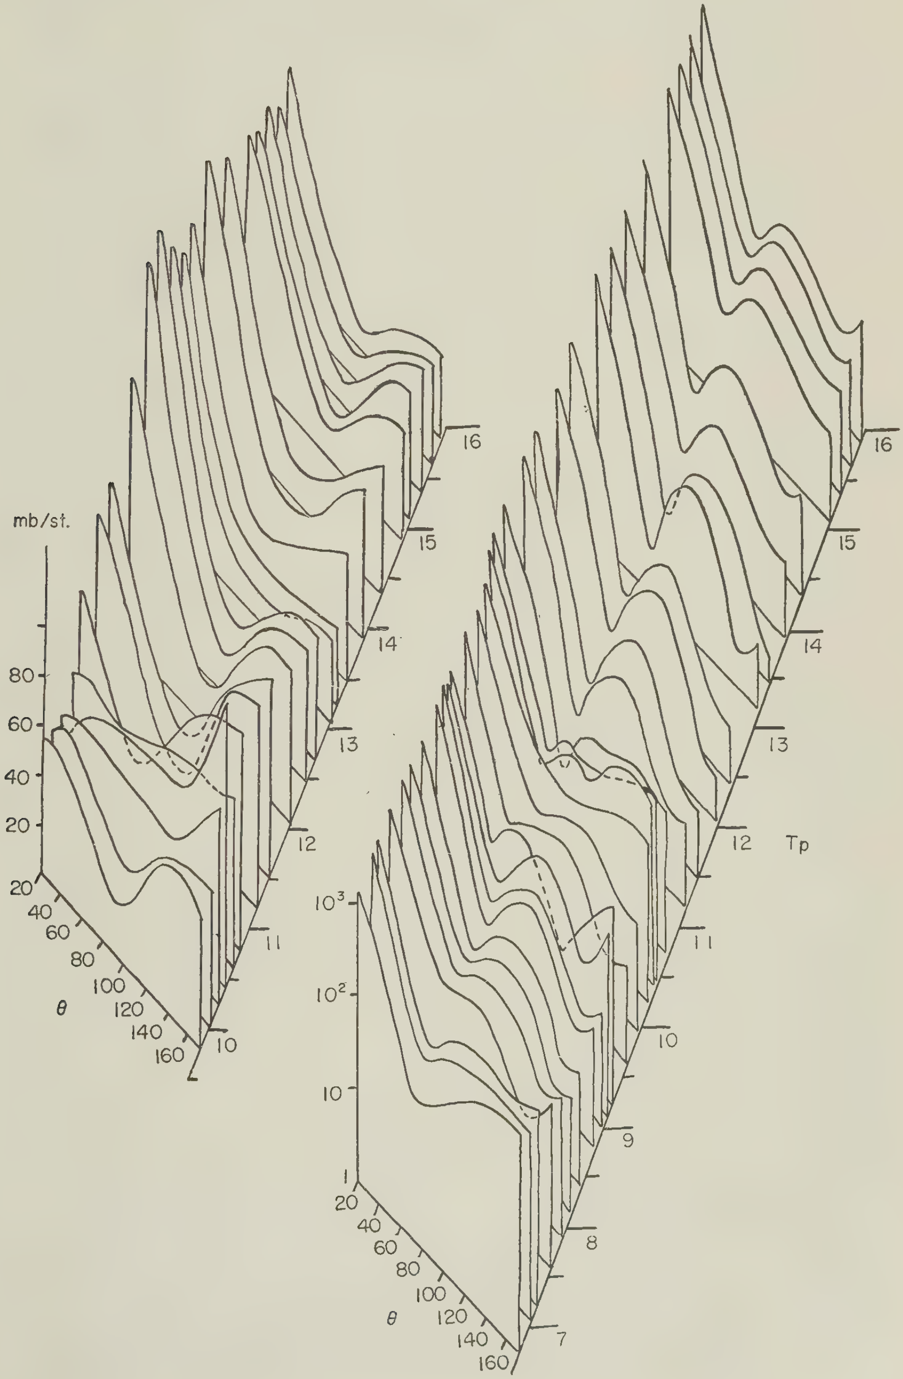

Fig. 4. Angular distributions of the elastic and inelastic ($Q=-4.43$ Mev) scattering.

T_p (Mev)—Proton energy at the center of the target; relative error ~±30 kev; absolute error ~±30 kev. All in lab. system.
Cross-section (mb/sterab)—In the center of the system.
δ_1 in parenthesis; δ_2 in the last column. Both in %.
θ (degree)—Scattering angle in the center of mass system.

2) *Self-consistency of our results*

The first check is done on the reproducibility of our results. The energy region ranging from 11.25 Mev to 10.60 Mev was doubly scanned in different days and both results were found to be quite consistent.

The second check is on the smooth joining of CH_2 foil results and CH_4 gas results. As is shown in Fig. 5 to 9, it is quite apparent that the excitation functions join together smoothly (for $\theta_{\mathrm{Lab}}=125°$ and $155°$, it must be take into consideration that the gas results are $120°$ and $150°$, respectively).

After all, we can conclude that our results are self-consistent.

3) *Comparison with other experiments*

Referring to Fig. 5 to 10, it is quite obvious that our results are in good agreement with those of Peelle ($T_p=14.0$, 14.7, 15.2 and 15.6 Mev) and of Conzett ($T_p=12$ Mev) in both the elastic and inelastic scattering[16), 17)].

Fisher's results ($T_p=9.94$ Mev) have no

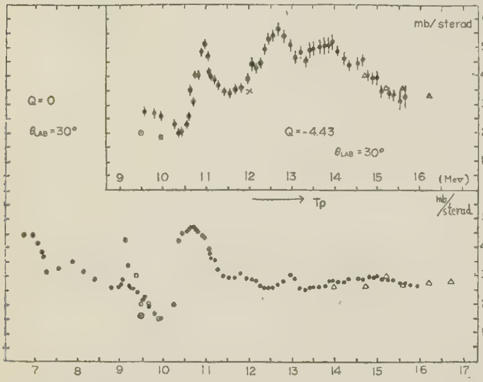

Fig. 5. Excitation functions of the elastic and inelastic scattering ($Q=-4.43$ Mev) at $\theta_{\mathrm{lab}}=30°$. Notations; ● present results, △ Peele, ○ Gibson et al., × Conzett, ⊙ Burcham et al., ⊡ Fisher.

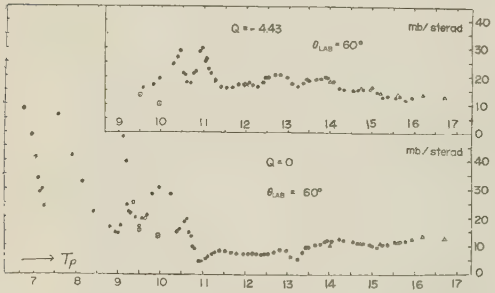

Fig. 6. Excitation functions of the elastic and inelastic scattering ($Q=-4.43$ Mev) at $\theta_{\mathrm{lab}}=60°$. Notations; see Fig. 5.

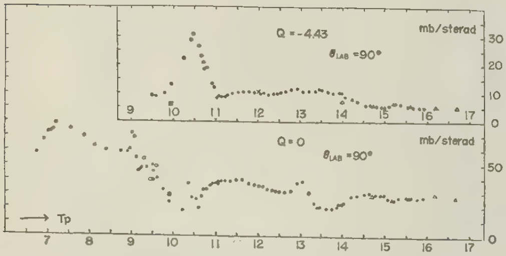

Fig. 7. Excitation functions of the elastic and inelastic scattering ($Q=-4.43$ Mev) at $\theta_{\mathrm{lab}}=90°$. Notations; see Fig. 5.

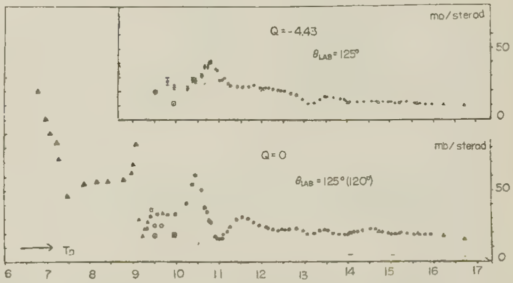

Fig. 8. Excitation functions of the elastic and inelastic scattering ($Q=-4.43$ Mev) at $\theta_{\mathrm{lab}}=125°$ for $T_p>9.80$ Mev and at 120° for $T_p<9.65$ Mev. Notations; see Fig. 5.

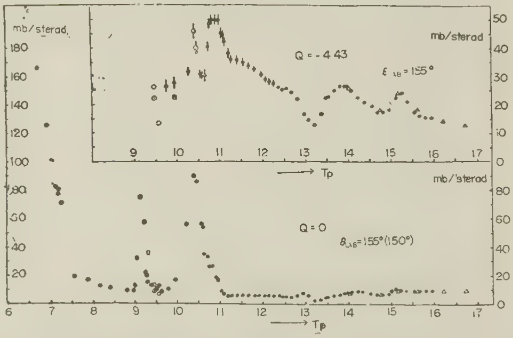

Fig. 9. Excitation functions of the elastic and inelastic scattering ($Q=-4.43$ Mev) at $\theta_{\mathrm{lab}}=155°$ for $T_p>9.80$ Mev and at 150° for $T_p<9.65$ Mev. Notations; see Fig. 5.

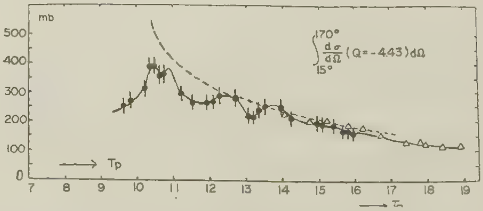

Fig. 10. Integrated partial cross-sections $\int_{15}^{170}\frac{d\sigma}{d\sigma}\cdot d\sigma$ for the inelastic scattering ($Q=-4.43$ Mev). Notations; see Fig. 5.

counterpart in ours[18]. For elastic scattering, his results most resembles to our 9.80 Mev run. As to the inelastic scattering, his angular distribution shape is quite similar to ours but the absolute values amount to only 0.6 times of ours.

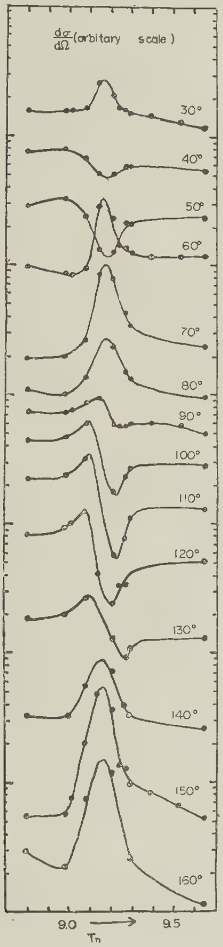

Fig. 11. Behavior of the elastic scattering around $T_p=9.1$ Mev.

The angular distribution of the elastically scattered protons by Burcham et al. at $T_p=9.5$ Mev[21], shows rather good agreement with our $T_p=9.5$ Mev run, but their absolute values are larger than ours about a factor of 1.2.

The results of the elastic scattering by Greenlees et al. at $T_p=9.37$ Mev[30] fall between our 9.29 Mev run and 9.26 Mev run.

The results by Gibson et al. for the elastic scattering at $T_p=9.58$, 9.49 and 9.45 Mev[20] are in good fit with ours. The inelastic scattering at $T_p=9.58$ Mev, however, shows rather large difference at backward angles.

As to the above-mentioned three cases, if we take into account of the uncertaintly involved both in beam energy and absolute value, we can say that good agreement exists.

Braid and Yntema[23] reported the existence of the large anomaly around $T_p=10.8$ Mev which occurs in our results around $T_p=10.5$ Mev. As the detailed report has not yet been available, further comparison will be postponed.

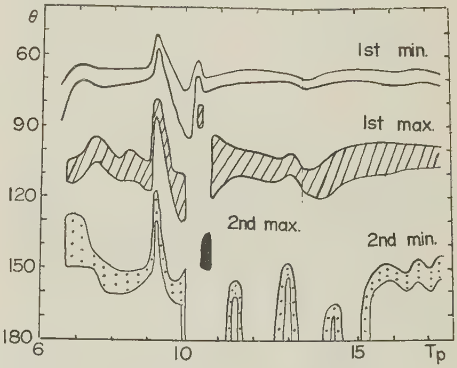

Fig. 12. Variation of the angular distribution shape of the elastic scattering with the proton energy. For detailes, see the top of paragraph 4) of § V.

4) *Qualtative description of the results*

To clarify the variation of the angular distribution of the elastic scattering with energy, in Fig. 12, the angular band, where the differential cross-sections differ by less than some percent (say, 5%) from those at the 1st minimum, 1st maximum, 2nd minimum and 2nd miximum in the angular distribution curve, are drawn against T_p, including those obtained by Peelle. From this figure, it seems reasonable to divide the whole energy region investigated into following four; $T_p>11.2$, $11.2>T_p>10$, $10>T_p>7$ and $T_p<7$ Mev.

a) $T_p>11.2$ Mev

For elastic scattering, the angular distribution is of diffraction type and the positions of the 1st minimum and 1st maximum are roughly constant. This means that the main feature of the elastic scattering is determined by the "shape" of the nucleus. Moreover, the presence of the 2nd minimum seems to become stable for $T_p>15$ Mev, but intermittent for $T_p<15$ Mev. This may suggest that some partial wave (e.g. $l=3$) becomes to participate to the reaction constantly for $T_p>15$ Mev, which may reflect the level structure of the compound nucleus N^{13}. Excitation function show small anomaly around 15.1 Mev.

The inelastic scattering for $T_p>15$ Mev has a smooth U-type angular distribution with forward-backward asymmetry which was first discovered by Peelle. σ_t (integrated partial cross-section) shows a small stagnation around 15.1 Mev and monotone decrease with increasing energy.

For $T_p<15$ Mev, several anomalies are observed around 13 Mev. For $14.2>T_p>13.5$, the positions of the 1st minimum and maximum shift backward and the width of the angular band becomes broader. The excitation functions of the elastic scattering show small depression and, on the other hand, those of the inelastic scattering show small bump. Rather clear bump is seen in σ_t. As will be seen later, this mutual compensating behavior of the elastic and inelastic scattering holds in every anomalous region.

For $13.5>T_p>12.7$, the diffraction pattern shifts forward and the excitation functions show rather sharp peak, for elastic scattering. On the other hand, the angular distribution of the inelastic scattering exhibits a strong forward-backward asymmetry; e.g., at $T_p=13.21$ Mev, the angular distribution is substantially flat for $\theta>90°$.

Fairly distinct anomaly accurs around 12.5 Mev, where the inelastic scattering becomes large. Its angular distribution gradually recovers from the above-mentioned strong forward-backward asymmetry.

For $12.0>T_p>11.2$, the most remarkable feature is that the variations are fairly gradual. The inelastic scattering continues to go on towards the 90° symmetry shape and between 11.8 Mev and 11.2 Mev, approximate 90° symmetry is established.

b) $11.2>T_p>10$

Drastic variations occur. With decreasing energy, the diffraction pattern disappears, and the angular distribution of the inelastic scattering varies violently (Fig. 4a and 4b). σ_t becomes very large (about 380 mb) and has some structures.

c) $10>T_p>7$

At about 10 Mev, elastic scattering recovers the diffraction pattern and the inelastic scattering establishes another stable 90° symmetrical shape, which was first observed by Gove and Stoddard at $T_p=7.26$ Mev[19] and later by Fisher[18], Burcham et al.[21] and Gibson et al.[20].

Around $T_p=9.1$ Mev, the elastic scattering shows very sharp anomaly. Its angular distribution shifts strongly forward and gives typical resonance-like excitation functions (see Fig. 11).

For $8.9>T_p>7.0$, the elastic scattering varies slowly. Here, it must be noted that the behavior of the excitation functions strikingly resembles to those in the region above the 10.5 Mev large anomaly at each angle.

d) $T_p<7$

This region is the higher energy side tail of 6.65 Mev broad anomaly which corresponds to the 8.08 Mev broad level of N^{13}. Here, it must also be noted that the behavior is quite similar to 10.5 Mev large anomaly.

§ 6. Qualitative Discussions

1) *Correlation between elastic and inelastic scattering*

As is clear from the foregoing descriptions, there exist remarkable correlations between elastic and inelastic scattering.

As already pointed out, the excitation functions of the inelastic scattering behave in compensating manner to those of the elastic scattering. This is one of the most striking features in the proton-carbon reaction in the energy region here investigated. In fact, in the similar experiments on $O^{16}+p$[6], $Ne^{20}+p$[6] and $Mg^{24}+p$ reactions[7] carried on at INS in the same energy region, no such marked correlations have not been found. The existence of this correlation may be attributed to the non-existence of the other open channel of large yield.

Next, when the inelastic scattering cross-section shows a bump, the diffraction pattern of the elastic scattering shifts backward and grows shallower, as is most obviouse around $T_p=13$ Mev. This feature would lead us to remember the optical model interpretation in which the optical potential varies with proton energy. But, as will be seen in the next paragraph, this energy region rather belongs to the resonance region and also the obtained cross-sections are not the averaged ones. So, we cannot literally adopt the optical potential interpretation.

Table III. Resonance levels of the compound nucleus N^{13}

C^{13}			N^{13}			
E_x (Mev)	Γ (kev)	Decay	T_p (Mev)	E_x (Mev)	Γ (kev)	Decay
(8.33)	1000	n	(6.65)	(8.08)		
10.76						
10.94			9.1*	10.4*	150	(*p*, *p*)
11.97	70					
12.21	140		10.5*	11.6*	700	(*p*, *p*) and (*p*, *p*) group of 3(?) levels
12.24	140					
13.41	50		12.5*	13.5*	500	$(p, p) < (p, p')$
13.77	280		13.2*	14.2*	500	$(p, p) > (p, p')$
14.1	210		13.7*	14.6*	500	$(p, p) < (p, p')$
16.1			15.1*	15.9*		(*p*, *p*) and (*p*, *p'*)

*s denote the new levels proposed by us. For other levels, see Ref. 31).

2) *Comparison with $C^{12}+n$ system*

In Fig. 13, the excitation functions of the related reactions are drawn against the excitation energy of the compound nucleus C^{13} and N^{13} [31].

Striking similarity is found between curve d) and e), though d) is of σ_t and e) is of excitation functions at some angle. Moreover, curves e) and f) also correspond each other, and further, all the anomalies which were discovered in our experiment have their corresponding part in the reactions which pass through C^{13}. Also, it is noted that the excitation function of pure reaction $Be^9(\alpha, n)C^{12}$ shows the corresponding anomalies.

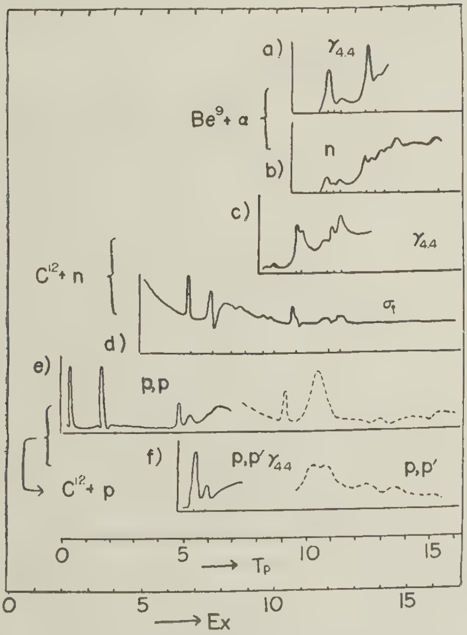

Fig. 13. Excitation functions of the related reactions via the compound nucleus N^{13} and C^{13}. Dotted lines—our results. Full lines—reproduced from reference 31).

Consequently, we can conclude that the discovered anomalies in $C^{12}+p$ reaction are in close relation to the resonance levels of the compound nucleus N^{13}. Table III tabulates the newly found levels. But, as the beam energy resolution is of order of 1% ($\sim\pm100$ Kev) and also as any detailed analysis has not been made, the tabulated figures should not be considered to be decisive.

3) *Qualitative comparison with theory*

a) Inelastic scattering

It may be a very interesting matter to investigate how the various mechanisms of the direct process can explain the experimental evidences, especially in the energy regions which lie between the anomalies where the direct process could be expected to be predominant.

For $T_p > 11$ Mev, the results obtained by Levinson and Banerjee (shell model, volume direct)[14], Glendinning (shell model, surface direct)[15] and Hayakawa and Yoshida (collective model, surface direct)[9] can be compared with our results. They all show roughly good, though qualitative, agreement. Whether they can also explain the gradual variation with energy of the angular distribution or not, is one of the remaining problems. As to the total cross-section, the result of Levinson and Banerjee only is now available, which excellently reproduces the general trend of the experimental σ_t. (See Fig. 10).

As to the other stable pattern of Fisher type ($T_p < 10$ Mev), Fujimoto and Sasagawa[32] has tried to realize it theoretically. More extensive studies are desired.

Braid and Yntema[23] investigated (p', γ) angular correlation around the 10.5 Mev large anomaly and found that the symmetrical axis shifted away largely from the recoil nucleus direction, which might suggest either the predominancy of the compound process or the strong distortion of the proton wave in the direct process. Angular correlation measurements are now in progress at INS in several energy regions selected by the inspection of our results.

b) Elastic scattering

Many calculations have been performed on the elastic scattering of nucleons from light potential nuclei using the optical of various type. The common features are as follows; 1) they cannot obtain good fit for the backward angular distribution, 2) the imaginary part is large (say, 4 Mev for carbon).

Now, in spite of the fact that our energy region is surely included in the resonance region, the averaged feature of the angular distribution roughly exhibits the diffraction type pattern (Fig. 12). This is the evidence advantageous to the optical model. The approximate constancy of the positions of the 1st minimum and maximum against the energy, may be attributed either to the long wavelength of the incident protons, or to the large diffuseness of the carbon nucleus.

At the same time, however, it is to be noted that the individual angular distribution (that is, not averaged) has the diffraction type only in the off-anomaly regions. This fact suggest that the diffraction type elastic scattering, in the energy region here considered, may have its origin in the potential scattering in the old resonance theory.

As to the large imaginary part, there seems to exist the possibility that it may be the reflection of the out-of-step application of the optical potential analysis on the individual angular distribution. Or, it may be the true reflection of the large yield of the inelastic scattering.

c) Concluding remarks

Almost all of the theories ever presented treat the elastic and the inelastic scattering separately. In other words, the reaction from the inelastic events on the elastic scattering is not explicitly formulated in them.

A. Bohr and Mottelson[33] solved the elastic scattering of nucleon by properly taking account of the reaction from the collective mode excitation, and Yoshida has succeeded to give general and compact formalism for the unified treatment of the elastic and inelastic events[10),13)]. He showed that 1) the reaction yield was distributed among the elastic and inelastic events according to the degree of the matching of the wave functions of the various channels, 2) giant anomaly could occur which was interpreted as the virtual trap of the incident nucleon in the surface interaction potential, 3) the perturbation treatment was not a good approximation to the exact solution. So, his theory has many promising characters for the explanation of our results, where the large yield suggests that the 1st excited state of C^{12} is of collective nature*.

If this theory can explain the experimental evidences, the level structure of the compound nucleus (C^{13} or N^{13}) will also have the possibility to be interpreted based upon the picture in which the excited states are formed by the C^{12} core excitation and the single particle excitation of the extra nucleon in the potential formed by C^{12} core or its excited states**. This possibility has already been proposed by Reich et al. for the 6.4 and 6.9 Mev levels of N^{13} as a doublet[34].

§ 7. Acknowledgements

We wish to express deep thanks to Prof. I. Nonaka and the members of the Low Energy Group of the Institute for Nuclear Study for their hospitality and many valuable discussions. Deepest thanks must be expressed to Drs. K. Matsuda and S. Kobayashi for their kind guidance and support without which this study could not be performed. Thanks are also given to Prof. Y. Oda and Mr. N. Yamamuro for their active participation in obtaining data and their kind help. Our thanks have to be given to the members of the Electronics Division of INS for their kind co-operation. We are very glad to express our deep thanks to the INS cyclotron crew for their excellent operation and their contact co-operation throughout this study.

---

* We owe much to Profs. S. Yoshida and T. Tamura for their kindly pointing out the importance of Yoshida's theory.

** We owe to prof. Morinaga for his encouraging discussions on this point.

We wish to express our thanks to Profs. H. Shimazu and T. Tamura for their elucidating discussions in the theoretical field. Our thanks are also given to Prof. M. Takeuchi for his continuous encouragement on this study.

Short-lived Activity of Ag^{106}

By Mitsuo SAKAI, Hidetsugu IKEGAMI and Toshimitsu YAMAZAKI

Institute for Nuclear Study, University of Tokyo, Tokyo, Japan

(Received June 25, 1960)

24-min Ag^{106} was produced by (n, 2n) reaction. New gamma rays of 295, 450, 625, 883, 1045, 1190, 1398, 1525, 1730, 1880 and 2170 KeV were observed with scintillation gamma-ray spectrometer. These gamma rays were compared with those appearing in the decay of Rh^{106}, Rh^{106m} and Ag^{106m}. The beta transition to the second excited level was discussed in light of the new beta-decay selection rule.

§ 1. Introduction

24-min Ag^{106} has been known[1] to emit two components of positrons and one gamma ray. Recently the spin of this isotope was measured[2] by atomic-beam methods and found to be $I=1$. The excited levels of the daughter nucleus Pd^{106} have been well investigated from the decay of 30-sec Rh^{106} which is produced by the decay of parent 1.0-year Ru^{106}[3] and also from the decay of 130-min Rh^{106m}[4] and 8.3-day Ag^{106m}[5]. The spins of the low excited levels were measured by gamma-gamma angular correlation measurement[6] and Coulomb excitation experiment[7]. The decay scheme proposed from these informations is shown in Fig. 1.[8] Since 24-min. Ag^{106} is now found to have the same spin as that of Rh^{106}, of which the decay involves many gamma rays as shown in Fig. 1, a rather complicated decay scheme could be expected also for 24-min. Ag^{106}. The simple decay scheme known up to the present is contrary to this prediction. Therefore, it was thought worth while to undertake once again study of this isotope by using the scintillation techniques developed since the previous publication[1] appeared in 1953.

§ 2. Source Preparation

24-min Ag^{106} was induced by bombarding silver metal with fast neutrons in the INS cyclotron which were produced by the bombardment of a carbon target with 22-MeV deuteron beam. The silver metal was inserted behind the carbon piece. Hence, the reaction utilized was Ag^{107}(n, 2n)Ag^{106}. Since the bombardment may induce also 8.3-day Ag^{106m}, 2.3-min Ag^{108}, 24.2-sec Ag^{110} and 270-day Ag^{110m}, the bombardment was done for twenty minutes and the measurement started ten minutes after the end of the bombardment.

§ 3. Gamma-Ray Scintillation Spectrometry

The gamma-ray spectrum was measured by means of three scintillation spectrometers. The first consisted of a cylindrical NaI(Tl) crystal, 2-in. long and 1^3/$_4$-in. in diameter, coupled to an RCA 6342 photomultiplier, the second of a cylindrical NaI(Tl) crystal, 3-in. long and 3-in. in diameter, coupled to a Dumont 6363 photomultiplier and the third of a cylindrical NaI(Tl) crystal, 4-in. long and 4-in. in diameter, coupled to a Dumont 6364 photomultiplier.

3.1 *Single Spectrum*

Fig. 2 shows the single spectrum taken by a gamma-ray scintillation spectrometer with 4-in. NaI(Tl) crystal. In this case, the source was placed 10 cm in distance from the front of the scintillation crystal, and the gamma rays were collimated by a Pb shield with a hole of 20-mm diameter. From this spectrum gamma rays of 295, 450, 510, 625, 883, 1045, 1190, 1398, 1525, 1730, 1880 and 2170 KeV were noticed. Some of these peaks may be composite peaks. These gamma rays were compared with those appearing in the decay of Rh^{106}, Rh^{106m} and Ag^{106m} (see Table I). The radiation caused by the annihilation of positrons in flight[9] may contribute to the pulse height distribution above 0.51 MeV. However, this effect was not found to change the main feature of the spectrum.

The decay of each peak was followed and found to have the same half-life of 24 min. within the experimental error, except 625 KeV peak. The latter peak had a fast component due to Ag^{108}. Decay curves were presented in Fig. 3.

In order to check the possibility of the sum peak or the pile-up peak, a Pb absorber of 12.5 mm thickness was placed between the source and the crystal. The counting rates N_a and N_i with and without the absorber were

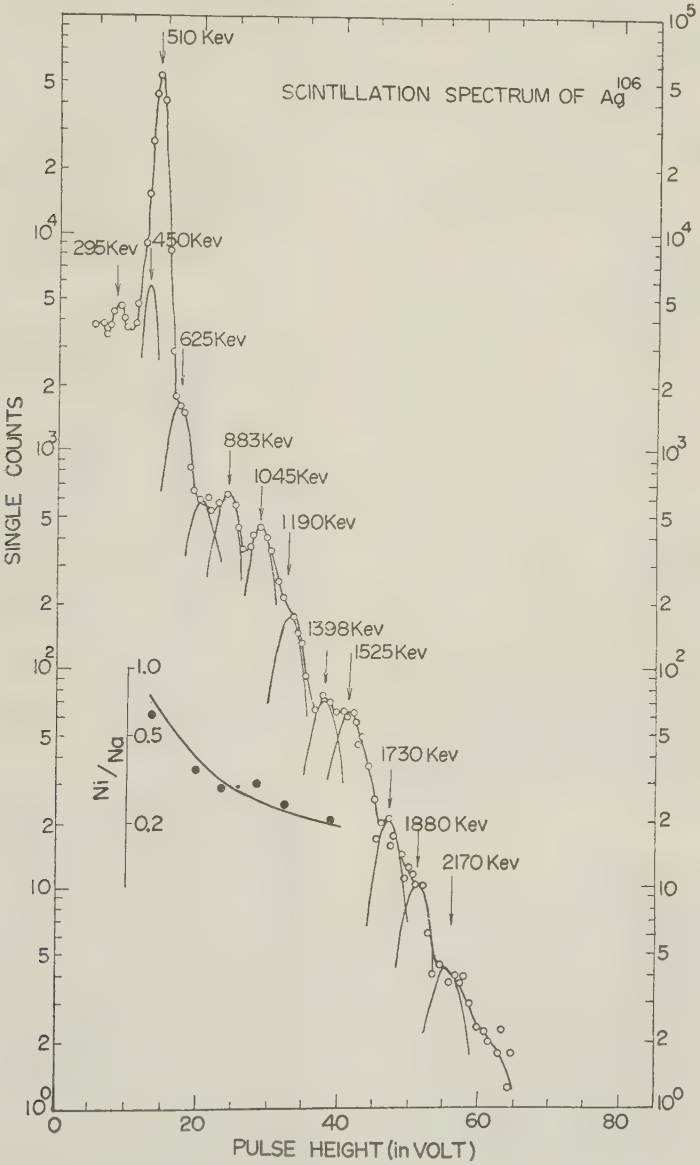

Fig. 2. Single gamma-ray scintillation spectrum taken by 4-in. diameter 4-in. long NaI(Tl) crystal. The full line in the under part of the figure shows a theoretical absorption ratio N_i/N_a with a Pb absorber of 12.5 mm thickness where N_a and N_i are the counting rates with and without the absorber, respectively. The circles are the experi-mental ratio N_i/N_a.

measured and the ratio N_i/N_a was compared with the theoretical absorption curve. The comparison was shown in Fig. 2. Although we could notice a slight contribution of sum peak about at 1.05 MeV resulting from the strong 0.51 MeV peak, it was concluded that the spectrum was caused by genuin gamma rays.

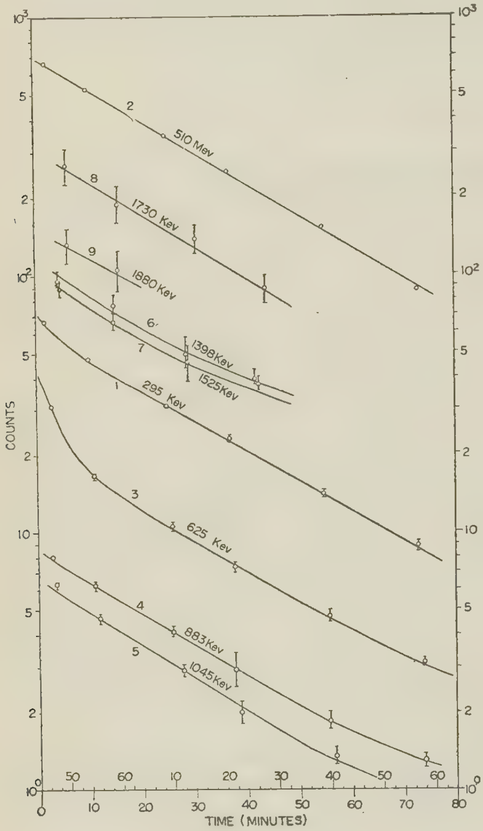

Fig. 3. Decay of scintillation spectrum.
Each curve concerns the decay of pulse height indicated in Fig. 2.

3.2 *Coincidence Spectrum*

For the coincidence experiment a conventional slow coincidence circuit of $2\tau=1.1\,\mu$s was used. The main and gate system used were a $1^3/_4$-in. diameter 2-in. long NaI(Tl) crystal with an RCA 6342 photomultiplier and a 3-in. diameter 3-in. long NaI(Tl) crystal with a Dumont 6363 photomultiplier, respectively. Fig. 4 shows the coincidence spectrum with the reference gate set at 0.51 MeV gamma ray which presents both of the annihilation radiation and the 0.51 MeV gamma ray. The ratio of the true coincidence rate N_{tr} to the accidental coincidence rate N_{ac} is also plotted in Fig. 4. A nearly constant ratio was obtained above 0.6 MeV. This fact means that the gamma rays of the energy higher than 0.6 MeV has about the same genetic relation with that of the 0.51 MeV.

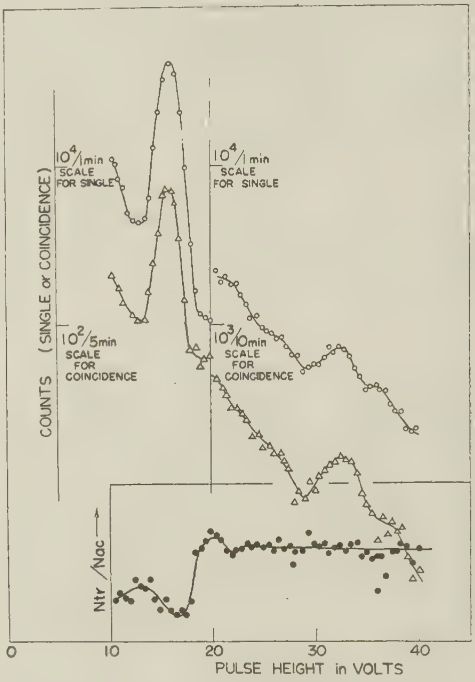

Fig. 4. Coincidence spectrum (—△—△—) with the reference gate set at 0·51 MeV peak. The spectrum in the right-hand side has an experimental set-up with a larger solid angle than that in the spectrum of the left hand-side. The in-set in the under-part is the ratio N_{tr}/N_{ac}, where N_{tr} and N_{ac} are the counting rate of the true coincidence and the accidental coincidence, respectively.

§ 4. Discussion and Conclusion

As we can see in Table I, the gamma radiations which have been expected from the decay of Rh^{106}, Rh^{106m} and Ag^{106m} were also found in the decay of Ag^{106}, so that the contradiction mentioned in § 1 disappears.

In the recent study[10] we had a new selection rule on the beta transition from odd-odd nuclei which can be described as follows: In general, nuclei having the spin and parity of 1+, 2+ or 3+ is hindered to decay to the second 2+ level, while the decay to the first 2+ and to the first or second 0+ level is allowed. Therefore, it is very interesting to study intensity relation of the beta transitions to 0+ and 2+ doublet at about 1.1 MeV excitation energy.

In the present case, the problem can be reduced partly to the determination of the intensity of 625 KeV and 607 KeV gamma rays, which are emitted by $0+\rightarrow 2+$ and $2+\rightarrow 2+$ transitions.

Table I. Gamma Rays in De-excitation of Pd^{106}

Parent Nucleus	Rh^{106}	Rh^{106m}	Ag^{106m}	Ag^{106}
Half Life	30s.	130 min	8.3d	24 min
Spin and Parity	1+	—	6	1+

12	1205	1225	1205	
13		1380	1225 1388	1398
14	1540	1550	1530	1525
15	1760	1760	1720	1730
16		1860	1850	1880
17	1960			2170
18	2100	2090	2100	
19	2370	2260		
20	2660		2630	

Therefore, the pulse-height spectrum in the region of 510 KeV peak was carefully analysed. First, the Compton tail resulted from the gamma rays of higher energy than 625 KeV was subtracted. Then, the remained spectrum which is presented in Fig. 5 was compared with the 510 KeV anihilation peak of Na^{22} which was obtained by the subtraction of Compton tail of 1.28 MeV gamma ray. We can see clearly both of 450 KeV and 625 KeV peaks. The expected peak position of 607 KeV gamma ray was indicated by the arrow. From this analysis, we were lead to conclude that, if 607 KeV gamma ray exists, its intensity is weaker than that of 625 KeV gamma ray. This fact may suggest that the third beta component mainly consists of the decay to the 0+ level. It is consistent with the new beta-decay selection rule.

The author's thanks are due to Drs. H. Morinaga and K. Sugiyama for the kindful collaboration for the bombardment of fast neutrons.

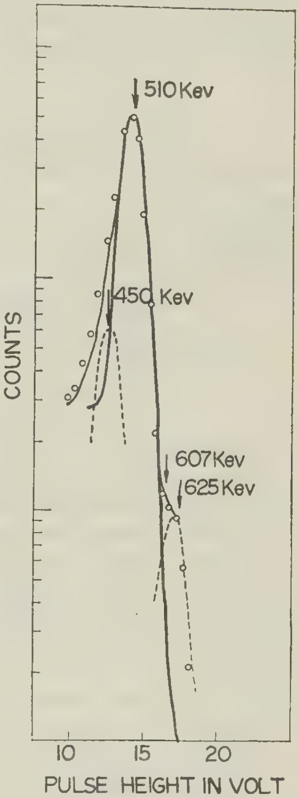

Fig. 5. Analysis of the pulse-height spectrum in the region of 510 KeV peak.

Open circles are the experimental points. The broad line is the pulse height spectrum of 510 KeV annihilation radiation of Na^{22} obtained by subtracting the tail of 1.28 MeV gamma ray. The expected peak position of 607 KeV gamma ray is indicated by the arrow.

Counting Efficiency of Gamma Rays in Counter Tubes

By Tatsusaburo SUZUKI and Jiro YUHARA

First Research and Development Center Technical Research and Development H. Q., Japan Defense Agency, Tokyo

(Received September 6, 1960)

The counting efficiency of gamma rays in cylindrical counters and end-window counters is examined by means of a very thin sheet and a collimated fine pencil beam of gamma rays. The distribution of the number of gamma rays emitted from the thin slit is measured by means of a end-window counter or by the effect of the fine anode wire of the cylindrical counter. When the plane of thin sheet of gamma rays reaching from side to a cylindrical counter is parallel to the axis, the counting efficiency registers a maximum value at the position where the sheet of gamma rays is in contact with the inner surface of the counter, and a smaller value near the central wire, but when the pencil beam of gamma rays is parallel to the anode wire and the gamma rays entering the counter through the end-window plate, the counting efficiency gives a maximum value at the anode wire and the inner surface of the counter. An average efficiency for a sheet of gamma rays which are in a plane perpendicular to the counter axis is also investigated.

§ 1. Introduction

Investigations have been performed on the counting efficiency near the ends of the counter[1),2)]. In the present work the collimated gamma rays (energy 0.662 MeV) are used to study the efficiency of the central portion of cylindrical counters and the variation of efficiency with distance from the anode wire in the end-window counters.

Because the range of the Compton-electrons or photo-electrons emitted by the interaction of 0.662 MeV gamma ray is greater than that by soft X-rays, many electrons from counter wall and anode wire can enter the counter. Therefore, the counting efficiency mainly depends upon the number of Compton-electrons or photoelectrons emitted from the counter wall. A sheet of gamma rays emitted from a slit, 0.25 mm wide and 8 mm long, and a fine pencil beam (1 mm × 1 mm) of gamma rays are used to study the variation of the efficiency with the distance between the gamma sheet the anode wire and or the distance between the anode wire and the fine gamma pencil beam. Using this method, the efficiency of the Geiger counter was compared with that of the proportional counter.

§ 2. Experimental Arrangements and Procedures

This experiment was counducted by using a stainless steel flow counter (radius of the anode wire $r_w=0.025$ mm, external radius $r_e=30$ mm, internal radius $r_c=25$ mm) and end-window counters (TGC-2 type $r_e=18.5$ mm, $r_c=16.5$ mm, TEN GM 132 type $r_e=22.7$ mm, $r_c=10$ mm and halogen quenched philips 18514 type $r_e=15.1$ mm, $r_c=13.0$ mm) as shown Fig. 1.

A Cs^{137} source which emits homogeneous gamma rays (energy 0.662 MeV) was used, the intensity being 2 curie. The CsCl gamma source is put into the cylindrical container 4 mm in diameter and 4 mm in length. The source is embedded in a lead collimating arrangement as shown in Fig. 2a and 2b.

The radiation from the source passes through an opening 8 mm in diameter and 200 mm in depth and a narrow channel (0.25 mm wide, 8 mm long and 100 mm deep) or a fine hole (1 mm × 1 mm and 100 mm deep). Thus homogeneous gamma rays parallel or perpendicular to the axis of the counter pass through the counter. The counter can be displaced accurately by the screw shown in Fig. 2a and we can measure the counting efficiency and the distribution of the number of gamma rays. The counting rate is measured at each position of the counter with a standard deviation less than a few percent.

§ 3. Experimental Results

For the purpose of measuring the intrinsic efficiency of the central portion of the cylindrical proportional counter for 0.662 MeV gamma

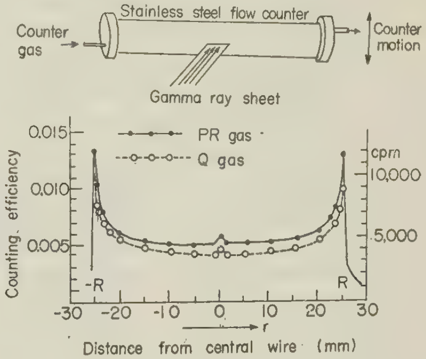

Fig. 3a. Variation of counting efficiency and counting rate with distance between central wire and gamma ray sheet. (Stainless steel flow counter)

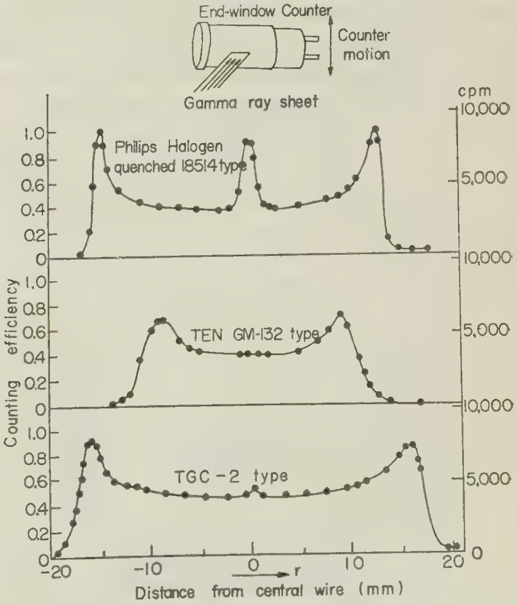

Fig. 3b. Variations of counting efficiency and counting rate with distance between central wire and gamma ray sheet. (End-window counters)

rays, the counting rates for gamma rays emitted from a 1 mc standard gamma source and enter the cylindrical counter through a lead hole (20 mm × 20 mm or 20 mm × 40 mm) are measured. The counting rates for 7.08×10^4 and 1.416×10^5 gamma ray quanta per minute which enter the counter are 358.7 and 702.6 cpm respectively. Thus the intrinsic counting efficiency of the central portion of the counter for 0.662 MeV gamma ray is 0.0050. The total number of gamma rays emitted from the thin slit per unit time is determined from the counting efficiency and the counting rate near the anode wire. The total number of gamma rays thus obtained is 9.12×10^5 gamma photons per minute.

The variation of counting rate with distance between the anode wire and the sheet of gamma rays is measured as shown in Fig. 2a. In this experiment, PR gas (90% argon and 10% methane) and *Q* gas (99% helium and 1% isobutane) were used in the same stainless steel flow counter. The experimental data for stainless steel flow counter is as shown in Fig. 3a, and those for end-window counters are as shown in Fig. 3b. Since the number of gamma rays crossing the counter per unit time is obtained as described above, the counting efficiency of gamma rays at each position is determined from the counting rate and the number of gamma rays passing through the counter per unit time. The counting efficiencies thus determined are also shown in Fig. 3a and Fig. 3b (left scale).

In this case the counting efficiency mainly depends on the number of Compton-electrons and photoelectrons emitted into the counter gas from the wall material per unit time. The smaller the angle between the inner surface of the counter and the sheet of gamma rays, more electrons are emitted into the counter. Thus each counting efficiency curve gives two maximum values at the position where the sheet of gamma rays is in contact with the inner surface of the counter. The increased counting efficiency due to the anode wire in efficiency curve in Fig. 3a is shown in Fig. 4. This curve can show the distribution of gamma rays along 0.25 mm width. When the stainless steel counter is used as a flow counter, the counting efficiency of gamma rays depends on the atomic number of the gas, in view of their absorption coefficient. The difference of counting efficiency in proportional and Geiger counters at the same position depends on the traveling distance of the gamma rays in the counter gas. This gives maximum values at the central wire, and almost zero at the position where the sheet of gamma rays comes in contact with the inner surface of the counter as shown in Fig. 3a.

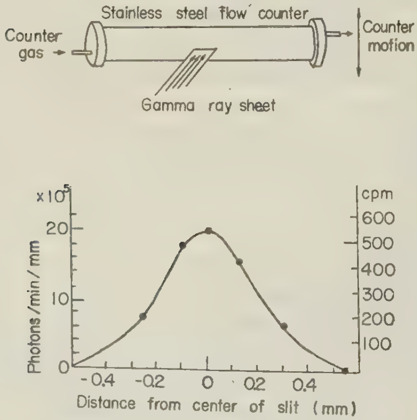

Fig. 4. Counting rate due to the electrons emitted from central wire which can show the distribution of number of gamma rays along 0.25 mm slit width.

When a fine pencil beam of gamma rays is parallel to the axis of an end window counter

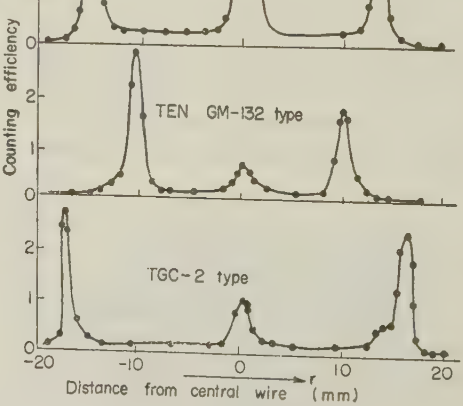

Fig. 5. Variations of counting efficiency with distance between central wire and center of gamma ray pencil beam. (End-window counter)

the efficiency gives three maximum values as shown in Fig. 5. In this case the counting efficiency registers a large value at the central wire of the counter because the fine beam is parallel to the anode wire and a great number of Compton-electrons and photoelectrons are emitted from both anode wire and the glass bead attached to the end of the wire.

For the purpose of measuring the counting efficiency for collimated gamma ray sheet end-window Geiger counters along their axes, the counters are moved in a direction of their axes as is shown in Fig. 6. The experimental results are as shown in Fig. 6.

The distribution of the number of gamma ray sheet from the slit along its 8 mm length is determined from the number of gamma rays per unit time and the counting rate which is measured as shown in Fig. 2b. The experimental data obtained is as shown in Fig. 7.

To measure the average counting efficiency or the counting rate for gamma rays whose distribution is as shown in Fig. 7., the counter is moved in the plane of gamma ray sheet. This arrangement is shown in Fig. 8. Fig. 8 also shows the observed counting rate (scale

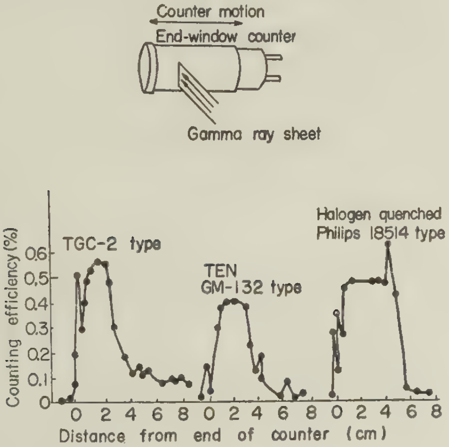

Fig. 6. Counting efficiency for collimated gamma ray sheet moved parallel to the axis of end window counter.

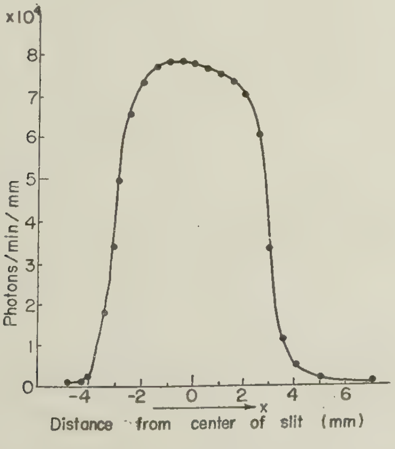

Fig. 7. Distribution of number of gamma rays emitted from slit along its 8 mm length.

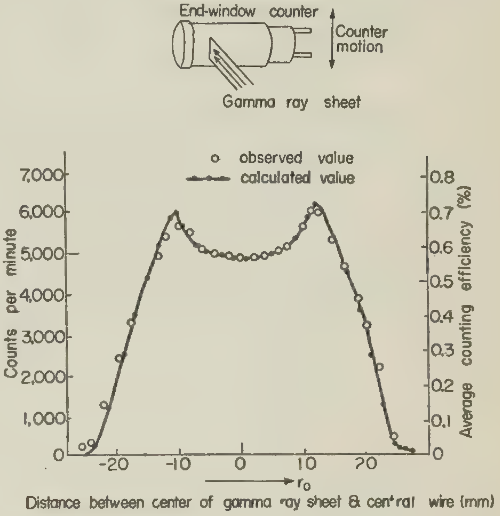

Fig. 8. Variation of counting rate or average counting efficiency for collimated gamma ray sheet whose distribution is shown in Fig. 7. (TGC-2 type counter)

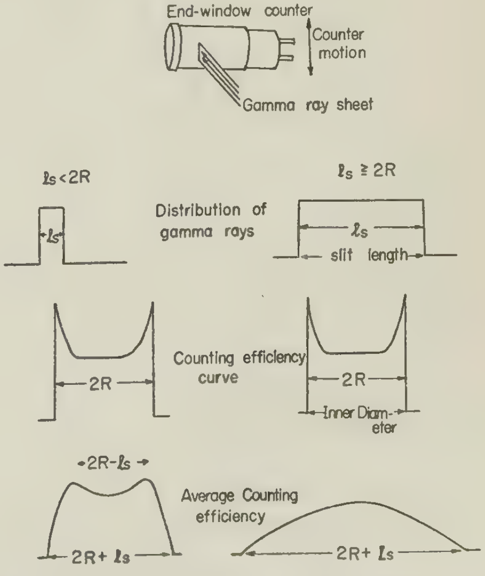

Fig. 9. Relation of average counting efficiency and slit length.

left) or the average counting efficiency (scale right). This result can be also obtained from the counting efficiency shown in Fig. 3b and the distribution of number of gamma rays in Fig. 7. If the counting efficiency shown in Fig. 3b is represented by $E(r)$ and photons per unit length per unit time shown in Fig. 7 is represented by $D(x)$, where r is the distance from the central wire and x is the distance from the center of the slit, the counting rate $C(r_0)$ at r_0 can be formularized as

$$C(r_0)=\int_{-\infty}^{\infty} D(x)E(r_0+x)dx\ .$$

The numerical integration is calculated from Fig. 3b and Fig. 7, and is compared with the observed counting rate as shown in Fig. 8.

When the distribution of the number of gamma rays is uniform as shown in Fig. 9, the average efficiency has two maximum values at the positions separated at $2R-l_s$ distance if the length of slit l_s is shorter than the inner diameter $2R$ of the counter, but the average efficiency gives only one maximum value at the center as shown in Fig. 9 if the length of slit is equal or larger than the inner diameter.

§ 4. Conclusion

It is important to know that the counting efficiency gives variation to positions when counters are used to measure gamma rays, and especially when they are collimated. The distribution of the number of gamma rays emitted from a thin slit can be measured by means of the increased local counting efficiency due to the anode wire of the counter.

On the Protons from the $N^{14}(d, p)N^{15}$ Reaction

By Nawoyuki KAWAI*

Department of Physics, Kyushu University, Fukuoka, Japan

(Received October 6, 1960)

Angular distributions for the $N^{14}(d, p)N^{15}$ reaction were investigated at nine deuteron energies ranging from 1.5 to 3.2 MeV. Measurements were carried out in the angular range from 0 to 165 degrees at intervals of 15 degrees. The results for the $N^{14}(d, p)N^{15}$ ground state reaction showed generally a forward peak, as was expected from deuteron stripping, and a considerable rise in backward directions. These experimental data were analyzed with the heavy particle stripping theory and parameters adjusted to get a best fit were obtained.

With the exception at forward directions, the main feature of angular distributions was found to be very similar to that for the $N^{14}(d, n)O^{15}$ ground state reaction, which is the mirror reaction, at the same deuteron energies. At forward directions proton yields from the $N^{14}(d, p)N^{15}$ reaction were substantially larger than neutron yields from the $N^{14}(d, n)O^{15}$ reaction.

Angular distributions for the first excited doublet state reaction were found to be nearly isotropic, but a slight peak was observed at about 60 degrees similarly at all deuteron energies.

Total cross sections for both state reactions were also estimated. Excitation functions for the $N^{14}(d, p)N^{15}$ and $N^{14}(d, n)O^{15}$ ground state reactions showed similar behavior, having some resonance-like structures.

§1. Introduction

In our previous work[1], angular distributions and absolute cross sections for the $N^{14}(d, n)O^{15}$ ground state reaction have been investigated at seven deuteron energies from 1.5 to 2.9 MeV. It has been found that the main feature of the angular distributions is a strong forward peak attributed to deuteron stripping with $l_p=1$ and a remarkable rise in backward directions. The neutron yields at backward directions varied considerably with the deuteron energy and at 1.96 MeV it reached the value of almost three times as that of the forward maximum. Retz-Schmidt and Weil[2] have made the same measurements at the energy range of deuterons from 0.91 to 5.27 MeV with larger energy intervals and obtained the similar results. It is considered, therefore, to be worthwhile to investigate the angular distributions for the $N^{14}(d, p)N^{15}$ reaction and to compare them with these for the $N^{14}(d, n)O^{15}$ reaction, which is the mirror reaction to the former, at the same bombarding energies. Such comparison will be useful for the investigation of reaction mechanisms of deuteron induced reactions in this energy region. The present investigation was undertaken to measure total cross sections and angular distributions for the $N^{14}(d, p)N^{15}$ ground state and first excited 5.28 and 5.31 MeV doublet state reactions at nine deuteron energies ranging from 1.5 to 3.2 MeV.

Up to present, the angular distributions for this reaction have been investigated by many authors at deuteron energies from 5 to 20 MeV, that is, by Gibson and Thomas at 7.89 MeV[3], Eby at 11.9 MeV[4], Green and Middleton at 9 MeV[5], Warburton and McGruer at 14.8 MeV[6], and Morita *et al.* at 16 MeV[7]. The results for the $N^{14}(d, p)N^{15}$ ground state and 6.33 MeV state reactions which were obtained by these authors could be fitted qualitatively by means of deuteron stripping with $l_n=1$. As for the 5.28 and 5.31 MeV doublet state reaction, the obtained results are contradictory to each other. Gibson and Thomas have obtained the roughly isotropic distribution indicating that the deuteron stripping did not contribute to any appreciable extent, while Eby has reported the anisotropic distribution showing a forward maximum. Unlike to their results, the angular distribution obtained by Green and Middleton had a broad maximum at about 50 degrees in consistent with the fact that one of the doublet was formed by deuteron stripping with $l_n=2$ and the other was probably isotropic.

---

* Now at Nippon Atomic Industry Group Co., Ltd., Chiyoda-ku, Tokyo, Japan.

Many measurements have also been accumulated at deuteron energies below one MeV. At 400, 500 and 600 keV, Jongerius *et al.*[8] have observed angular distributions for the ground state reaction which have appreciable forward maximum and a slight backward rise. Then, they have concluded that deuteron stripping seems to take place considerably in addition to compound nucleus formation at such lower deuteron energies as mentioned above. Booth *et al.*[9] have made the same investigations at 595, 805 and 990 keV and found the angular distributions, contradicting to those of Jongerius *et al.*, which were rather symmetrical about 90 degrees. It will be noted that in the energy region below one MeV, angular distributions for the ground state reaction become more symmetrical with increasing deuteron energy. For the 5.28 and 5.31 MeV doublet state reaction, Sjögren and Ahnlund[10] have observed the angular distributions for these state separately with a double-focusing heavy particle spectrometer. At 800 keV, their results revealed the distribution for the 5.276 MeV state reaction to have a broad maximum at about 100 degrees and that for the 5.305 MeV state reaction to have a characteristic minimum at about 80 degrees. Stanley[11] has measured the angular correlation between protons and gamma-rays emitted from the 5.28 and 5.31 MeV doublet state at the deuteron energy of 630 keV.

In the energy region of several MeV, very few investigations on the angular distributions for this reaction have been done. Wyly[12] has measured them at five different deuteron energies only in the angular range from 15 to 135 degrees. The angular distributions obtained by him for the 5.28 and 5.31 MeV doublet state reaction were essentially isotropic at every deuteron energy, while those for the ground state reaction were found generally to have a forward maximum.

§ 2. Experimental Arrangements and Procedures

Arrangements of a scattering chamber and detector are shown schematically in Fig. 1. The scattering chamber used in this experiment is 23 cm in its inner diameter and 10 cm in height. On one side of its side wall with respect to the incident beam, eleven apertures of 6 mm in diameter were bored at intervals of 15 degrees in the angular range from 15 to 165 degrees and on the other side, ten apertures with the same intervals from 22.5 to 157.5 degrees. These apertures, to which a detector system was attached directly, were sealed with 20 microns thick aluminum foils for vacuum tight. A insulated Faraday cup was mounted to measure the deuteron beam and secondary electrons were suppressed by magnetic field produced by two pieces of Ferrite. In the case of the measurement of protons emitted to zero degree, the detector system was mounted instead of the Faraday cup. In this case a silver absorber of 23 mg/cm² thick was inserted before the aluminum foil to cut off the deuteron beam.

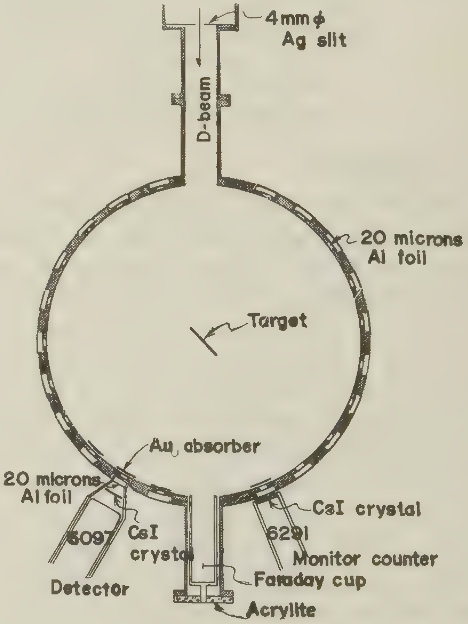

Fig. 1. Arrangements of the scattering chamber and the detector system.

As a nitrogen target, melamine ($C_3H_6N_6$) evaporated on a silver backing was used. Three targets of different thickness of melamine were prepared and these thickness were determined by weighing to be 0.30, 0.42 and 0.48 mg/cm².

Measurements were made at nine deuteron energies from 1.5 to 3.2 MeV, five of which were chosen to be almost same as those used in the previous investigation on the $N^{14}(d,$

$n)O^{15}$ reaction. The deuteron beam from the electrostatic generator at Kyushu University was magnetically analyzed and led into the scattering chamber after through a defining silver slit of 4 mm in diameter. The target was placed at the centre of the scattering chamber to make 45 degrees to the deuteron beam. The incident deuteron energy which was expected to have an uncertainly of less than 0.5 per cent was corrected for the energy loss in traversing one-half of effective target thickness. Finally, the deuteron beam was collected with the Faraday cup and was measured to be from 0.05 to 0.5 microamperes.

In order to evaluate the absolute cross sections, the excitation function for the $N^{14}(d, p)N^{15}$ reaction was measured at 15 degrees. In such case, a gas target was used instead of the melamine target. This target chamber was made of brass cylinder of 2 cm long and 2 cm in diameter and was supported with a brass pipe which served also for gas inlet. It has three windows sealed with 1.09 mg/cm² thick nickel foils, through which the deuteron beam and emitted protons pass. The mixed gas of 92.0 per cent nitrogen and 8.0 per cent deuterium was introduced into the target chamber up to 20 cm Hg pressure. Protons from these two elements are detected simultaneously. It is, then, possible to evaluate absolute differential cross sections for the $N^{14}(d, p)N^{15}$ reaction by refering to the proton yield from the $D(d, p)T$ reaction[13].

The proton detector is made of an one mm thick CsI(Tl) crystal and an EMI 6097 photomultiplier. The thickness of the CsI(Tl) crystal was chosen to be 1.0 mm so as to stop all emitted protons completely. At several angles in forward directions gold absorbers of suitable thickness are inserted, if necessary, in front of the detector to stop the elastically scattered deuterons. Output pulses from the detector were amplified and fed to a twenty channel pulse height analyzer. At 22.5 degrees, a monitor counter consisted of a 2 mm thick CsI(Tl) crystal and a Dumont 6291 photo-multiplier was mounted and its discriminator level was set in such a way that only the protons from the $N^{14}(d, p)N^{15}$ ground state reaction were detected.

§ 3. Experimental Results

Complete pulse height spectra were taken at each angle and each bombarding energy. Typical spectra of measured protons are shown in Fig. 2, (A) and (B), which were taken with the melamine and the gas target, respectively. Errors indicated in figures are those due to counting statistics only. In each spectrum a well separated group of protons of the highest energy, designated by p_0, is the one from the $N^{14}(d, p)N^{15}$ ground state reaction. p_1 corresponds to the group from the 5.28 and 5.31 MeV doublet state reaction. Because of the small difference in energy by only about 25 keV, it is not possible to distinguish separately the protons corresponding to this doublet state reaction. The group of protons emitted from the 6.33 MeV state reaction, p_2, was also clearly separated from other groups in the case of the gas target. In the case of the melamine target, however, this group is obscured by that from the $C^{12}(d, p)C^{13}$ ground state reaction and is hardly resolved. Moreover, the group of alpha-particles from the $N^{14}(d, \alpha)C^{12}$ ground state reaction was observed at forward directions. At the angles larger than 105 degrees, this group of alpha-particles overlapped on or smeared out into the groups of protons from

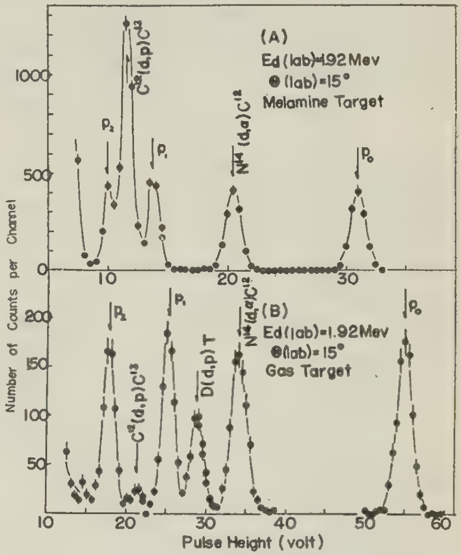

Fig. 2. Pulse height spectra of protons and alpha-particles. (A) and (B) were obtained using the melamine and the gas target, respectively. p_0, p_1 and p_2 indicate the groups of the protons from the $N^{14}(d, p)N^{15}$ ground state, 5.28 and 5.31 MeV doublet state and 6.33 MeV state reactions, respectively.

the $N^{14}(d, p)N^{15}$ and $C^{12}(d, p)C^{13}$ reactions. In such case in order to detect the protons from the $N^{14}(d, p)N^{15}$ 5.28 and 5.31 MeV doublet state reaction only, a 20 microns thick aluminum absorber was attached in front of the detector to discriminate those alpha-particles. Background protons were measured using the silver backing without melamine and it was confirmed that those having the energy in question were not observed to any appreciable extent.

From these pulse height spectra obtained at each angle, angular distributions for the $N^{14}(d, p)N^{15}$ ground state and first excited doublet state reactions are obtained. In Figs. 3 and 4, these results are shown with solid

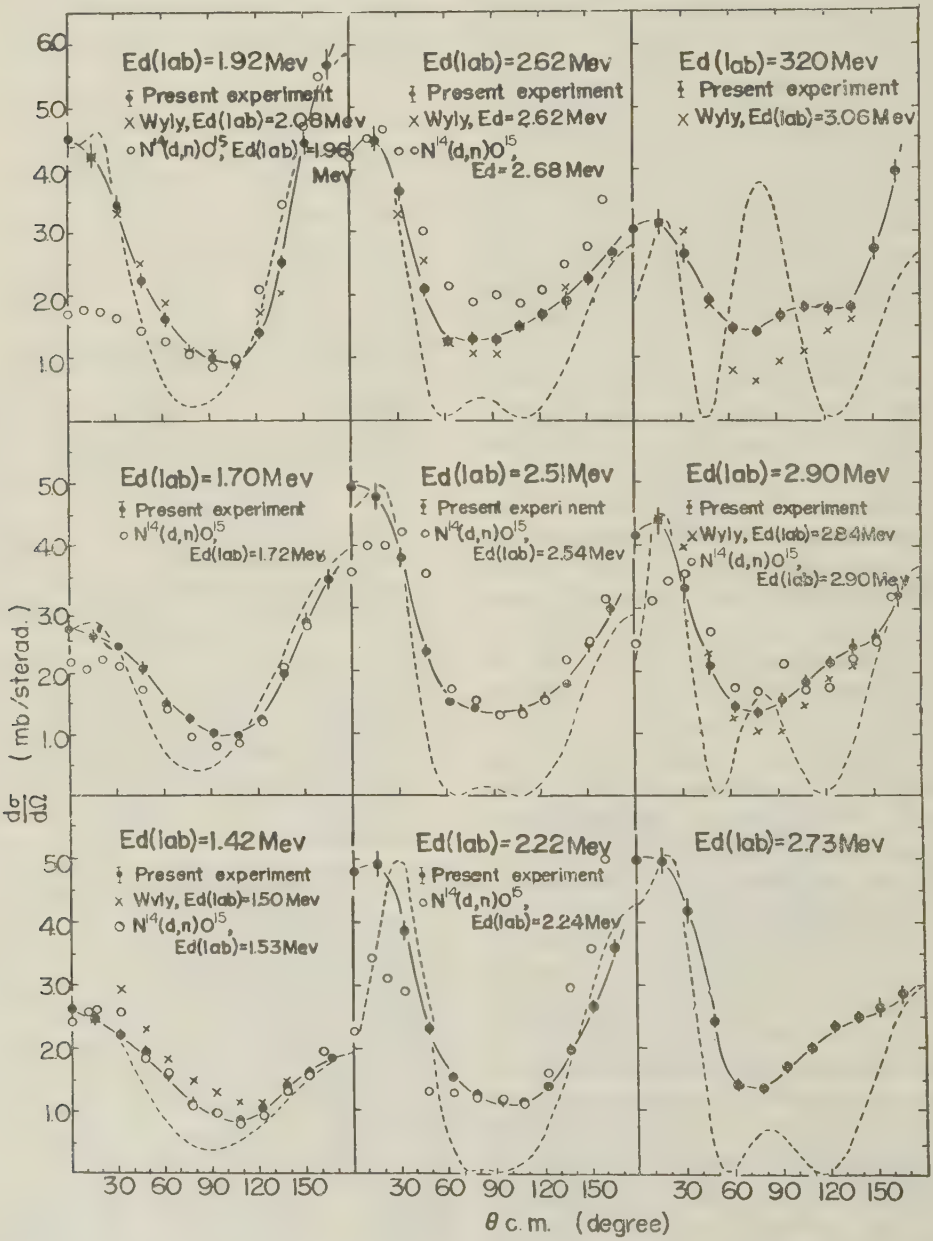

Fig. 3. Angular distributions for the $N^{14}(d, p)N^{15}$ ground state reaction. Dotted curves were calculated using the heavy particle stripping formula of Owen and Madansky. Open circles and crosses are results for the $N^{14}(d, n)O^{15}$ ground state reaction obtained in our previous work and the $N^{14}(d, p)N^{15}$ ground state reaction by Wyly, respectively.

lines. The relative errors indicated in figures include the ambiguities of the separation of overlapped proton groups and the statistical ones due to counting. Absolute values of differential cross sections were evaluated from the mixing ratio of target gases and the known value of cross sections for the $D(d, p)T$ reaction[13]. Uncertainties in the absolute scale of angular distribution for each deuteron energy, thus determined, are considered to amount to 15 per cent at maximum. As shown in Fig. 3, nine angular distributions for the ground state reaction are found to have a similar characteristic in shape which is a pronounced forward maximum and a remarkable backward rise. However, the absolute values of differential cross sections, in particular in backward directions, vary slowly with the deuteron energy. The position of minimum at medium angles also moves to smaller angles with the increasing deuteron energy from 100 degrees at 1.42 MeV to 70 degrees at 3.20 MeV, respectively. In Fig. 3, Wyly's results which were normalized to the present ones at 15 degrees were also presented. Satisfactory agreements can be seen between the present results and Wyly's ones, considering the difference of deuteron energies. For the comparison with the mirror reaction, the angular distributions for the $N^{14}(d, n)O^{15}$ ground state reaction were also plotted in Fig. 3. At every seven bombarding energies, the backward yields of emitted particles from both reactions show the striking agreements. It will be noted that with the exception at 1.42 MeV the proton yields from the $N^{14}(d, p)N^{15}$ reaction at forward directions are considerably larger than the neutron yields from the $N^{14}(d, n)O^{15}$ reaction.

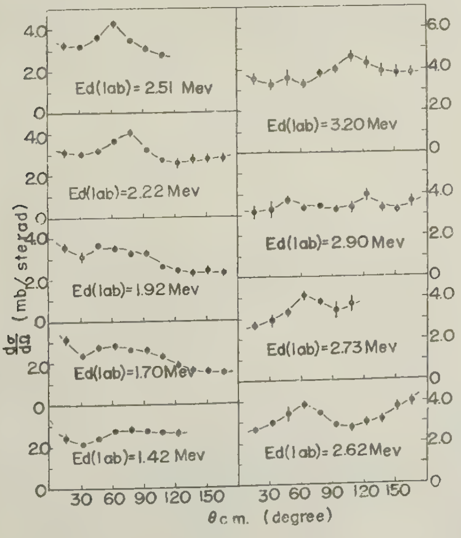

Fig. 4. Angular distributions for the $N^{14}(d, p)N^{15}$ 5.28 and 5.31 MeV doublet state reaction.

Fig. 4 shows angular distributions for the 5.28 and 5.31 MeV doublet state reaction. Their patterns are found to be essentially isotropic and to agree with the results obtained by Wyly. Considering in more detail, however, a broad maximum at about 60 degrees, though is not so remarkable, is observed similarly at every bombarding energy and a second slight maximum seems to take place at about 120 degrees in the case of 3.20 and probably of 2.90 MeV.

Total cross sections estimated by integrating the angular distributions are plotted in Fig. 5. Both yield curves for the $N^{14}(d, p)N^{15}$ ground state and first excited doublet state reactions increase rapidly with the increasing deuteron energy up to 1.92 MeV. Beyond 1.92 MeV, the yield curve for the ground state reaction is nearly constant, while that for the

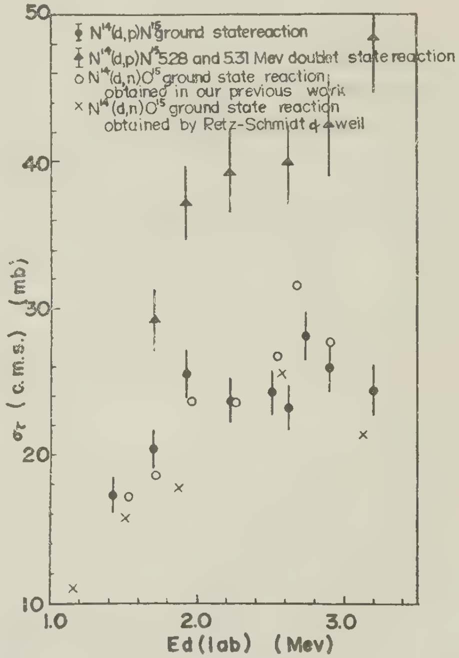

Fig. 5. Excitation curves for the $N^{14}(d, p)N^{15}$ ground state and 5.28 and 5.31 MeV doublet state reactions. Open circles and crosses are results for the $N^{14}(d, n)O^{15}$ ground state reaction obtained in our previous work and by Retz-Schmidt and Weil, respectively.

5.28 and 5.31 MeV doublet state reaction still increases gradually. Absolute cross sections for the doublet state reaction are generally larger by a factor of 1.5 than that for the ground state reaction over the whole range of deuteron energies investigated. It must be noted that at 1.92 and 2.73 MeV, slight maxima for the ground state reaction and sharp knicks for the doublet state reaction are observed, respectively. For comparison, total cross sections for the $N^{14}(d, n)O^{15}$ ground state reaction are also presented in Fig. 5 together with that obtained by Retz-Schmidt and Weil. The yield curves for these two reactions are all found to be very similar both in shape and in absolute value.

§ 4. Discussions

The $N^{14}(d, p)N^{15}$ ground state reaction

In the energy region of a few MeV, deuteron induced reactions are usually considered to proceed through a mixture of compound nucleus formation and deuteron stripping with comparable importance. Moreover, in deuteron stripping the distortion of wave function by the Coulomb and nuclear forces may not be neglected. Accordingly, it is not certain that the pure stripping theory will give a good fit to the present data obtained at such a energy region of deuterons as mentioned above. As shown in Fig. 3, however, nine angular distributions have a striking similarity in shape, namely the characteristic forward peak and the remarkable backward rise. This similarity of patterns over the entire energy range and the pronounced forward peak immediately suggest that deuteron stripping contributes appreciably to this reaction. The backward rise will be also interpreted in terms of heavy particle stripping. Angular distributions, then, have been attempted to analyze using the deuteron and heavy particle stripping theory of Owen and Madansky[14]. In spite of some inconsistency of its derivation as was pointed out by Hasegawa and Ichikawa[15], the formula of Owen and Madansky was used because of its simplicity and was considered enough to see the qualitative agreement.

The values of orbital angular momenta of captured particles which appear in the theoretical formula were estimated as follows. The l_n- value for a captured neutron was decided to be 1 by refering to the shape of angular distributions and also by the values of spins and parities of N^{14} and N^{15} nuclei. Secondly, the orbital angular momentum of a captured C^{13} core is limited by the conservation of parity and angular momentum. The ground state of N^{15} nucleus is known to have odd parity and spin 1/2. The deuteron has even parity and spin 1 and the C^{13} core has odd parity. Accordingly, the l_c-value of the captured C^{13} core must be even and is limited to 0 or 2. Since $j_2(k_2R_2)$ approches zero at backward angles and d-wave penetrability is much less than that for the s-wave, the $l_c=2$ term would be possibly neglected. The formula for the differential cross section at a given deuteron energy, following the notation of Owen and Madansky, is

$$d\sigma/d\omega=\text{const.}|G_D(K_1)j_1(k_1R_1)+(\lambda_2/\lambda_1)G_H(K_2)j_0(k_2R_2)|^2 ,$$

where

$$G_D(K_1)=1/(K_1^2+\alpha_D^2)$$

and

$$G_H(K_2)=[1/(\alpha_N^2-K_2^2)+1/(\beta_N^2+K_2^2)][K_2r_Nj_1(\alpha_Nr_N)j_0(K_2r_N)-\alpha_Nr_Nj_0(\alpha_Nr_N)j_1(K_2r_N)] .$$

are momentum distribution functions for deuteron and heavy particle stripping, respectively. λ_2/λ_1 is the ratio of amplitudes for heavy particle stripping to deuteron stripping. A radius and depth of the potential well used to determine the neutron wave function for the calculation of $G_H(K_2)$ were chosen to be 3.37×10^{-13} cm and 40 MeV, respectively. The parameters that are adjustable to get a fit to experimental data are the interaction radii, R_1 and R_2, and the ratio of two stripping amplitudes, λ_2/λ_1. The value of interaction radius R_1 was chosen to be 7.0×10^{-13} cm constantly for every deuteron energy. With this value of R_1, the experimental angular distributions at forward directions could be all fitted satisfactorily by pure deuteron stripping. For simplicity, constant value of 7.0×10^{-13} cm was also chosen for the interaction radius R_2, being the same as that for R_1. The interaction radii, R_1 and R_2, in themselves, should be adjusted to get the best fit to experimental data independently to each other and to the deuteron energy. Owen and Madansky pointed out that these two parameters should not necessarily be a constant over the entire energy range, since they represent phenomenological expressions for the behavior of the incoming rather complicated wave functions in the interior of the nucleus. In the case of the $B^{11}(d, n)C^{12}$ reaction, Owen and Madansky have chosen the value of R_1 and R_2 to be both constant, while Weil and Jones[16)] have obtained the energy dependent ones in the analysis of $N^{15}(d, n)O^{16}$ ground state reaction.

The dotted curves in Fig. 3 are theoretical ones thus calculated. With the exception of the curve at 3.20 MeV the agreement with experimental angular distributions is satisfactory, considering the crude choise of parameters. At 3.20 MeV, it was impossible to obtain a good fit for any value of the amplitude ratio, λ_2/λ_1, because the calculated interference term between both amplitudes of deuteron and heavy particle stripping resulted to be abnormaly large. Such interference is in itself one of the important features of the formula obtained by Owen and Madansky and was evaluated to be appreciable even at other lower bombarding energies. But it was not so unreasonably large value. On the other hand, some of the experimental angular distributions show also rather considerable humps at medium angles that would be attributed, at least partially, to the interference effect. In the formula obtained by Hasegawa and Ichikawa, another parameter was introduced in the interference term between the both stripping processes. With the suitable choise of parameters as a function of the deuteron energy and also using the formula of Hasegawa and Ichikawa, it would be sure that much better fits to experimental data could be obtained.

The values of amplitude ratio, λ_2/λ_1, adopted in the calculation of theoretical curves in Fig. 3, were plotted in Fig. 6 together with that for the $N^{14}(d, n)O^{15}$ ground state reaction. It was found that the amplitude ratio, λ_2/λ_1, for the $N^{14}(d, p)N^{15}$ ground state reaction remained fairly constant with the increasing deuteron energy, while this ratio for the $N^{14}(d, n)O^{15}$ ground state reaction showed a sharp maximum and a slight rise at 1.96 and 2.90 MeV, respectively. In the case of the $B^{11}(d, n)C^{12}$ and $N^{15}(d, n)O^{16}$ ground state reactions, these amplitude ratios increased gradually up to the deuteron energy corresponding to the Coulomb barrier and then became nearly flat. Owen and Madansky have pointed out, as the possible explanation for the behavior of the amplitude ratio for the $B^{11}(d, n)C^{12}$ reaction, that a reduction of the heavy particle stripping amplitude relative to the deuteron stripping amplitude would be expected at lower deuteron energies than that of the Coulomb barrier. However, the amplitude ratio for the $N^{14}(d, p)N^{15}$ reaction does not exhibit such reduction even at lower deuteron energies. On the other hand, the emitted particle yields in forward directions from the $N^{14}(d, n)O^{15}$ reaction was found to be considerably smaller than that from the $N^{14}(d, p)N^{15}$ reaction, especially at 1.96 and 2.90 MeV, as was shown in Fig. 3. This evidence seems to imply that the deuteron stripping amplitude would rather decrease considerably. It is interesting to notice that the amplitude ratios for the three (d, n) reactions, described above, have abnormally sharp maximum or minimum at the deuteron energy corresponding to the Coulomb barrier, while that for the $N^{14}(d, p)N^{15}$ reaction has not any such anomaly.

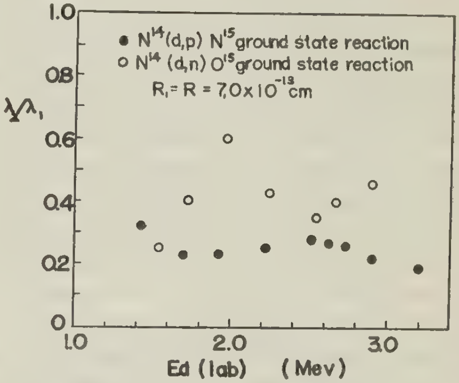

Fig. 6. The experimental ratio of the heavy particle stripping amplitude to the deuteron stripping amplitude, λ_2/λ_1, for $R_1=R_2=7.0\times10^{-13}$ cm. Those for the $N^{14}(d, n)O^{15}$ ground state reaction obtained in our previous work are also shown with open circles.

Comparison of yield curves for the $N^{14}(d, p)N^{15}$ and $N^{14}(d, n)O^{15}$ ground state reactions is also expected to give some informations on the reaction mechanism. As shown in Fig. 5, the yield curves for both reactions rise gradually up to 1.9 MeV with a shape that will be fitted by the deuteron penetrability through the Coulomb barrier. At the bombarding energies of 1.92 and 2.73 MeV, there can be seen slight resonance-like maxima. Moreover, absolute values of yield curves for both reactions are roughly equal over the whole range of deuteron energy investigated. It can not be decided yet whether these maxima are due to the distortion effect of wave function in the stripping process or to compound nucleus formation. In the usual derivation of the stripping formula, the incoming deuteron and the outgoing particle are represented by plane waves. A more exact formulation taking into account the distortion of these waves by the Coulomb and nuclear forces has been investigated by several authors17). It may be possible that the use of distorted waves would explain those resonance-like structures of the yield curves. However, it will be more reasonable to consider that those evidences would show both reactions to proceed appreciably through compound nucleus formation in these lower energy range of deuterons. In the present experiment the compound nucleus O^{16} is formed in the excitation approximately by 22 MeV. The level structure of O^{16} nucleus at this region of excitation has been investigated with photo-disintegration reactions18). In particular, Penfold and Spicer have found ten levels, widths of which are less than 40 keV. The above described resonance-like maxima are certainly considered to correspond to 22.4 and 23.1 MeV excited levels of O^{16} nucleus which were well confirmed by other reactions. Other levels observed in the photo-disintegration reactions, however, were not found in the present yield curves. This situation would be understood by the isotopic spin selection rule, assuming that this reaction proceeds through compound nucleus formation. As the isotopic spins of N^{14} nucleus and deuteron are both zero, the levels of the compound nucleus O^{16} formed by the $N^{14}+d$ reaction must have the isotopic spin of zero. The gamma-ray absorption in the 20 MeV region of excitation will be mainly electric dipole, which requires the difference of isotopic spin to be 1. The levels of O^{16} nucleus excited by gamma-ray will have, then, the isotopic spin 1. It must be pointed out, of cource, that data points did not space closely enough to detect the narrow levels and so some resonance structure might be missed in the present experiment.

The yield curves and angular distributions show two rather conflicting evidences about the mechanism by which these reactions take place. Considering the angular distribution alone, the mechanism would appear to be the stripping reaction. But if that is the case, then it is difficult to explain the resonance-like structure in the yield curve. This double-faced behavior was also observed in the $C^{12}(d, p)C^{13}$ reaction19),20). Bonner *et al.* took a viewpoint in their analysis on this reaction that a small amount of compound nucleus formation could interfer with the stripping reaction and cause the resonant behavior of the yield curve, almost not affecting the shape of the angular distribution.

The $N^{14}(d, p)N^{15}$ 5.28 and 5.31 MeV doublet state reaction

The close doublet structure of the first excited 5.28 and 5.31 MeV states of N^{15} nucleus complicates the interpretation of the present results. Fig. 4 shows that the angular distributions for the $N^{14}(d, p)N^{15}$ 5.28 and 5.31 MeV doublet state reaction are roughly spherical symmetric. Such results have been obtained also by Gibson and Thomas and by Wyly. These distributions seem to infer that stripping process does not take place to any appreciable extent. The angular distributions for the $C^{14}(d, n)N^{15}$ reaction leading to this doublet state were measured by R. Chiba21) and found to have a remarkable forward peak attributed to deuteron stripping with $l_p=0$. This results requires that the spin of at least one of the doublet states should be 1/2 and even parity. Halbert and French22) have predicted on the basis of the single particle model that the 5.31 MeV state has spin 1/2 and even parity and belongs to $s^4p^{10}s^1$ configuration of N^{15} nucleus. The internal conversion coefficient of the 5.299 MeV gamma-ray from N^{15} nucleus following the beta-decay of C^{15} nucleus has been observed by Alburger *et al.*23) to be E1-transition. They have, then, concluded that this evidence is consistent with spin 1/2 and even parity for the 5.31 MeV state of N^{15} nucleus. If that is the case, it is implausible that the $N^{14}(d, p)N^{15}$ reaction leading to this state would proceeds through the stripping process appreciably. The reason is that the stripping process should be followed with the rearrangement of nucleons in the residual nucleus to lead to this state and such mechanism would not take place to any appreciable extent.

On the other hand, it cannot be overlooked that a broad maximum at about 60 degrees is observed, though is not so intense, commonly in every angular distribution. If it can be approved that those maxima show the contribution of deuteron stripping, the reaction corresponding to at least one of the doublet states, probably 5.27 MeV state, is considered to proceed through this process with $l_n=2$. The contribution of deuteron stripping with $l_n=2$ has also observed by Green and Middleton and by Sjögren and Ahnlund. In particular, the latter authors have reported the angular distribution for the 5.276 MeV state reaction showing that this reaction proceeds through deuteron stripping with $l_n=2$ undoubtedly. It is interesting to notice that the 5.31 MeV state of N^{15} nucleus is likely to be led through the (d, n) stripping process alone, while the 5.27 MeV state through the (d, p) stripping process. Of course, more precise investigation is required to obtain the definite conclusion.

In conclusion, the deuteron induced reactions in the present energy region do not appear to take place through any one pure reaction mechanism. It may be natural that such reactions are not able to be explained by one of the pure reaction mechanisms which based on particular approximation.

The author wishes to express his cordial thanks to Prof. I. Nonaka, Prof. S. Morita and all other staffs of the nuclear laboratory of Kyushu University for their support and discussions throughout this work. This work has been supported by the Scientific Research Expenditure of the Ministry of Education.

Inelastic Scattering of Neutrons by the Time-of-Flight Method

By Kineo TSUKADA, Shigeya TANAKA and Michio MARUYAMA

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken

(Received October, 20, 1960)

Neutrons scattered by Ti, Fe, Zn and Se have been observed by the time-of-flight technique in the energy range of 3.4 to 4.6 MeV. The inelastic scattering cross sections for the excitations of the 1st, 2nd and 3rd levels of these elements except Se, were obtained. The excitation functions of these levels were compared with those calculated with a formula which was made by modifying Hauser-Feshbach's formula so as to be used without detailed knowledge about the levels of high excitation.

Agreement was fairly well except for the case of the 2nd and 3rd levels of Zn, where calculated values were about twice as large as experimental values. Thus it has been concluded that the compound-formation process is considered to predominate over the direct process in these energy and mass regions.

§ 1. Introduction

According to the current theory of nuclear reaction, scattering of fast neutrons proceeds partly through compound-formation process and partly through direct process. Although quite a lot of theoretical works have been published by various authors[1),2)], the mechanism of the reaction is not yet known definitely. From the standpoint that much more experimental data are required to improve the theory, it will be worth while to measure the energy and angular dependence of the cross sections of scattering leading to definite levels of the residual nucleus.

It is not so easy to observe the energy spectrum of the scattered neutrons with good accuracy and resolution. Experimental data[3),4)] available at present are rather few. Of the various methods of measuring neutron energies: the nuclear emulsion[5)], the proton-recoil proportional counter[6)], the He^3 counter[7)] the counter telescope[8)], the time-of-flight method[3),9),10)], etc. the time-of-flight method is the most promising in the energy range of several MeV.

In the present investigations, it has been tried to observe the energy spectra of the neutrons scattered inelastically from several medium-weight nuclei, Ti, Fe, Zn and Se (in Sec. 2) and to obtain the differential cross sections at 90° direction for the excitation of several low-lying levels as the functions of the incident-neutron energy in a range of 3.4 to 4.6 MeV (in Sec. 3). Cross sections observed were then compared with those calculated using a formula, which was made by modifying Hauser-Feshbach's formula so as to be applied to the cases where levels in the residual nucleus were not known definitely except the lowest-lying levels (in Sec. 4).

§ 2. Experimental

The neutrons were generated from the $D(d, n)He^3$ reaction by using a 2-MV Van de Graaff accelerator, and energy spectra of inelastically scattered neutrons were measured by the pulsed-beam time-of-flight method which had been developed by Cranberg et al[11)].

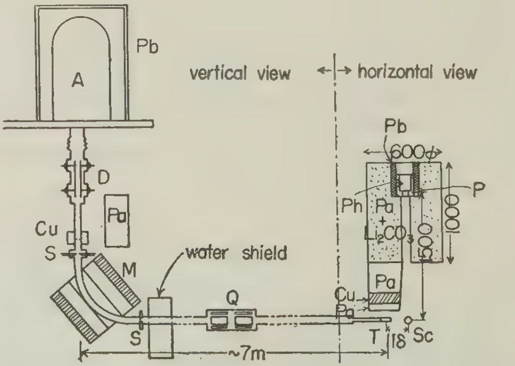

Fig. 1. Schematic diagram of the experimental arrangement. A: 2-MV Van de Graaff accelerator. D: Rf deflector for pulse operation. S: Slit. M: Beam-analysing magnet. Q: A couple of electrostatic quadrupole lenses. T: Gas target. Sc: Scatterer. P: Plastic scintillator. Ph: Photomultiplier. Pa, Pb and Cu: Paraffin, lead and copper shields, respectively.

A. *Arrangement*

As shown in Fig. 1 the continuous deuteron beam from the 2-MV Van de Graaff accelerator is chopped by a 3.7-Mc rf deflector which makes the beam sweep a slit with a width of 1.5 mm. The duration of the ion-beam pulse was calculated to be about 4 mμ sec by a calculation, and was checked by measuring the total- and the pulsed-beam current.

The pulsed ion beam is deflected by an analysing magnet and then focused on a gas target[12], which is located about 7 m distant from the magnet by means of a couple of electrostatic quadrupole lenses. The chamber of the gas target has a diameter of 1 cm and is 3 cm long. Deuterium is stored in a uranium oven attached to the chamber. The entrance window of the chamber is covered with a nickel foil with a thickness of 0.00005 in. In the present experiments the pressure of the deuterium was 50 cm Hg. But only in the case of a low neutron energy of 3.4 MeV, the gas pressure was decreased to 25 cm Hg in order to prevent the increase of the spread of neutron energy. The spread of the neutron energy was estimated to be 350 keV and 280 keV at neutron energies of 3.8 MeV and 4.6 MeV, respectively.

The scatterers were placed at 0° with respect to the direction of the deuteron beam and 11 cm distant from the gas target. The dimensions of the Fe and Zn scatterers were 5 cm long and 2.5 cm in diameter, and those of the Se scatterer were 6.5 cm and 2.5 cm respectively. As the Ti sample was granular, it was packed in a 5 cm × 5 cmϕ vessel made of polyethylene. The correction for multiple scattering was estimated not to be serious in the present experiments.

The neutron detector was placed at 90° with respect to the direction of the incident neutrons and at 150 cm distant from the scatterer.

B. *Background and shielding*

The background radiation is composed of the natural radiation, the room-scattered radiation, the machine background (the radiation from the accelerator, the ion-beam chopper and the analysing magnet) and the radiation which enters the detector from the gas target directly. In the case of deuteron acceleration, the machine background is serious and it is necessary to shield the detector especially from this background.

The measurement was carried out at the middle of a large room (24.2 m × 13 m) which had a pit of 2.5 m in depth in order to decrease the effect of neutrons scattered from the walls and the ground. The Van de Graaff accelerator was covered with a box made of lead 6 m thick, which served as a shield against the X rays generated in the accelerator, and other sources of machine background was also shielded properly, but the machine background was most effectively reduced by setting the target far away from the accelerator by means of electrostatic quadrupole lenses. As shown in Fig. 1, the detector was surrounded by a lead collar 6.5 cm thick and a shield tank 100 cm in length and 60 cm in diameter which was filled with a mixture of paraffin and lithium carbonate (mixing ratio 3 : 1 by weight). In order to shield the neutrons which entered the detector directly, paraffin blocks 10 cm thick and copper blocks 20 cm thick were placed between the gas target and the shield tank.

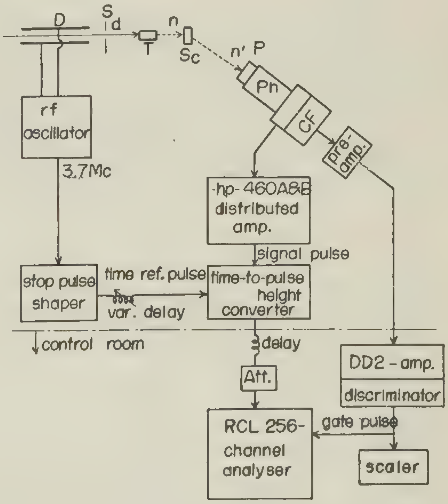

Fig. 2. Block diagram of the detector system. D: Rf deflector. S. Slit. T: Gas target. Sc. Scatterer. P: 2″×2″ϕ plastic scintillator. Ph: RCL 6342 photomultiplier. Cf: Cathode follower. Att: Attenuator.

The block diagram of the neutron-detecting system is shown in Fig. 2. A 2″×2″ϕ plastic scintillator and an RCA 6342 photomultiplier composed the neutron detector. The fast-rise single pulses delivered from the detector were amplified by Hewlett-Packard 460A and 460B distributed amplifiers and then brought to a time-to-pulse height converter[11]. The output of the converter was next fed to an RCL 256-channel pulse-height analyser. A side channel composed of a nonoverloading amplifier and a discriminator was used to open the gate of the pulse-height analyser. This side channel cut off small pulses and reduced the time jittering due to the variation of the pulse height. The discrimination level for the side channel was 2 to 3 times higher than that for the time-to-pulse height converter.

The linearity of the time-to-pulse height conversion was checked by using a double-pulse generator having calibrated delay intervals between pulses. The deviation from the linearity was smaller than ±1 mμsec in the whole time range. The time interval per channel was estimated to be 0.98 mμsec.

A current integrator was used to measure the deuteron beam entering the gas target and to estimate the neutron yield. The yield was also monitored by a Hanson-and-McKibben long counter.

C. *Time spectra*

Fig. 3 shows a typical time spectrum of the neutrons scattered from Fe. In this figure, time increases to the left, i.e. from the right to the left there appear several peaks corresponding to the gamma rays (γ) which are produced in the scatterer at the moment of the inelastic scattering, elastically scattered neutrons (n) and inelastically scattered neutrons (n', n'', n''', $\cdots$) corresponding to the excitation of the low-lying levels of the residual nuclei of the scatterer. Since two neutron bursts were generated every time-reference pulse, two similar patterns appear in the time spectrum. The peaks corresponding to the gamma rays were used as the fiducial points to determine the flight time of the scattered neutrons. It took 1.5 to 2 hours to accumulate counts as are shown in this figure. In the present experiments, the pulsed beam entering the gas target was 0.2 to 0.4 μA in the average. The dashed line in Fig. 3 represents the background obtained in the absence of the scatterer.

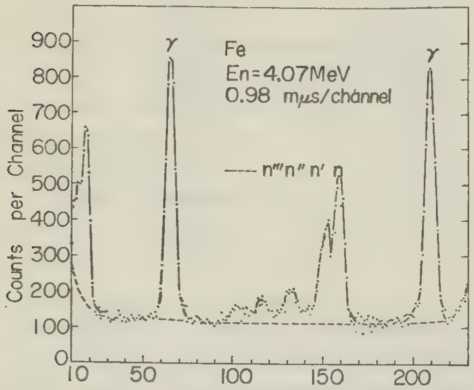

Fig. 3. Time spectrum obtained at 90° for neutron scattering at 4.07 MeV from Fe. The dashed line under the spectrum is the background obtained in the absence of the scatterer. Peaks corresponding to gamma rays, elastically scattered neutrons and inelastically scattered neutrons are marked with γ, n and n', n'', $\cdots$, respectively.

D. *Efficiency*

The efficiency of the neutron detector was determined as a function of the energy by calculating the yield[13] of neutrons at the target.

The measurements of the efficiency were made several times during the experiment. The efficiency was estimated to be 0.25±0.05 in the range of 2 to 4.5 MeV, where the error gives the maximum deviation from the mean of the measured values. For neutron energies less than 2 MeV, the efficiency decreases gradually and becomes zero at 0.7 MeV. These observed values are in good agreement with those calculated by using the neutron cross section of hydrogen in the plastic scintillator and taking account of the discrimination of neutrons below 0.7 MeV by the side channel.

E. *Resolution*

There are several reasons why the peaks in the time spectrum have finite widths. The gamma-ray peak has a half-width of about 6 mμsec, which is due to the following three effects: (1) the time jittering in the time-analyser system, (2) the finite duration of the deuteron pulse (~4 mμsec), and (3) the variation in the paths of the neutron in the gas target and the scatterer (~2.7 mμsec for 4-MeV neutrons). For the width of the neutron peak, the following effects are to be added: (4) the spread of the neutron energies due to the energy loss of the deuterons in the gas target and, also, due to the large solid angle subtended by the scatterer at the target (~2 mμsec for 4-MeV neutron energy) and (5) the spread in the flight-path lengths of the scattered neutrons ($\sim$2 mμsec for 4-MeV neutron energy). The energy of the deuterons incident to the target was homogeneous enough to have negligible effect on the width of the peak. The half-width for the elastically scattered neutrons of 4-MeV was observed to be 6 to 7 mμsec.

From the observed half-width of the gamma-ray peak and the time spreads of (2) and (3) stated above, the jittering in the time-analyser system was estimated to be less than 3.5 mμsec. Since the rise time of the signal pulse from the neutron detector was about 5 mμsec, this estimation will be reasonable, if one takes into consideration a fact that the small signal pulses were cut off by the discriminator in the side channel.

The half-width of the neutron peaks was calculated to be 6.5 mμsec by adding the time spread of (4) and (5) to the observed half-width of the gamma-ray peaks, assuming that all of the time spreads were also of Gaussian forms.

§ 3. Results

Figs. 4, 5, 6 and 7 show the energy spectra of neutrons scattered by Ti, Fe, Zn and Se, respectively. The energies of the incident neutrons are 3.44, 3.83, 4.07, 4.30 and 4.61 MeV. In these figures, the abscissas are expressed in the energy scale. The excitation energies of the residual nuclei increase to the left, and the peaks at the right-most are due to the elastic scattering. The ordinates give

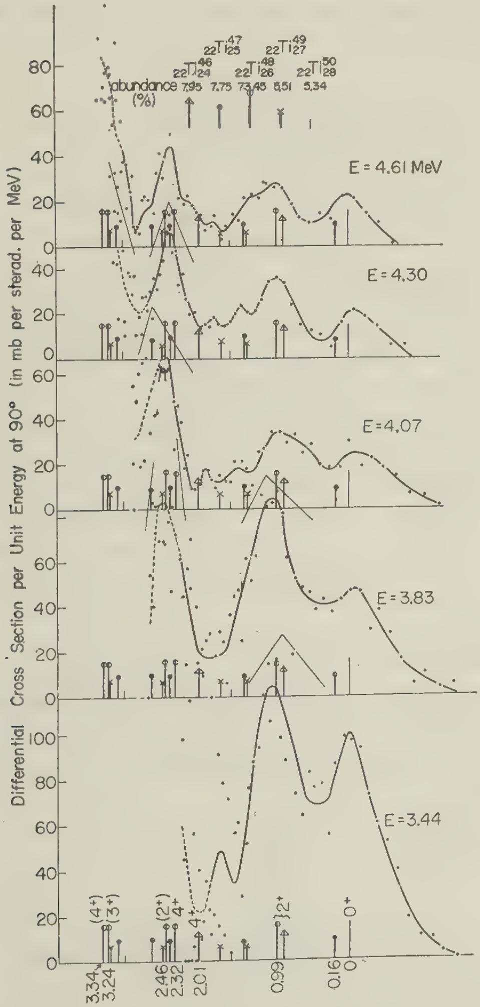

Fig. 4. Energy spectra for Ti. The vertical lines under the spectra show the positions of levels. Isotopes are specified by the marks as shown at the top of the figure.

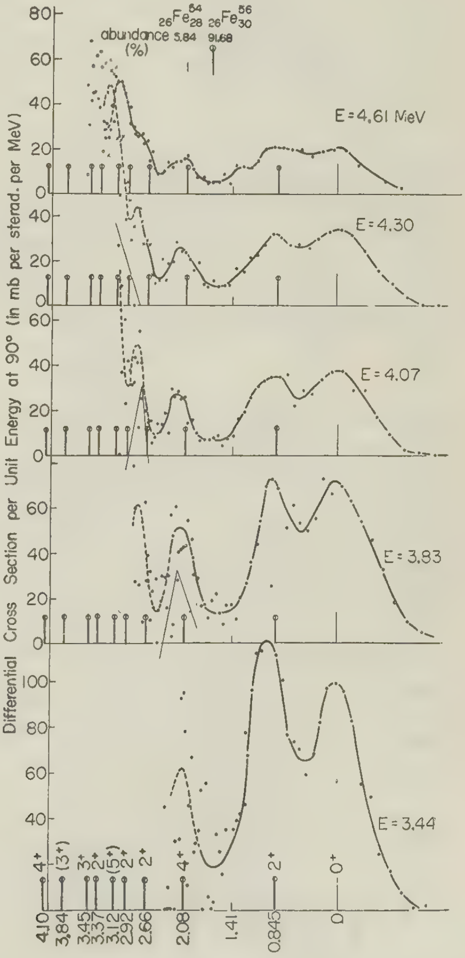

Fig. 5. Energy spectra for Fe.

the differential cross sections in mb per steradian per MeV of the energy of the scattered neutrons measured at 90° with respect to the direction of the incident neutrons. Those parts of the spectra which are shown by dashed curves have large errors, because, in those parts (1 to 2 MeV), determination of the efficiency of the detector suffers rather large uncertainty.

In the present investigations, the absolute value of the cross section has a large systematic error which is derived from the measurement, of the efficiency of the detector (±20%). But, as far as the relative magnitudes of peaks are concerned, the error from this origin is canceled out, because the variation of the efficiency was small in a series of measurements.

These figures show that the differential cross section of the inelastic scattering at 90° is comparable with that of the elastic scattering at the same direction. Generally speaking, the cross sections corresponding to the excitation of higher levels in the residual nuclei are smaller, and the level density increases with the excitation energy, so that the neutron groups corresponding to the excitation of the higher levels are not resolved. In the case of Se (and Ge also, which is not presented in this paper), even the peaks corresponding to the excitation of low-lying levels are not resolved as shown in Fig. 7.

The differential cross sections of the elastic scattering and of the inelastic scattering corresponding to the excitation of lowlying levels for Ti, Fe and Zn are shown in Fig. 8 as as functions of neutron energies. The peeling-

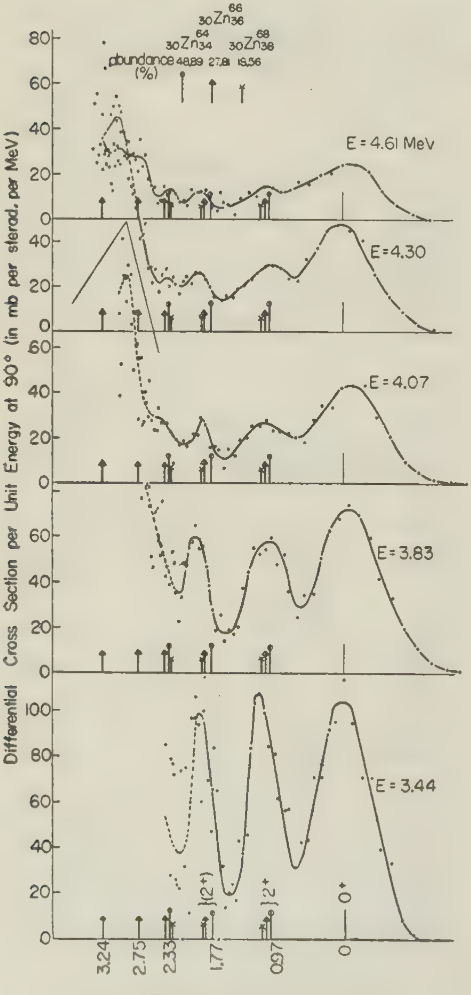

Fig. 6. Energy spectra for Zn.

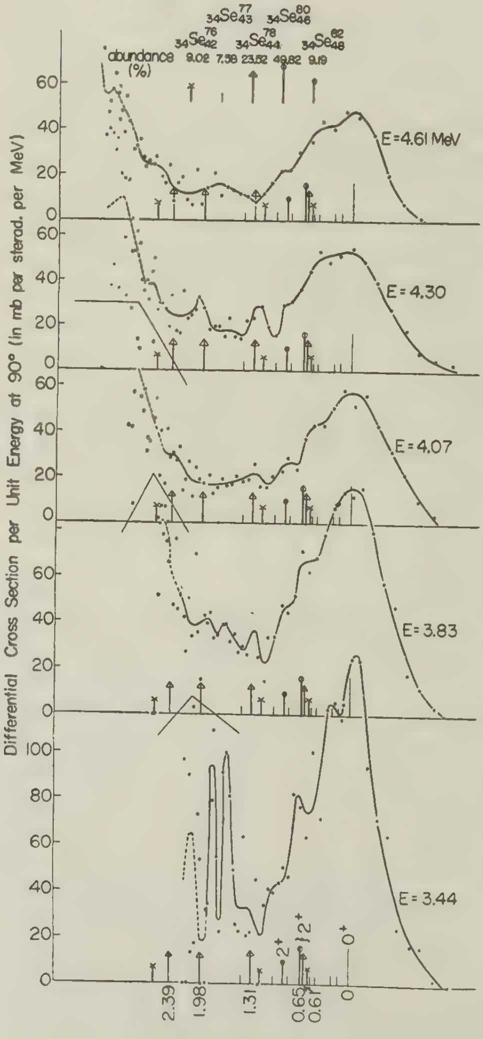

Fig. 7. Energy spectra for Se.

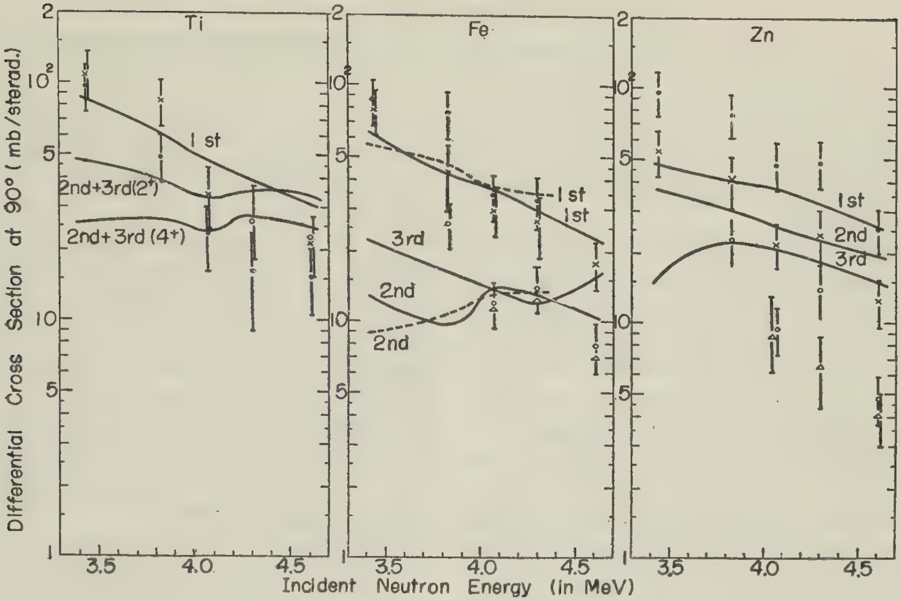

Fig. 8. Differential cross sections of Ti, Fe and Zn at 90°. The points shown by closed circles represent the data of the elastic scattering, and those shown by the crosses, open circles and triangles represent the data of the inelastic scattering corresponding to the excitation of the 1st, 2nd and 3rd levels in each residual nucleus, respectively. The dashed curves represent the theoretical calculations by Hauser-Feshbach's formula and the full curves by the modified Hauser-Feshbach formula.

off method was used to separate the peaks overlapping partially with each other, and the errors due to this procedure were estimated to be 10 to 15% of the differential cross sections. For Se, this procedure was not applied. In these figures, it is shown that all of the excitation functions decrease rapidly with the increase of the energy of the incident neutrons.

§ 4. Discussion

In order to investigate which process, the compound-formation process or the direct process, will be predominant in the inelastic scattering in the energy and mass regions of the present work, the total cross sections of the inelastic scattering through the compound-formation process were calculated by using Hauser-Feshbach's formula[1] on the following assumptions.

Assumption 1: The levels of the compound nucleus are so dense that the statistical treatment can be allowed for these levels.

Assumption 2: The angular distribution of the inelastically scattered neutrons is nearly isotropic.

According to Hauser and Feshbach, the total cross section for the inelastic scattering with respect to the transition from the initial nucleus with spin i to the final nucleus with spin i' is given by

$$\sigma(i/i')=\frac{\pi\bar{\lambda}^2}{2(2i+1)}\sum_{l}\mathrm{T}_l(E)\sum_{J}\frac{\mathcal{E}_{jl}{}^{J}(2J+1)\sum_{l'j'}\mathcal{E}_{l'j'}{}^{J}\mathcal{E}_{l'j'}{}^{J}\mathrm{T}_{l'}(E')}{\sum_{l''j''E''}\mathcal{E}_{j''l''}{}^{J}\mathrm{T}_{l''}(E'')}, \qquad (1)$$

where

$\mathrm{T}_l(E)$: the penetration factor,
E, E' : the initial and the final channel energy, respectively,
j, j' : the initial and the final channel spin, respectively,
l, l' : the initial and the final orbital angular momentum, respectively,
J : the spin of the compound nucleus,

and

$$\varepsilon_{jl}{}^{J} \text{ is equal to } \left\{ \begin{array}{l} 2, \text{ if both } j_1 \text{ and } j_2 \\ 1, \text{ if either } j_1 \text{ or } j_2 \\ 0, \text{ if neither } j_1 \text{ nor } j_2 \end{array} \right\} \text{ satisfy } |J-l| \leqq j_k \leqq J+l\,. \tag{2}$$

Double primed quantities are associated with those channels to which the compound nucleus is feasible to decay.

Fortunately, as the level scheme including the spin and parity had been reported in a recent work of beta decay[14], calculation of the cross sections for Fe^{56}* was feasible to be made. Although contributions of the (n, p) reaction were to be taken into summation in the denominator of the formula (1), they were neglected because the cross section of the (n, p) reaction is small, for example, (0.08 ± 0.12) mb[15] for the neutron energy of 4.4 MeV. The penetration factor $T_l(E)$ was calculated by Beyster et al[16] assuming the Woods-Saxon potential[17]. The calculated results are shown by the dashed curves in Fig. 8. They are in good agreement with the experimental results not only in the absolute values but also in the relative values of the cross sections corresponding to the excitation of the 1st and 2nd excited levels. Therefore, it may be said that the inelastic scattering of the neutrons with the energy of several MeV proceeds mainly through the compound-formation process. The slopes of the calculated curves, however, are less than those of the experimental curves. This deviation may be due not to misapplication of Hauser-Feshbach's formula, but to the fact that undiscovered levels** are not taken into the calculation.

For Ti and Zn, the calculation similar to that for Fe was impossible, because the level schemes were not available in the range higher than 3.4 MeV for Ti and 2 MeV for Zn. Therefore, the formula (1) was modified by using the notion of level density under the following assumption.

> Assumption 3: The residual nucleus has so many excited levels in the range of several MeV that the spins and parities of these levels can be treated as distributed statistically***.

The formula (1) is then modified as follows:

$$\sigma(i/i') = \frac{\pi\lambda\!\!\!^{-2}}{2(2i+1)} \times \frac{\sum_l [T_l(E) \sum_J \{\varepsilon_{jl}{}^J \sum_{j'l'} \varepsilon_{j'l'}{}^J T_{l'}(E')\}]}{\int_0^E \frac{1}{D_0(E-E'')} \sum_{l''} (2l''+1) T_{l''}(E'') dE''} \tag{3}$$

where $(2i''+1)/D_0(U)$ is the level density with spin i'' at the excitation energy U. The derivation of this formula is given in Appendix I. The functional forms of $D_0(U)$ have been given by Newton[19], Cameron[20] and others. Newton's formula is adopted here because of its simplicity. The results of the calculation of the formula (3) are shown by the full curves in Fig. 8. Since the absolute magnitude of level-density formula is not expected to be dependable, these curves are normalized to the experimental values for the excitation of the 1st levels by the neutrons of 3.83 MeV. The normalization factors for the level densities are 0.0538, 0.123 and 0.186 for Ti, Fe and Zn, respectively. In Appendix II, a comparison is made between the calculated values of level density and the experimental

---

* It is apparent from the published level scheme that the energy spectrum of the neutrons shown in Fig. 5 is due to the major isotope of Fe, i.e. Fe^{56} (91.68%).

** In order to check how much the undiscovered highly excited levels contributed to the cross section, it was tried to compare the published total non-elastic cross section[18] $\sigma_{ne}(E_n)$ at the incident-neutron energy E_n with $\Sigma(E_n)$ which was defined as follows,

$$\Sigma(E_n) = 4\pi \int_{E_{exc}} \left(\frac{\partial^2 \sigma_{inel}}{\partial\Omega \partial E} \right)_{obs} dE\,,$$

where $(\partial^2\sigma_{inel}/\partial\Omega\partial E)_{obs}$ is the observed value of the differential cross section per MeV of the excitation energy for the inelastic scattering. The angular distribution was assumed to be isotropic. The integration was taken from the excitation energy of the 1st excited level up to $(E_n - 1.2)$ MeV. In the range of excitation energies higher than $(E_n - 1.2)$ MeV, the cross section could not be observed, because of the decrease of the efficiency of the detector. For Ti, Fe and Zn, $\sigma_{ne} \approx \Sigma$ at 3.6 MeV, but $\sigma_{ne} \approx 2\Sigma$ at $E_n = 4.6$ MeV. This fact suggests that there exist a number of excited levels between the excitation energies of 3.6 and 4.6 MeV.

*** Of course, this assumption holds only approximately. It will not lead, however, to erroneous results as fas as the discussion is limited to the competition between the channels decaying to individual levels of the residual nucleus.

ones is the case of Fe^{56}. The resonance-like structures in these curves are due to the behaviors of the penetration factors.

In the spectra of Ti (in Fig. 4), the peak neighbouring with the elastic peak was due to Ti^{46} and Ti^{48}, so that the calculation was carried out with respect to these isotopes. The peaks corresponding to the excitation of the 2nd and 3rd levels of Ti^{48} were not resolved in this experiment, so that the sum of the cross sections for these levels was calculated. Since the spin and parity of the 3rd excited level of Ti^{48} were not definitely known, two series of calculations were carried out, assuming the spin and parity to be 2^+ and 4^+, respectively. As seen in Fig. 8, better agreement between the observed and calculated results is obtained if one assumes the spin and parity of 4^+, but one cannot conclude the spin and parity of 4^+, because experimental errors are rather large and the contribution from isotopes other than Ti^{48} is neglected in the calculation.

In the case of Fe^{56}, where calculations both by the original Hauser-Feshbach formula (1) and by the modified one (3) were done, the modified Hauser-Feshbach formula shows better fitting at high incident energies. This suggests that Assumption 3 holds, i.e. there exist a number of excited levels, and their spins and parities are distributed statistically.

For Zn^{64}, Zn^{66} and Zn^{68}*, the calculated values of the cross sections corresponding to the excitation of the 2nd and 3rd levels are about twice as large as the observed values. It is not clear why this disagreement** occurs.

In conclusion, it may be possible to say that the compound-formation process is predominant in the inelastic scattering of 3.4 to 4.6-MeV neutrons by Ti, Fe and Zn. In order to get further confirmations, measurements of the angular distributions of scattered neutrons are now in progress.

The authors whould like to express their appreciation to Dr. T. Momota for invaluable help and advice. They are greatly indebted to Mr. C. Kobayashi, Mr. Y. Sato and members of the fast-neutron group for operation and maintenance of the accelerator, and to Dr. A. Sugie, Dr. K. Harada and Dr. T. Terasawa for helpful discussions. The authors also wish to express their thanks to Mr. F. Kurosawa for assistance in these experiments.

Appendix I The Modification of Hauser-Feshbach's Formula

When the energy of the incident particle is high and many levels can be excited in the residual nucleus, Hauser-Feshbach's formula (1) can be modified by taking the following three aspects into consideration.

(A) The numerators of the form must be preserved from the modification to give the dependence of the inelastic-scattering cross section on the spin i' of the residual nucleus, because the most parts of the spin dependence of the formula (1) come from the numerators.

(B) It is assumed that many levels of the residual nucleus are excited, the spins and parities of which are distributed statistically, and the density of the levels with spin i is expressed in the form[19),20)] of

$$\rho(U, i)=\frac{2i+1}{D_0(U)},$$

where $D_0(U)$ is the function of the excitation energy U.

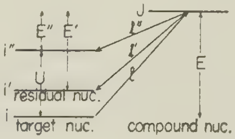

Fig. 9. Schematic energy-level diagram for the inelastic scattering.

(C) To get a good approximation without the detailed knowledge on the levels of the residual nucleus, the denominators of the formula are rewritten in a form of integral, using the expression of level density.

Representing the denominators of the formula (1) by $H(E, J)$,

---

* The predominant isotopes of Zn are Zn^{64} (48.89%), Zn^{66}(27.82%) and Zn^{68}(18.56%), and the level schemes of these isotopes are similar with each other.

The (n, p) reaction cross section for Zn is (56 ± 4.0) mb[20)] at the incident energy of 3.6 MeV. The contribution of this reaction was neglected in the calculation.

** This disagreement may be remedied by revision of the magnitude of imaginary part of the optical potential.

$$\mathrm{H}(E,J)=\sum_{j''l''E''}\varepsilon_{j''l''}{}^{J}\,\mathrm{T}_{l''}(E'')\,, \tag{A.1}$$

where

$$\varepsilon_{j''l''}{}^{J} \text{ is equal to } \left\{\begin{array}{l} 2, \text{ if both } j_1'' \text{ and } j_2'' \\ 1, \text{ if either } j_1'' \text{ or } j_2'' \\ 0, \text{ if neither } j_1'' \text{ nor } j_2'' \end{array}\right\} \text{ satisfy } |J-l''|\leqq j_k''\leqq J+l''\,. \tag{A.2}$$

Taking the aspect (B) into consideration, (A.1) and (A.2) may be replaced by

$$\mathrm{H}(E,J)=\sum_{E''=0}^{E}\sum_{l''=0}^{\infty}\sum_{j''}\mathrm{T}_{l''}(E'') \tag{A.3}$$

and

$$|J-l''|\leqq j''\leqq J+l''\,, \tag{A.4}$$

respectively. The number of the channels with a definite l'' and j'', through which the compound nucleus can decay, is given by

$$\frac{1}{2}\left\{\frac{2(j''+\frac{1}{2})+1}{\mathrm{D}_0(E-E'')}+\frac{2(j''-\frac{1}{2})+1}{\mathrm{D}_0(E-E'')}\right\}dE''=\frac{2j''+1}{\mathrm{D}_0}dE''\,,$$

where dE'' is a small energy interval in the residual nucleus. Here, the factor 1/2 before the parentheses results from the assumption of the equal populations of two parities in the residual nucleus. Then replacing the summation over E'' in (A.3) by an integral,

$$\mathrm{H}(E,J)=\int_0^E\sum_{l''=0}^{\infty}\sum_{j''=|J-l''|}^{J+l''}\mathrm{T}_{l''}(E'')\frac{2j''+1}{\mathrm{D}_0(E-E'')}dE''=(2J+1)\int_0^E\frac{1}{\mathrm{D}_0(E-E'')}\sum_{l''=0}^{\infty}(2l''+1)\mathrm{T}_{l''}(E'')dE''\,.$$

Thus, the formula (3) is obtained.

Appendix II The Level Density of Fe^{56}

The use of the formula (3) requires the knowledge of the level density $(2i+1)/\mathrm{D}_0$. As the expression of the level density, Newton's formula[18] was adopted in this paper, but there is no justification for using Newton's formula in the energy range up to several MeV, because of the following two reasons. One reason is that the pairing energy (~3 MeV) is neglected in the Newton's formula. The other is that this formula is based on the data obtained from the thermal-neutron capture and hence related to levels with excitation energies nearly equal to the binding energy of a neutron. So it will be adequate to remark that, in this paper, it was used only as an approximate formula with an adjustable constant factor (~0.1, See § 4).

This normalized level density was checked by the level scheme of Fe^{56} which had been obtained by the beta-decay experiments[18]. But this level scheme was not sufficient to see the complete level scheme in the energy range related to this paper, because the levels corresponding to the beta-transitions of higher order or small energy difference might have not been found. Tentatively we regarded all transitions in the aforesaid experiments as the allowed transitions and the following process was used for derivation of $1/D_0$ as a function of excitation energy.

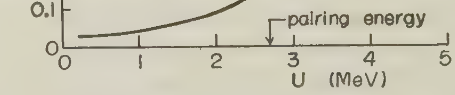

Fig. 10. Level density of Fe^{56}.

$$\left(\frac{1}{\mathrm{D}}\right)_{\mathrm{obs}}=\frac{1}{2}\sum_i\frac{2i+1}{\mathrm{D}_0} \tag{A.5}$$

Here, $(1/\mathrm{D})_{\mathrm{obs}}$ is the level density at an excitation energy obtained from one beta-decay scheme. For Fe^{56}, there are two beta-decay schemes, i.e. $\mathrm{Mn}^{56}\rightarrow\mathrm{Fe}^{56}$ and $\mathrm{Co}^{56}\rightarrow\mathrm{Fe}^{56}$. The range of summation $\sum$ is limited to i's corresponding to the allowed transition. In Fig. 10 these values of $1/D_0$ calculated by the formula (A.5) are compared with Newton's formula normalized by 0.123. The agreement is not bad.

The Crystal Structure of $KCuF_3$

By Atsushi OKAZAKI and Yasutaka SUEMUNE

Department of Physics, Faculty of Science, Kyusyu University, Fukuoka, Japan

(Received July 29, 1960)

The crystal structure of potassium trifluorocuprate (II) $KCuF_3$ has been determined by an X-ray analysis. The structure was refined by Fourier method. The crystals are tetragonal, $a=\sqrt{2}a_0=5.855$ and $c=2c_0=7.852$Å; space group $D_{4h}^{18}-I4/mcm$, with four formula units ($KCuF_3$) in the unit cell, where a_0 and c_0 designate the lattice constants of the fundamental pseudo-perovskite structure. This superstructure is due to a displacement of fluorine ions along the copper-fluorine-copper bonds only in the c plane. The atoms are in the following positions: 4 K^+ in (a): $(0, 0, 0; \frac{1}{2}, \frac{1}{2}, \frac{1}{2})+(0, 0, \frac{1}{4}; 0, 0, \frac{3}{4})$: 4 Cu^{2+} in (d): $(0, 0, 0; \frac{1}{2}, \frac{1}{2}, \frac{1}{2})+(0, \frac{1}{2}, 0; \frac{1}{2}, 0, 0)$: 4 F^- in (b): $(0, 0, 0; \frac{1}{2}, \frac{1}{2}, \frac{1}{2})+(0, \frac{1}{2}, \frac{1}{4}; \frac{1}{2}, 0, \frac{1}{4})$: 8 F^- in (h): $(0, 0, 0; \frac{1}{2}, \frac{1}{2}, \frac{1}{2})\pm(x, \frac{1}{2}+x, 0; \frac{1}{2}-x, x, 0)$ with $x=0.228$. In this structure a Cu^{2+} ion is surrounded by a distorted octahedron of F^- ions with copper-fluorine distances of 2.25, 1.96 and 1.89Å.

§1. Introduction

In recent years attention of many researchers has been drawn to the crystal structures and the magnetic properties of ABO_3 compounds with the perovskite structure because the magnetic ions form the simple cubic lattice in this structure. For the same reason antiferromagnetic substances KMF_3 have been investigated on their crystal structures[1] and magnetic properties[2] in our laboratory, where M indicates the $3d$ transition group elements.

At room temperature ($>T_N$) the structures of $KMnF_3$, $KFeF_3$, $KCoF_3$ and $KNiF_3$ are of the ideal perovskite type, but $KCuF_3$ crystallizes as a modification of the perovskite type, which is tetragonal ($a>c$).

In the perovskite structure a $3d$ cation is in an octahedral anion interstice where the crystal field splits the $3d$ levels of the magnetic cation into two groups—a set of three degenerate $d\varepsilon$ orbitals and a set of two $d\gamma$ orbitals of higher energy. The divalent $3d$ ions under consideration have electronic configurations as follows:

	$3d\varepsilon$	$3d\gamma$
Mn^{2+}	↑ ↑ ↑	↑ ↑
Fe^{2+}	↑↓ ↑ ↑	↑ ↑
Co^{2+}*	↑↓ ↑↓ ↑	↑ ↑
Ni^{2+}	↑↓ ↑↓ ↑↓	↑ ↑
Cu^{2+}	↑↓ ↑↓ ↑↓	↑↓ ↑

Since the electronic charge distribution of Cu^{2+} ion has the $d\gamma$ symmetry a distortion of the local octahedron around Cu^{2+} ion to tetragonal symmetry is expected as a result of the Jahn-Teller effect as discussed by Dunitz and Orgel[3]. As to the direction of the distortion, Öpik and Pryce[4] showed theoretically that Cu^{2+} in octahedral coordination always distorts its surroundings so that the central ion has four near and two far neighbours. On the other hand Liehr and Ballhausen[5] predict that the distortion for Cu^{2+} can go either way, that is, with c/a for the distorted octahedron greater than or less than unity.

Besides $KCuF_3$, so far as we know, there are two more examples of distorted octahedron formed by F^- ions around Cu^{2+} ion. These are in CuF_2[6] with distorted rutile structure and in K_2CuF_4[7] with tetragonal K_2NiF_4 structure where the distortions of the local octahedra are both tetragonal, but $c/a>1$ for the former and $c/a<1$ for the latter.**

Recently Kanamori[9] has shown that the sign of the superexchange interaction is closely connected with the cation orbital state, when the cation is subject to the crystalline field arising from octahedrally or tetrahedrally surrounding anions. Therefore it should be interesting to determine the crystal structure of $KCuF_3$ and to compare with the magnetic properties.

---

* The configuration of Co^{2+} can be represented by a single one-electron configuration only in an approximation.

** Kanamori[8] has pointed out that the distortion in K_2CuF_4 can not be attributed to the Jahn-Teller effect, because K_2NiF_4 has the isomorphous structure.

§ 2. Experimental

The compound, prepared by Hirakawa, Hirakawa and Hashimoto[2] of our laboratory, crystallized in the form of pseudo-cubes which were mostly a few mm^3 in volume and pale violet. The specimens on which the X-ray work was performed were formed into nearly cylindrical shape, length 0.4∼0.8 mm and diameter 0.14∼0.12 mm, by cutting with a razor blade and by grinding with sand paper.

The preliminary data were obtained from rotation and oscillation photographs taken with Cu$K\alpha$ radiation. The lattice constants were determined as follows: at first a_0 was determined from high angle $(hk0)$ reflexions about the [001] by graphical extrapolation against $\cos^2\theta$, next using this a_0 value c_0 was determined from high angle $(h0l)$ reflexions about the [010] by the same extrapolation.

Integrated intensities were recorded on multiple film equi-inclination Weissenberg photographs of the $(hk0)$, $(hk1)$, $(hk3)$ and $(h0l)$ layers using Mo$K\alpha$ radiation. The ranges of intensities measured were about 10^4 to 1 for the $(hk0)$, about 10^3 to 1 for the $(h0l)$ and about 10^2 to 1 for the $(hk1)$ and $(hk3)$, the estimate being made visually. Oscillation photographs were used to bring the relative intensities of reflexions in different layers to a common scale.

The integrated intensities were corrected for Lorentz and polarization factors. Since the linear absorption coefficient for Mo$K\alpha$ radiation is 96.9 cm^{-1}, the absorption corrections of Bradley[10] were applied to the intensities, assuming the crystals to be exactly cylindrical. No corrections were made for extinction and dispersion.

§ 3. Structure Analysis

a) *Preliminary analysis*

The oscillation photographs about [100] and [001] as rotation axes were obtained with Cu$K\alpha$ radiation by spending enough time. Very weak reflexions due to a superstructure were found on these films. The cell dimensions of the superstructure are twice as large as those of the fundamental pseudo-perovskite structure, that is:

$$a'=b'=2a_0=8.280\pm0.002\ \text{Å}\ ,$$

$$c'=2c_0=7.852\pm0.004\ \text{Å}\ ,$$

where the prime and the suffix indicate the super- and fundamental structures, respectively. Indexing on the basis of the above superlattice all the reflexions are classified into two groups as follows:

i) h, k, l all even, whose intensities are corresponding to the pseudo-perovskite structure,

ii) h, k, l all odd, which are due to the superstructure.

(hhl) reflexions of the second group are systematically absent. Moreover the relative intensities between the first and the second group reflexions suggest that this superstructure should not be attributed to an ordering of ion vacancies but to an ordered displacement of F^- ions from the original positions of the pseudo-perovskite structure.

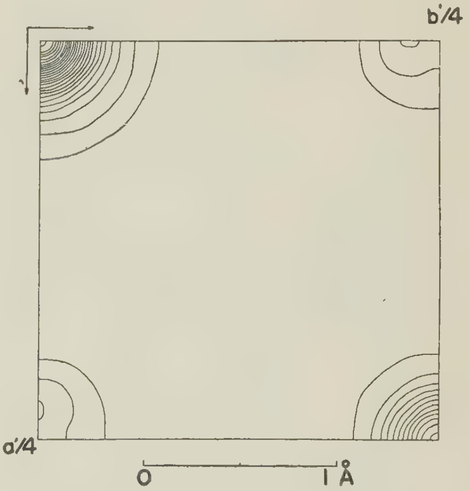

Fig. 1. Electron-density projection along [001], with contours at intervals of 10 e.Å^{-2}. Over the whole region the density is positive.

b) [001] *and* [010] *projections*

Structure factors $F(hk0)$ and $F(h0l)$ of $KCuF_3$ are all positive if the origin is chosen at Cu^{2+} and if the departure from the original pseudo-perovskite structure is not large. Therefore a final F_0 synthesis could be calculated directly using Beevers and Lipson strips. Fig. 1 shows the [001] projection by the F_0 synthesis and the displacement of F^- ions is obvious, although the F^- ions of which displacements are in the opposite direction in successive (001) planes are superposed. A preliminary comparison of calculated and observed $hk0$ structure factors, $F_c(hk0)$ and $F_0(hk0)$, by Wilsons' method[11] for the 34 reflexions out to $(\sin\theta/\lambda)^2=0.99$ provided a provisional temperature factor $B=1.27$ Å^2, and resulted in a reliability factor $R=\sum|F_0-F_c|/\sum|F_0|$ of 0.052 (0.048, if the non-observable reflexions are omitted). The calculated structure factors are based on the atomic scattering factors of Thomas and Umeda[12] for Cu^{2+} and of Berguis et al.[13] for K^+ and F^-.

The refinement of the structure was carried out by the successive use of difference Fourier projection along [001]. The final (F_0-F_c) synthesis is shown in Fig. 2. The final values of the parameters and the temperature factors, given in Table I, were used to calculate a set of structure factors, which is given together with the observed set, in Table II. The reliability factor for the 58 reflexions on the $hk0$ layer is reduced to 0.046 (0.042). The standard deviation of the atomic coordinate of the displaced F^- ion was estimated as 0.008 Å by the methods given by Cruickshank[14].

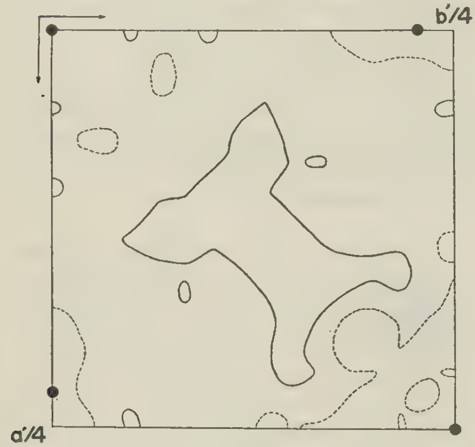

Fig. 2. Final (F_0-F_c) Fourier projection along [001], with contours of ±1 and −3 e.Å^{-2}; negative contours are shown as broken lines. Solid circles represent atomic sites.

Table I. Atomic parameters and temperature factors obtained from [001] projection.

	Parameters		Temperature factors (Å^2)
	x	y	
K^+	$\frac{1}{4}$	$\frac{1}{4}$	1.30
Cu^{2+}	0	0	1.33
F^-	0 0.228 0	0 0 0.228	1.00

A similar procedure was carried out about the $h0l$ data. On the [010] projection by the F_0 synthesis shown in Fig. 3, it is clear that the displacement of F^- ion occurs along the Cu-F-Cu bond only in the c plane. The same parameter value for the shift of F^- ion as the [001] projection was confirmed by the difference

Fourier projection, while the temperature factors obtained by the third synthesis were somewhat different from those obtained earlier as shown in Table III. In Table IV $F_0(h0l)$ are compared with $F_c(h0l)$. Since the experiments for the $(h0l)$ data were carried out under rather worse condition—shape and size of specimen, exposure time and size of integration—than those for the $(hk0)$ data, the reliability factor for the 92 $(h0l)$ reflexions is 0.087 (0.061).

c) *Analysis of* (*hk*1) *and* (*hk*3) *data*

Although the [001] and [010] projections of electron density have shown a displacement of F^- ions, a contribution by the displacement to $F(hk0)$ and to $F(h0l)$ is very small in general. Since the superstructure reflexions, on the contrary, are purely due to the displacement, (*hk*1) and (*hk*3) data were examined. The intensities of (*hk*1) and (*hk*3) reflexions were brought into an absolute scale by comparing with those of (*hk*0) reflexions. The parameter and the temperature factor of F^- ion shown in Table V were determined so as to get the best agreement between the observed and calculated structure factors, which are given in Table VI.

Table V. Parameter and temperature factor of the displaced F^- ion.

	From (*hk*1) reflexions	From (*hk*3) reflexions
Parameter	0.232 [1.92]	0.230 [1.90]
Temperature factor (Å²)	2.36	2.36

Values in the brackets show the shortest Cu-F distances (Å) corresponding to these parameters.

Table VI. Observed and calculated structure factors of (*hk*1) and (*hk*3) reflexions.

h k 1	$\|F_o\|$	F_c	*h k* 3	$\|F_o\|$	F_c
1 3 1	20.9	21.4	1 3 3	16.8	17.6
5	14.1	−12.3	5	11.8	−10.9
7	12.9	13.9	7	11.8	12.7
9	8.6	−7.2	9	9.1	−6.6
11	4.7	5.9	11	0	5.5
3 5 1	22.2	−20.7	3 5 3	18.8	−18.6
7	4.0	5.5	7	3.2	−4.9
9	12.3	−11.0	9	12.7	−9.6
5 7 1	12.6	13.6	5 7 3	11.6	12.8
9	0	−2.2	9	0	−1.9
7 9 1	6.8	−7.9	7 9 3	7.1	−7.5

These superstructure reflexions have weak asterism along the c^* axis of the reciprocal lattice†, while the fundamental reflexions have no asterism. Then this parameter may be an upper limit for the displacement and is in good agreement with those obtained from [001] and [010] projections.

Another way to attack this problem is the method of the bounded projection of electron-density[15], that is,

$$\int_{z_1}^{z_2}\rho(x, y, z)dz\ ,$$

which enable to separate the individual atoms if z_1 and z_2 are chosen properly. For the present case it is convenient to choose as $z_1=-1/4$ and $z_2=+1/4$. Then this integral is expressed as follows[16]:

$$\begin{aligned}\int_{-1/4}^{+1/4}\rho(x, y, z)\,dz \\ =\frac{1}{a'^2}\Big[&\frac{1}{2}\Sigma\Sigma\,F(hk0)\cos 2\pi(hx+ky) \\ &+\frac{2}{\pi}\Sigma\Sigma\,F(hk1)\cos 2\pi(hx+ky) \\ &-\frac{2}{3\pi}\Sigma\Sigma\,F(hk3)\cos 2\pi(hx+ky) \\ &+\frac{2}{5\pi}\Sigma\Sigma\,F(hk5)\cos 2\pi(hx+ky)-\cdots\Big]\,.\end{aligned}$$

Although only $F_0(hk0)$, $F_0(hk1)$ and $F_0(hk3)$ are used, the termination error is very small.

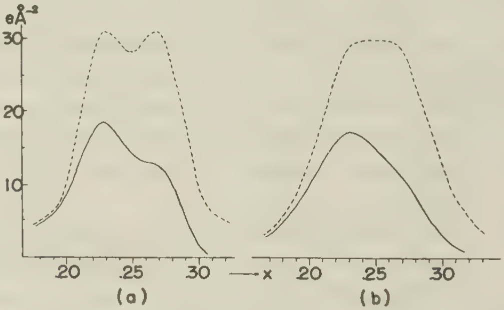

Fig. 4. Cross-section of the bounded projection at $y=0$; in (a) $F(hk0)$, $F(hk1)$ and $F(hk3)$, in (b) $F(h0l)$, $F(hk1)$ and $F(hk3)$ are synthesized, respectively. Broken lines indicate the corresponding cross-sections of [001] and [010] projections.

The cross-section of the projection at $y=0$ is shown in Fig. 4(a). Not only $F_0(hk0)$, but also $F_0(h0l)$ can be used to obtain this cross-section, the result being shown in Fig. 4(b). In these figures the cross-sections of [001] and [010] projections at $y=0$ are also shown by broken lines for comparison. The same results were obtained when $F_c(hk1)$ and $F_c(hk3)$ were used instead of $F_0(hk1)$ and $F_0(hk3)$, respectively.

d) *High and low temperature study*

This superstructure was examined also at high and low temperatures. In the temperature region of 670∼135°K any intensity change was not observed on the super- and fundamental reflexions which were recorded on the oscillation photographs taken using a single crystal high temperature camera having a cylindrical Ni-foil heater (Dent and Taylor[17]) and a low temperature camera by gas cooling method. There was no change of lattice symmetry over the same temperature region.

---

† This asterism will be discussed in § 5.

§ 4. Description of the Structure

Fig. 5 shows the crystal structure of $KCuF_3$ obtained from [001] and [010] projections, where the displacement of F^- ions is exaggerated. For this structure the unit cell should be chosen as indicated by broken lines.

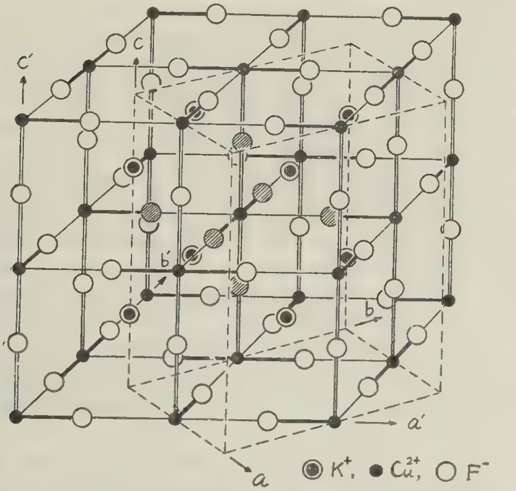

Fig. 5. Structure of $KCuF_3$. Single, double and bold lines are long, medium and short Cu-F distances, respectively, where the displacement of F^- ions is exaggerated. 6 F^- ions which surround a Cu^{2+} ion distorted-octahedrally are shown as shaded circles. Broken lines indicate the unit cell.

Therefore the lattice constants, space group and atomic coordinates are as follows:

$a=\sqrt{2}\,a_0=5.855\pm0.001_5$Å,

$c=2c_0=7.852\pm0.004$Å,

space group: $D_{4h}^{18}-I4/mcm\ (Z=4)$

atomic coordinates: $(0,0,0;\ \frac{1}{2},\frac{1}{2},\frac{1}{2})+$

4 K^+ in (*a*): $(0,0,\frac{1}{4};\ 0,0,\frac{3}{4})$

4 Cu^{2+} in (*d*): $(0,\frac{1}{2},0;\ \frac{1}{2},0,0)$

4 F^- in (*b*): $(0,\frac{1}{2},\frac{1}{4};\ \frac{1}{2},0,\frac{1}{4})$

8 F^- in (*h*): $\pm(x,\frac{1}{2}+x,0;\ \frac{1}{2}-x,x,0)$, $x=0.228$.

In this structure a Cu^{2+} ion is surrounded by a distorted octahedron of F^- ion with copper-fluorine distances as follows:

$$l=2.25\pm0.01\,,\quad m=1.96\pm0.001$$
$$\text{and } s=1.89\pm0.01\text{Å}\,,$$

where l, m and s mean the long, medium and short distances as shown in Fig. 5 by single, double and bold lines, respectively.

Table VII. Cu-F distances (Å) in $KCuF_3$, CuF_2[6] and K_2CuF_4[7].

	$KCuF_3$	CuF_2	K_2CuF_4
	2.25 (2)	2.27 (2)	2.08 (4)
	1.96 (2)	1.93 (4)	1.95 (2)
	1.89 (2)		
mean	2.03_3	2.04_3	2.03_7

Figures in the parentheses show the number of the Cu-F bonds.

In Table VII these Cu-F distances are compared with those in CuF_2 and K_2CuF_4. Although the directions of the distortion are different, the averages of the 6 Cu-F distances are nearly the same. In $CuF_2\cdot2H_2O$[18] the shortest Cu-F distance is 1.89 Å, although the Cu^{2+} surroundings are different from those in the others.

§ 5. Discussion

The electronic configuration of the lowest orbital state of Cu^{2+} ion which is subject to an octahedral cubic field is $(d\varepsilon^6)(d\gamma^2)d\gamma^1$; those in parentheses indicate paired electrons. Therefore a $d\gamma$ orbital oriented to the two far F^- ions (dz^2) should be completely filled.

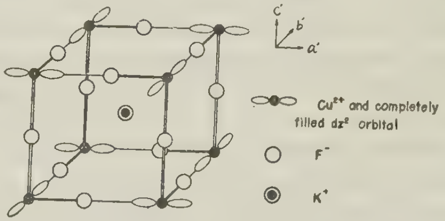

Fig. 6. Ordering of dz^2 orbitals for $KCuF_3$.

The ordering of these dz^2 orbitals is shown in Fig. 6. In the z'-direction, the intervening F^- ion p orbital overlaps on each side a half filled Cu^{2+} ion orbital, while in the x'- or y'-direction, overlapped Cu^{2+} ion orbital is half filled on one side, completely filled on the other. Then superexchange interaction between Cu^{2+} ions on opposite side of F^- ion may be antiferromagnetic for the former and ferromagnetic for the latter as suggested by Goodenough[19] and Kanamori[8]. Below the Néel temperature (243°K), consequently, an A-type antiferromagnetic structure may be expected, that is, all the magnetic moments within any (001) sheet are arranged ferromagnetically but with antiferromagnetic coupling between successive sheets.

The dispositions of the magnetic cations relative to the intervening anions in $KCuF_3$ are very similar to those in MnF_3[20] with distorted ReO_3 structure and in $LaMnO_3$[21] with distorted perovskite ($GdFeO_3$) structure. By neutron diffraction studies the A-type antiferromagnetic structures have been confirmed for both MnF_3[22] and $LaMnO_3$[23]. However the local distortions of these compounds are more complicated than that of $KCuF_3$ and, as pointed out by Gilleo[21], the distortion of $LaMnO_3$ may not be attributed purely to the Jahn-Teller effect, because $LaCrO_3$ and $LaFeO_3$ also have the isomorphous structures, for which the effect cannot be expected.

On the other hand the distortion of $KCuF_3$ seems to be mainly due to the Jahn-Teller effect, because except for $KCuF_3$ there are no such distortions in KMF_3 compounds above their Néel temperatures and the magnitude of the distortion is in good agreement with that found in Mn^{3+}-containing spinels[19]. That is, ratio of long to average of medium and short Cu-F distances is 1.17.

As mentioned in § 3 c), the superstructure reflexions of $KCuF_3$ have weak asterism along the c^* axis of the reciprocal lattice while the fundamental reflexions have no asterism. These features are somewhat similar to those of cobalt[24], and suggest a kind of stacking disorder, say as follows: the displacements of F^- ions in successive (001) planes are in the opposite direction in the regions of perfect crystallization, but in real crystals the displacements in neighbouring (001) planes are in the same direction occasionally. Furthermore one specimen among six examined in detail, showed superstructure reflexions corresponding to the following unit cell: $a'=b'=2a_0$, $c'=c_0$, which means that in this structure the displacements in successive (001) planes are in the same direction. These facts suggest that the difference between the stability of these structures are rather small. This asterism did not disappear down to 135°K. Fortunately the disordered structure assumed here has no influence on $F(hk0)$ and $F(h0l)$.

The authors wish to express their hearty thanks to Prof. T. Okada for his continuous guidance and encouragement, to Dr. K. Hirakawa and Mr. T. Haghimoto for supplying the crystals for this investigation and for discussions, and to Miss K. Hirano for assistance in calculation. This investigation was partly supported by the Scientific Research Expenditure of the Ministry of Education.

Hall Effect on Some of the Magnetic Compounds

By Satoshi FUJIME, Miyuki MURAKAMI, and Eiji HIRAHARA
Department of Physics, Faculty of Science, Tōhoku University

(Received September 5, 1960)

A sensitive Hall measuring apparatus has been constructed, and making use of it some of magnetic compounds, nickel oxide, iron telluride, nickel telluride, and iron sulfide have been studied. Especially, iron sulfide was studied because of the interest for its remarkable anisotropies of conductivity and susceptibility. From the results, one may say that the anisotropy of the conduction is responsible to the anisotropy of its mobility but not to the carrier concentration.

§ 1. Introduction

The conduction phenomena of a semiconducting compound containing transition element has some difficult problems not to be explained by the simple current theory, for example, some of these compounds exhibit anomalous resistivity at the temperatures near the Curie or Néel points, and other exhibit a remarkable anisotropy at the temperatures below the Curie or Néel points. Furthermore, the nature of conduction carriers in most cases is unknown whether it is an s-like electron in the energy band or a d-like electron in the discrete levels. In order to elucidate the nature of conduction phenomena, it has been requested to study the Hall Effect for these materials. The Hall voltages of these materials observed in typical conditions, however, are always so feeble to be hardly detected in the ordinary measurements. For the compounds studied in our laboratory, for example, nickel telluride, iron telluride, and iron sulfide, the Hall voltages to be measured for typical conditions seem to be of the order or smaller than 10^{-7} volts. It is, to say, for nickel telluride 8×10^{-7} volts in the case of $H=5000$ oersteds, the sample thickness $d=0.1$ cm, and the sample current $I=200$ mA, so that the ordinary Hall coefficient will be 3.5×10^{-5} cm³/amp.sec.(3.5×10^{-13} volt.cm/amp.gauss).

Therefore, in the construction of the measuring apparatus, the noise level of the detector must be at least of the order of 10^{-9} volts in order to achieve a reasonable signal to noise ratio. The Hall equipment having the sensitivity mentioned above was assembled, and with it the Hall effect has been studied for the compounds above mentioned as well as nickel oxide.

Among these compounds, especially the iron sulfide has been studied in detail, because of the interest for its remarkable anisotropies of conductivity and magnetic susceptibility at the α-transformation.

§ 2. Apparatus and Experimental Procedures

Our apparatus is essentially same as Lavine's apparatus[1] except for some details. The block diagram of our equipments is shown in Fig. 1. The equipment is composed with a 1.025 kc.p.s. power supply, a microvoltor or an attenuater, an amplitude and phase controller, a bucking and adding circuit, a high gain phase sensitive detector, and a pen-recorder or oscilloscope.

The 1.025 kc.p.s. power supply is primarily

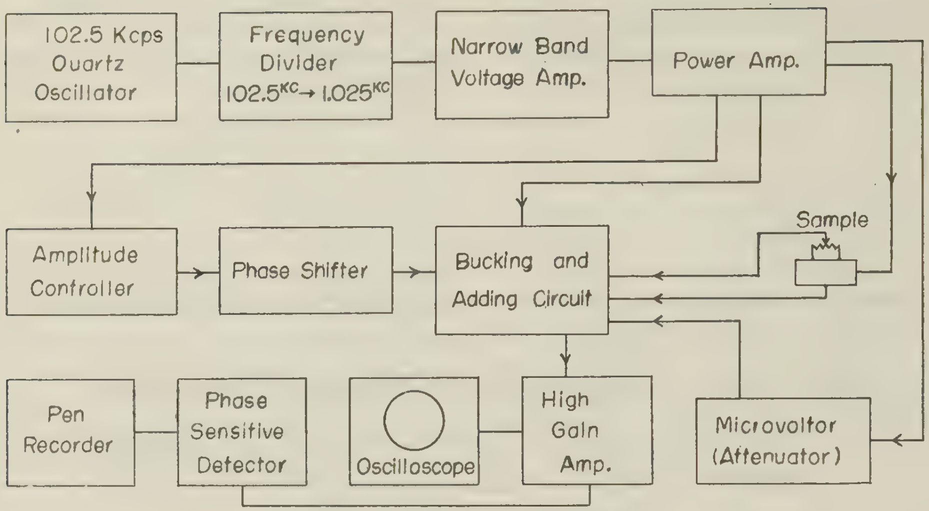

Fig. 1. Block diagram of sensitiue Hall equipment system.

drived by a 102.5 kc.p.s.-quartz oscillator which is stepped down to 1.025 kc.p.s. by a frequency divider or muti-vibrator, and then selected and magnified by a narrow band voltage amplifier and a power amplifier. This power is fed to the sample, the microvoltor, and the amplitude and phase controller, respectively. The voltage signals controled in the bucking and adding circuit are shown by the vector diagram in Fig. 2, in which the picked up voltage independent of magnetic field H is shown as IZ, and the Hall voltage V_H, the magnetoresistance voltage $V_m(H^2)$ and IR drop between the Hall probes are in phase with the current, and are shown collinear in the vector. The resultant vector of these four voltage vectors is shown as the vector $\boldsymbol{A}$. A voltage inverse to $\boldsymbol{A}$ is added by the amplitude and phase controller circuit ajusting the magnitude $|\boldsymbol{A}|$ and the phase as to just vanish the out put signal. The magnetic field is then reversed, the voltage out put of the system becomes $2V_H$ because the Hall voltage changes its sign, and IR and $V_m(H^2)$ does not change sign. The Hall voltage $2V_H$ is recorded by the high sensitive detector and recorder.

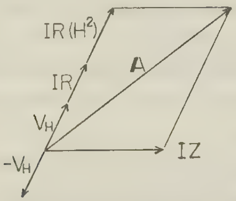

Fig. 2. Vector diagram of voltages controled in the Bucking and Adding Circuit.

A sample holder was constructed in special device to prevent the spurious signals from the sample and the Hall leads. The sample was set in a square hollow in a copper bar of 4 cm in diameter, 25 cm in length, the dimension of square hollow was 3 cm × 3 cm in base area, 2 cm in depth. For a heating furnace, the nichrome wire was wound in a bifilar winding around the mica plate 4 cm × 3.5 cm in area, and this furnace was inserted into the slice-shaped ditch which was cut deeply from the end of the copper bar. The Hall leads and sample current leads were fixed in the narrow channels which were cut along the length of the copper bar, for the sake of preventing a voltage induced in these leads vibrating in the magnetic field.

§ 3. Results

The results of measurement for these compounds are given in Table I. For nickel oxide and nickel telluride*, the Hall measurements could be performed only at the room temperature (at 16°C), because of the high resistivity of the former and of the very feeble Hall response of the latter. For iron telluride and iron sulfide the measurements could be performed in some wider range of temperature. Nevertheless the temperature variations

---

* The authors wish to thank Mr. Y. Nakazumi (Tochigi Chemical Industrial Co.) for supply of this single crystal.

Table I. Results of Hall measurements for Various compounds.

Compounds	Temperature (°C)	V_H (Volt)	R_H (cm³/amp.sec)	n (cm⁻³)	σ (Ω^{-1} cm⁻¹)	μ (cm²/Volt.sec)
NiO	16	4.2×10^{-7}	$+2.6\times 10^{4}$	2.7×10^{14}	1.4×10^{-8}	3.7×10^{-4}

for only iron sulfide are given in the Table for the purpose of the later discussions. The Hall voltages V_H observed and the Hall constants R_H calculated for these compounds are shown in the third and fourth columns, respectively.

The concentration n, and the mobility μ of the carrier given in the fifth and seventh columns are estimated by the following relations

$$R_H = 1/en \qquad (1)$$

$$R_H \cdot \sigma = \mu\,, \qquad (2)$$

where e is an electronic charge, σ a conductivity. These relations have been originally applicable to a simple band model of a metal and a semiconductor, however they may be, for present, used for the analysis of these compounds. In the present step, the conduction nature of these compounds has been remained obscure and no relations corresponding to Eqs. (1) and (2) have been obtained, it may be inevitable to use the above relations for the analysis of our compounds. Some of results obtained by the use of these relations will be discussed in later part of this paper.

§ 4. Discussions

Nickel oxide: Hall measurements of nickel oxide have not yet been reported, because of its high resistivity and of its very poor Hall response. Morin[2] has determined, by the measurements of Seebeck effect, the nature of conduction was the hole conduction. Our Hall measurement shows a positive Hall constant and so also a hole conduction. The hole mobility is of the order 10^{-4} cm²/volt.sec., and the hole concentration is of the order 10^{14} per unit volume. These values seem to be reasonable for a high resistivity material such as nickel oxide. Yamashita and Kurosawa[3] have investigated theoretically the conduction of this material as a d-hole diffusion with very small mobility. The very small value of mobility obtained as above may be compatible with the concept of the hopping model proposed by them.

Nickel telluride and Iron telluride: These compounds have a considerablly high conductivity with a poor mobility. In general, these compounds, containing a magnetic element and being low resistivity, have a apparent poor mobility estimated by the use of the relation (2), and an extraordinarily large number of carriers estimated by the use of the relation (1), as shown in Table I. These carrier numbers are larger than the lattice concentration, this means the relations (1) and (2) are unreasonable to apply to these compounds and the Hall constants might be under estimated. It may be necessary to consider a two bands model in stead of one simple band model. The extraordinarily small value of Hall constant may be attributed to the cancellation between the contributions from the electrons and the holes. The final conclusion will be reported after the more detailed experiments is made.

Iron sulfide: The iron sulfide has a remarkable anisotropy of conductivity at the temperature range below T_α, the temperature of the α-transformation, as seen in Fig. 3(a)[4]. σ_a and σ_c in the figure are the conductivities in the cases that an external electric field is applied in perpendicular, and in parallel to the c-axis of a single crystal, respectively. The anisotropy at the temperatures below T_α is very large ($\sigma_a/\sigma_c \doteqdot 800$), and becomes to be small ($\sigma_a/\sigma_c=1.5$) above T_α. The Hall measurements were carried out at the temperatures below and above T_α, and the almost same values of Hall constants have been observed both in the cases of σ_a and σ_c, within the limit of experimental error. These Hall constants observed and the mobility estimated by the use of the relation (2), are also shown in Fig. 3 (b). The concentration of carriers in the two cases of σ_a and σ_c, are same order. Nevertheless the mobility exhibits a remarkable anisotropy as seen in the conductivity. It may concluded that the anisotropy of conductivity is owing to the anisotropy of the mobility but not to the carrier number.

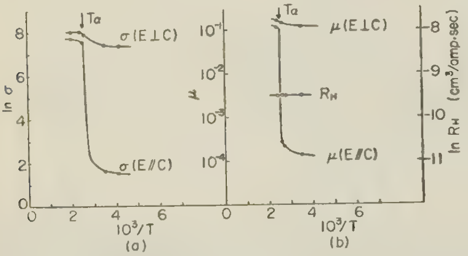

Fig. 3. Conductivity, Hall constants, and mobility for iron sulfide stoichiometric. (a) anisotropy of conduction. σ_a and σ_c are the cases the external electric fields are applied in perpendicular to, and in parallel to c-axis of crystal, respectively[4]. (b) the mobility μ and Hall constant R_H obtained in this work.

In order to interpret the fact that the carrier concentration does not change at the temperatures below and above T_α and that the mobilities very low, it may be natural to assume that there are two kinds of ions of different valences such as Fe^{2+} and Fe^{3+} for the lack of stoichiometry, and the electrons or holes hopping between these ions are responsible for the conduction and the low mobility.

The detailed estimation of this problem will be reported by one of the authors on the paper which will be published in this journal.

Anisotropy of Electrical Conduction in Iron Sulfide Single Crystal

By Miyuki MURAKAMI

Department of Physics, Faculty of Science, Tōhoku University

(Received September 5, 1960)

To investigate the anisotropy of the conductivity of iron sulfide single crystal, a simultaneous measurement of the conductivity and the thermal expansion was carried out.

The result is that the conductivity is intimately correlated with the lattice parameter (or exchange energy), but is not necessarily affected by the spin direction. From this result a spin sublattice structure of high temperature type is proposed, and the anisotropy of the conductivity in the range of temperature near the α-transformation temperature is interpreted qualitatively.

§ 1. Introduction

The anisotropies of susceptibility and conductivity in iron sulfide single crystal have been studied in our laboratory[1], the results reproduced are shown in Figs. 1 and 2. In Fig. 1, the solid lines show the susceptibilities in the heating process and dotted lines show those in the cooling process. In these measurement, especially the anisotropic behavior at the α-transformation is characteristic. The qualitative interpretation for the magnetic susceptibility has been given assuming that the exchange energy and anisotropy energy change those values simultaneously at the α-transformation[2),3)]. No report for the interpretation of the conductivity has been published at present.

For the stoichiometric iron sulfide single crystal, the ratio of conductivities, one the current flows along the direction perpendicular to and the other parallel to the c-axis, is of the order of 10^3 at the temperatures below T_α (the temperature of the α-transformation), and is about 1.5 at the temperatures above T_α. One of the purposes of this paper is to interprete the anisotropy qualitatively.

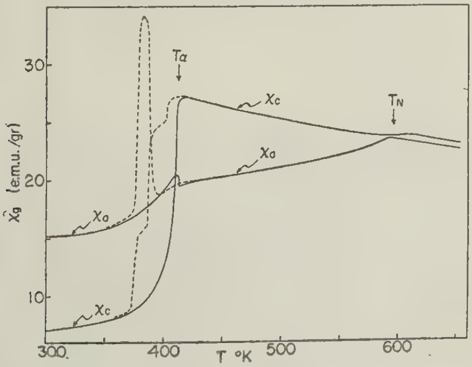

Fig. 1. Susceptibility versus temperature curves. Solid curves are in heating process, and dotted ones are in cooling process[1)].

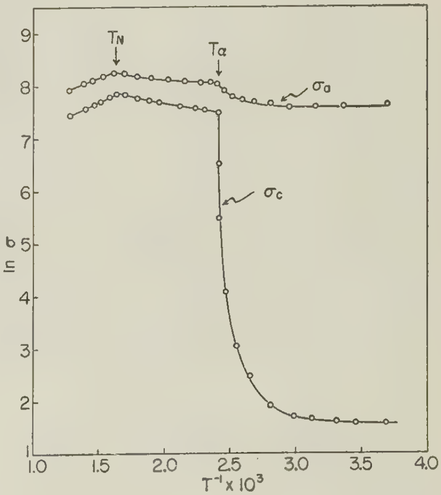

Fig. 2. Conductivity versus temperature curves.

For the interpretation of the anisotropy, it is necessary to perform more detailed investigation of the α-transformation than before (previous cooling experiment[2)]). The previous cooling experiment shows that the exchange energy and the sign of the anisotropy energy change at the different temperatures on the cooling process. On the theoretical consideration, though it is not clear, the exchange energy is considered to change its value with the lattice parameter or c/a of the crystal.

It is well known that a remarkable change of the c/a takes place at the α-transformation[3),4)]. To investigate the correlation between the exchange energy and the conduction, a simultaneous measurement of the conductivity and the thermal expansion of the crystal was carried out in the range of temperature near T_α. From the consideration of the experimental results, an antiferromagnetic sublattice structure of this substance has been proposed which is consistent with the magnetic properties, and explain the anisotropy of the conductivity.

§ 2. Experiments and Results

The apparatus for the simultaneous measurements of conductivity and thermal expansion was built up with a conventional dilatometer and a resistivity measuring potentiometer. The sample was set between the silica pieces, and its thermal expansion was measured by the double mirrors and telescope. Four resistivity probes were attached to the sample as shown in Fig. 3(a). The probes are made of tungsten wire. A plane figure of a probe ring is shown in Fig. 3(b); a small tungsten pin attached on the ring contacts with the sample. Two current leads and two voltage leads are connected with four rings, respectively. The sample crystal used for the measurement was the single crystal with the c-axis parallel to the length of the sample. The conductivity and the thermal dilatation both along the c-axis was measured simultaneously, and the results are shown in Fig. 4.

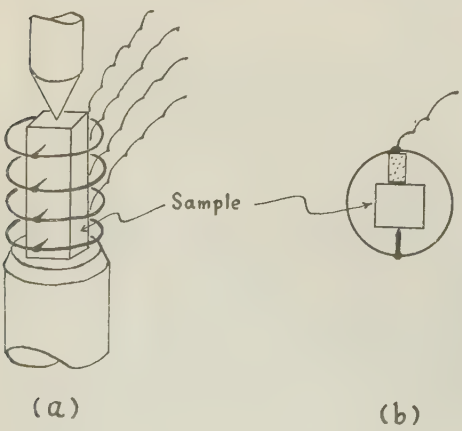

Fig. 3. Detailed figures of sample holder unit in apparatus for the simultaneous measurement of thermal dilatation and conductivity.

The susceptibility χ_a, obtained when the external magnetic field was applied perpendicular to the c-axis of the sample mentioned above, is also shown in Fig. 4. The rate of the temperature change for the susceptibility measurement was taken care to be the same with that of the conductivity and dilatation measurement. The arrows in Fig. 4 show the process of the thermal cycle in each measurement.

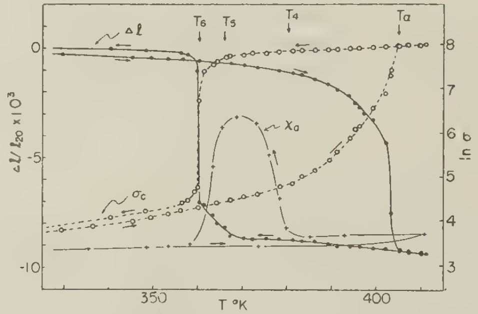

Fig. 4. Results for the simultaneous measurement of thermal dilatation and conductivity, and added to them result for susceptibility of the same sample. Arrows indicate the heating and cooling processes.

It will be significant to call attention to the cooling curves which show a intimate correlation between the conduction and the dilatation, but not between the conduction and the susceptibility or the easy axis direction of magnetization. When the temperature is decreased from T_α, at the temperature T_4 the susceptibility increases abruptly, but the conduction and the dilatation does not change, and at T_5 the susceptibility, conduction and the dilatation bigin to decrease, and then at T_6 the conduction and the dilatation both change abruptly.

§ 3. Discussion

a) *Schematical interpretation of the anomalous cooling curves.*

As mentioned before, the α-transformation on the heating process may be understood by assuming the simultaneous change of the exchange energy and anisotropy energy. The anomalous behavior of the α-transformation on the cooling process may be understood assuming the changes at different temperatures of the two energies.

These situations are schematically given in

Fig. 5. The exchange energy A, which will be intimately correlated with the lattice parameter, decreases abruptly at $T_1 \sim T_3$, and settles on the normal curve on the heating process, but on the cooling process, it jumps up at T_5 toward the normal curve (heating curve) and coinside with it at T_6. The exchange energy is assumed to change like as the lattice parameter. The anisotropy energy constant K, which is assumed uniaxial, will decrease at T_1, and its sign will change from positive to negative at T_2 on the heating process. On the cooling process, its sign will change at T_4 from negative to positive. For the anisotropy energy the change in sign will be important.

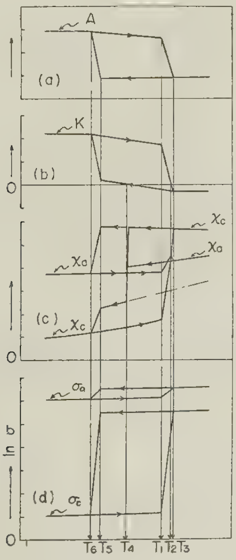

Fig. 5. Schematic interpretation of α-transformation.

a: variation of exchange coupling constant A.
b: variation of anisotropy constant K.
c: variation of susceptibilities of χ_a and χ_c.
d: variation of conductivities of σ_a and σ_c.

Combining the variations of the K and A mentioned above, the temperature variations of the susceptibility and the conductivity near T_α will be represented schematically as in Fig. 5(c) and (d). These figures represent qualitatively the experimental results.

b) *Estimation of the exchange energy at various temperatures*

As mentioned in the preceding paper[5], the Hall measurement for iron sulfide at the temperatures below and above T_α show that the mobility has a remarkable anisotropy and anomaly and the carrier concentration does not change in that temperature range. It may be assumed that the main part of the conduction will be caused by the electron transfer between Fe^{2+} ions and Fe^{3+} ions, and the anisotropy and anomaly will be ascribed to the spin correlation of the conduction electron with the lattice magnetization. There are two distinct cases for the electron transfer in the consideration of spin correlation in an antiferromagnetic material. One is the case in which the electron must transfer along the direction in which the lattice spins align in antiparallel alternately, and in this case the electron transfer will be assumed to need an activation energy for the spin flip, which is equal to the exchange energy J. The other is the case in which the electron will transfer along the direction in which the lattice spins align in parallel, and in this case no activation energy will be needed for the electron transfer. In a rough approximation the ratio of the conductivities in the two distinct directions mentioned above will be $\exp(-J/kT)$. The conductivities in the two cases will be, here after, designated $\sigma_\perp$ and $\sigma_{//}$ respectively.

To estimate the temperature dependence of σ_a/σ_c or $\sigma_\perp/\sigma_{//}$, the temperature variation of J has been estimated by the use of the results of susceptibility measurement. For the temperature range above T_N, it may be put that $J \simeq kT_N$. For $T<T_\alpha$, the estimated T_N' from Eq. (A, 4) in Appendix fitting to the experimental value of $\chi_{//}$ is not the same as T_N because the α-transformation changes the magnetic structure, or the magnitudes of the antiferromagnetic coupling constant A and of the ferromagnetic coupling constant Γ.

A may be estimated from Eq. (A, 1) in Appendix, and S is assumed to be 2, g-value has been estimased by the author[6] to be $g=2.14$ from the analysis for the paramagnetic region. Using these values, T_N' was obtained to be 900°K from Eq. (A, 4) fitting to the experimental values. Therefore, the exchauge energy J may be put as $J=kT_N'=k\times 900°\text{K}$ for $T<T_\alpha$.

For $T_\alpha<T<T_N$, the slightly temperature dependent value of A is estimated from the Eq. (A, 1) which is slightly increasing with temperature as the lattice parameter gradually changes. The value of $\chi_{//}$ in this region has been estimated as $\chi_{//}=2\chi_a-\chi_c$,[1] where χ_a is

the susceptibility when the external magnetic field applied in the direction perpendicular to the c-axis of the crystal. The T_N' in this region is obtained from Eq. (A, 4) using these values mentioned above, which is given in Fig. 6. The values of A and Γ at various temperatures are also given in the same figure.

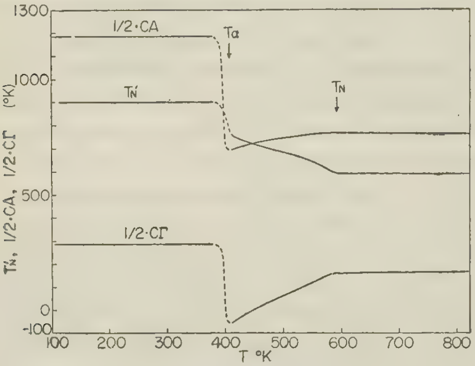

Fig. 6. Estimated values of A, Γ, and $T_N' \equiv \frac{1}{2}C(A-\Gamma)$.

c) *Anisotropy in the conductivity*

For $T<T_\alpha$ the easy magnetization axis is parallel to the c-axis of the crystal, therefore, the ratio $\sigma_a:\sigma_c$ may be approximately $\exp(J/kT):1$. As $J=k\times 900°\mathrm{K}$, this ratio is $\exp(900/100)\simeq 8\times 10^3$ for 100°K, ca. 10^2 for 200°K. Since the actual crystal will have some residual conductivity caused by some sort of lattice defects or by some s-, p- band electrons, these values may be considered to give the observed anisotropy in the conductivity qualitatively.

For the range $T_\alpha<T<T_N$, the spins align in c-plane, or easy magnetization axis lies in perpendicular to the c-axis. As marked in Fig. 5, the conductivity is not affected by the spin direction but intimately correlated with the exchange energy. In fact, it was impossible to evaluate the ratio σ_a/σ_c which agrees with the measured ratio of $\sigma_a/\sigma_c=1.5$, when the sublattices were chosen to be parallel with c-plane. It was considered that the sublattice would change its structure owing to the decrease of A at T_α. Hence it was attempted to find the types of sublattice which could be considered to be consistent with the experimental susceptibility results. Among these sublattices, the one which is able to explain the anisotropy and anomaly of the conductivity is shown in Fig. 7. The sublattice planes in this type incline to the c-axis by about 45° (more exactly 44.5°). In this type, the conductivity along the sublattice plane is $\sigma_{//}$, and $\sigma_\perp$ is the conductivity perpendicualr to the sublattice plane. Considering the experimental results[1)] that the rotationary measurements for the susceptibility around c-axis have shown no anisotropy in this temperature region, the crystal will be assumed to consist of three groups of domains, each domain will have the structure in Fig. 7 and will be disposed keeping angle of 120° with other domains. This domain structure will be designated as "Y-structure" for the sake of brevity.

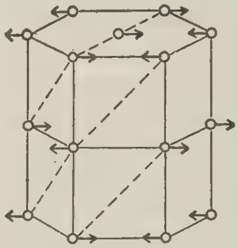

Fig. 7. Magnetic spin sublattice structure proposed in the temperature region between Γ_α and T_N. Circles are iron ions, neglecting sulfur ions for simplicity.

The conductivity along the c-axis may be

$$\sigma_c=\sigma_{//}\cos^2 45°+\sigma_\perp \sin^2 45°=(1/2)(\sigma_{//}+\sigma_\perp)\ .$$

At 420°K, just above T_α, $J=k\cdot 750°\mathrm{K}$ from Fig. 6, so

$$\sigma_c=(1/2)(1/6+1)\sigma_{//}=(7/12)\sigma_{//}\ .$$

At 593°K, the Néel point, $J=593°\mathrm{K}\times k$,

$$\sigma_c=(1/2)(1/2.7+1)\sigma_{//}=(3.7/5.4)\times\sigma_{//}\ .$$

The conductivity along the direction perpendicular to the c-axis may be calculated by Eq. (B, 4) in Appendix. It is

$$\begin{aligned}\sigma_a&=(1/4)(3\sigma_{//}+\sigma_\perp)\\&=(1/4)(3+1/6)\sigma_{//}=(19/24)\sigma_{//} &&\text{at } 420°\mathrm{K}\ ,\\&=(1/4)(3+1/2.7)\sigma_{//}=(91/108)\sigma_{//} &&\text{at } 593°\mathrm{K}\ .\end{aligned}$$

The ratio

$$\begin{aligned}\sigma_a/\sigma_c&\simeq 1.36 \quad \text{at } 420°\mathrm{K}\ ,\\&\simeq 1.23 \quad \text{at } 593°\mathrm{K}\ .\end{aligned}$$

These estimated values agree qualitatively with the experimental value $\sigma_a/\sigma_c=1.5$.

Recently, Hihara et al[7)] have reported the experimental results for the susceptibility and the conductivity of sulfur excess sample FeS_x, $\chi=1.05\sim 1.09$. They found that, in these samples the A and K independently changed at different temperatures. For example, the

K changed its sign at $-20°$C, and the A changed its value at 110°C owing to lattice parameter (c/a) change, for the sample $FeS_{1.05}$. They also have observed that the conductivity changes with A, and does not change at the temperature where K changes its sign.

Their results may be qualitatively explained by our model as follows. For FeS_x ($x=1.05 \sim 1.09$), the sublattice structure will change at T_α from " Y-structure " of the high temperature type to the simple sublattice structure of low temperature one, so that conductivity will be largely affected as expected. At the T_a', the temperature at which K changes its sign, the simple sublattice will be kept unchanged, and only the axis of easy magnetization changes its direction so that the $\chi_{\parallel}$ and $\chi_{\perp}$ interchange mutually their roles, however the conductivity will not be affected approximately by the spin flipping.

Finally the writer wishes to express his thanks to Prof. E. Hirahara for continuous guidance and helpful discussions given during this work.

Appendix

A. Formulas for the susceptibilities

In the simple theory of antiferromagnetism, the susceptibilities[8)] $\chi_{\perp}$ and $\chi_{\parallel}$ are

$$\chi_{\perp}=1/A \qquad (A, 1)$$

$$\chi_{\parallel}=\frac{3SB_s'(y_0)}{S+1}C\Big/\left[T+\frac{1}{2}(A+\Gamma)C\frac{3SB_s'(y_0)}{S+1}\right], \qquad (A, 2)$$

and the Néel temperature T_N is expressed as

$$T_N=(A-\Gamma)\ C/2\ . \qquad (A, 3)$$

The notations used in these formulas are same as in the reference. From the formulas (A, 1), (A, 2) and (A, 3)

$$\frac{1}{\chi_{\parallel}}=\frac{S+1}{3SC}\frac{T}{B_s'(y_0)}+A-\frac{T_N}{C}\ , \qquad (A, 4)$$

is obtained.

B. Calculation of the conductivity

If the $x'\,y'$-plane is chosen in a plane of one sublattice plane of the " Y-structvre ", and then the z'-axis is chosen in perpendicular to the plane, the conductivities along the x'-, y'- and z'-axis, respectively, are $\sigma_{\parallel}$, $\sigma_{\parallel}$ and $\sigma_{\perp}$. An electric field vector $\boldsymbol{E}$, and a current vector $\boldsymbol{I}$ are connected by a tensor $\boldsymbol{\sigma}$ as follows,

$$\boldsymbol{I}=\boldsymbol{\sigma}\cdot\boldsymbol{E}\ , \qquad \boldsymbol{\sigma}=\begin{pmatrix}\sigma_{\parallel} & 0 & 0\\ 0 & \sigma_{\parallel} & 0\\ 0 & 0 & \sigma_{\perp}\end{pmatrix}. \qquad (B, 1)$$

When the $x'\ y'\ z'$-system is rotated around x'-axis in 45°, and z'-axis coincide with the z-axis which is parallel to the c-axis of crystal, the $\boldsymbol{\sigma}$ is represented in the $x\ y\ z$-system as

$$\boldsymbol{\sigma}_{(xyz)}=\begin{pmatrix}1 & 0 & 0\\ 0 & 1/\sqrt{2} & -1/\sqrt{2}\\ 0 & 1/\sqrt{2} & 1/\sqrt{2}\end{pmatrix}\begin{pmatrix}\sigma_{\parallel} & 0 & 0\\ 0 & \sigma_{\parallel} & 0\\ 0 & 0 & 0_{\pm}\end{pmatrix}$$

$$\times\begin{pmatrix}1 & 0 & 0\\ 0 & 1/\sqrt{2} & 1/\sqrt{1}\\ 0 & -1/\sqrt{2} & 1/\sqrt{2}\end{pmatrix}$$

$$=\begin{pmatrix}\sigma_{\parallel} & 0 & 0\\ 0 & \frac{1}{2}(\sigma_{\parallel}+\sigma_{\pm}) & \frac{1}{2}(\sigma_{\parallel}-\sigma_{\perp})\\ 0 & \frac{1}{2}(\sigma_{\parallel}-\sigma_{\pm}) & \frac{1}{2}(\sigma_{\parallel}+\sigma_{\perp})\end{pmatrix}. \qquad (B, 2)$$

The conductivity σ_c along the z-axis is

$$\sigma_c=I_z/E_z=(1/2)(\sigma_{\parallel}+\sigma_{\pm})\ , \qquad (B, 3)$$

To calculate the conductivity perpendicular to the c-axis, it is necessary to take an average over the three sorts of domains distributed in every 120° around the c-axis. The tensor $\boldsymbol{\sigma}_{(xyz)}$ is transformed by rotation of φ around the c-axis to

$$\boldsymbol{\sigma}_{(\varphi}=\begin{pmatrix}\cos\varphi & \sin\varphi & 0\\ -\sin\varphi & \cos\varphi & 0\\ 0 & 0 & 1\end{pmatrix}\cdot\boldsymbol{\sigma}_{(xyz)}\cdot\begin{pmatrix}\cos\varphi & -\sin\varphi & 0\\ \sin\varphi & \cos\varphi & 0\\ 0 & 0 & 1\end{pmatrix}$$

$$=\begin{pmatrix}\sigma_{\parallel}\cos^2\varphi+\frac{1}{2}(\sigma_{\parallel}+\sigma_{\perp})\sin^2\varphi\ , & -\sigma_{\parallel}\sin\varphi\cos\varphi+\frac{1}{2}(\sigma_{\parallel}+\sigma_{\perp})\sin\varphi\cos\varphi\ , & \frac{1}{2}(\sigma_{\parallel}-\sigma_{\perp})\sin\varphi\\ -\sigma_{\parallel}\sin\varphi\cdot\cos\varphi+\frac{1}{2}(\sigma_{\parallel}+\sigma_{\perp}(\sin\varphi\cos\varphi\ , & \sigma_{\parallel}\sin^2\varphi+\frac{1}{2}(\sigma_{\parallel}+\sigma_{\perp})\cos^2\varphi\ , & \frac{1}{2}(\sigma_{\parallel}-\sigma_{\parallel})\cos\varphi\\ \frac{1}{2}(\sigma_{\parallel}-\sigma_{\perp})\sin\varphi\ , & \frac{1}{2}((\sigma_{\parallel}-\sigma_{\perp})\cos\varphi\ , & \frac{1}{2}(\sigma_{\parallel}+\sigma_{\perp})\end{pmatrix}.$$

The conductivity σ_a will be calculated taking average for φ over the three directions $\varphi+0°$, $\varphi+120°$ and $\varphi+240°$, and it will be, independently of φ,

$$\sigma_a=(1/3)\{\sigma_{\parallel}\cos^2\varphi+(1/2)(\sigma_{\parallel}+\sigma_{\perp})\sin^2\varphi+\sigma_{\parallel}\cos^2(\varphi+120°)+(1/2)(\sigma_{\parallel}+\sigma_{\perp})\sin^2(\varphi+120°)$$
$$+\sigma_{\parallel}\cos^2(\varphi+240°)+(1/2)(\sigma_{\parallel}+\sigma_{\perp})\sin^2(\varphi+240°)\}=(1/4)(3\sigma_{\parallel}+\sigma_{\perp})\ . \qquad (B, 4)$$

Heat Treatment Centers in Silicon

By Yasuo MATUKURA*

Electrotechnical Laboratory, Tokyo, Japan

(Received September 7, 1960)

Heat treatment of p-type silicon at temperatures above 900°C frequently results in a decrease of hole concentration. In the present experiments, heat treatment centers have been found to diffuse from the surface during such heat treatments in the case of sufficient concentration to account for the observed changes in the electrical characteristics. The heat treatment center has a deep donor level at 0.4 eV above the valence hand. This level is converted into a donor level 0.51 eV from the conduction band at room temperature. Heat treatment centers may perhaps be introduced into silicon by surface impurity. Diffusion of the surface impurity is classified by its speed into two species. Faster diffusing one is characterized by the diffusion coefficient of 1×10^{-5} cm²/sec at 1017°C and the activation energy for the solution, 1.8 eV. Observed properties on the heat treatment center show that heat treatment in the temperature range 900 to 1265°C results in diffusion of iron from the surface into bulk material.

§1. Introduction

Recently, the growth of silicon single crystals having long lifetime of minority carrier has become possible. However, in subsequent heat treatments to temperatures above 1000°C, the lifetime is frequently degraded.[1-4] The degradation of lifetime is sometimes accompanied by the decrease of hole concentration in p-type silicon, resulting in an increase of resistivity. G. Bemski[1] has reported that these phenomena have been caused by the formation of heat treatment centers at high temperatures, and that these centers are gold. Gold in silicon has an acceptor level at 0.54 eV below the conduction band and a donor level at 0.35 eV above the valece band.[5] By our preliminary experiments, it was seen that heat treated silicons had some donor levels. Neither this discrepancy has yet been made clear, nor the details for the formation of the heat treatment centers.

In the present work, observations are made on the diffusion of heat treatment centers from the surface of specimen and the temperature dependencies of Hall coefficient and resistivity of p-type crystals treated at high temperature. The results show that the heat treatment centers have some donor levels, and that these donors are introduced by diffusion from the surface with the diffusion coefficient of about or over 10^{-5} cm²/sec and precipitate in lattice defect by slow cooling from high temperatures. It seems that these heat treatment centers are originated from some surface impurities, one of which is probably iron atoms.

§ 2. Experimental

The electrical effects in heat treated silicon are studied by standard techniques. The changes in carrier density at room temperature are obtained from resistivity measurements by four point probe method. The energy level of heat treatment centers is obtained from Hall coefficient and resistivity measurements as a function of temperature by using vibrating reed electrometer.

Both pulled and floating zone refined *p*-type crystals are studied, and their resistivities are lying in the range of 10 to 1000 Ω cm at room temperature. For reducing some donors originated from oxygen, pulled crystals are heated for 5 hours at 1050°C and then cooled at the rate of 2°C/min. After cutting, samples are rinsed in a mixture of HNO_3 and HF and then in deionized water by an ultra-sonic machine. Heat treatments of the samples are performed at the temperature range of 900 to 1265°C in quartz tube using argon as a gas ambient.

§ 3. Results

When *p*-type silicon is heated at the temperature above 900°C and quenched, the concentration of hole is reduced to about 10^{14} cm^{-3} and its resistivity becomes high. By a long period treating at high temperature, *p*-type specimens are converted sometimes to the *n*-type of high resistivity indicating that the heat treatment center may act like a donor impurity. While high purity *n*-type silicon is heated at high temperatures and quenched, no change in resistivity or Hall coefficient are not observed. Thus there does not appear more than 10^{13} cm^{-3} of acceptor levels for the heat treatment centers.

Concentrations of the heat treatment center greater or smaller than the initial hole concentration are obtained by treating high purity *p*-type silicon at high temperatures and quenching. On these specimens, Hall coefficient and resistivity are measured as a function of temperature. Fig. 1 shows the typical temperature variations of Hall coefficient. Curve 1 is obtained on an untreated *p*-type specimen. Curve 2 is obtained on a sample treated at 1050°C for 5 hours, whose initial acceptor concentration is 1×10^{14} cm^{-3}, and the slope gives the activation energy of 0.2 eV. Curve 3 is got on another one treated at 1250°C for 5 hours, indicating the activation energy of 0.43 eV. The initial acceptor concentration is equal to the specimen of curve 1. From *p*- to *n*-type conversion is found on a sample which was heated at 1265°C for 2 hours and then kept at room temperature for 4 weeks, shown as curve 4, indicating the activation energy of 0.51 eV. Changes in type were not observed immediately after high temperature treatment but found to occure after 4 weeks. In general, it is seen that the specimen having the higher resistivity after a heat treatment has a tendency to show the larger slope on the Hall coefficient vs the inverse temperature curve. It seems that the decrease of hole concentration may result from the heat treatment center having deep

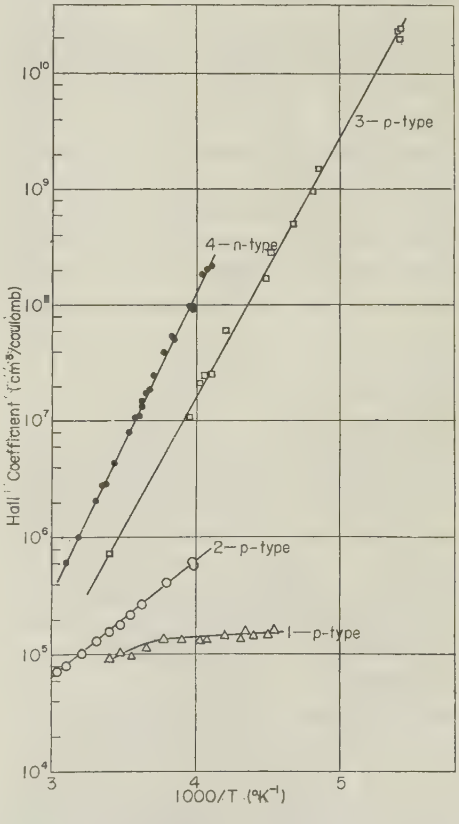

Fig. 1. Hall coefficient *vs* reciprocal temperature for heat treated *p*-type samples.

donor levels above the valence band, and that these centers are nearly ionized at room temperature.

As shown in Fig. 1, the treated *p*-type specimen are converted into *n*-type after about a month at room temperature. However, this conversion does not always take place in heat treated silicon. The specimens in which a large number of heat treatment centers were introduced have a tendency of this conversion.

Since the heat treatment center has deep donor levels lying near the center of forbidden gap, it is henceforth assumed in this work that that the change in hole concentration by heat treatment above 1000°C is a measure of the induced centers.

In order to make clear the mechanism on the formation of the heat treatment center, some experiments were performed. Pulled and floating zone refined *p*-type crystals are cut into rectangular specimens having different surface-to-volume ratios. These specimens are simultaneously heated for 5 hours at 1050°C and then cooled at the rate of 5°C/min. After removing the surface region, the changes of resistivity are measured. Successive lapping of the surface layer shows that the heat treatment centers distribute uniformly in the specimen. The variation of the concentration of formed heat treatment center with the surface-to-volume ratio is shown in Fig. 2. It is seen that the concentration of the heat treatment center increases linearly with the increasing surface-to-volume ratio. Therefore, it seems that the heat treatment centers are not resulted from the bulk properties such as oxygen atoms and quenched-in dislocations but from the surface impurities with high diffusion rate. If the heat treatment centers are resulted from the quenched-in vacancied or some impurities contained in the bulk silicon, it seems that the concentration of heat treatment center does not depend on the surface-to-volume ratio of the treated specimens. This result will predict that the heat treatment centers are formed by diffusion process from the surface into the bulk.

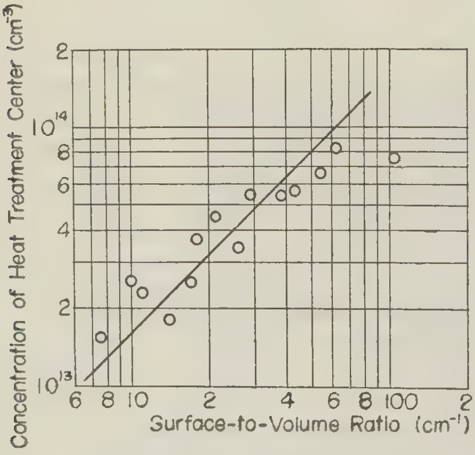

Fig. 2. Concentration of introduced heat treatment center *vs* surface-to-volume ratio of *p*-type sample at 1050°C.

As it is expected for the surface impurities to have a high diffusion rate, *p*-type specimens with the thickness of about 4 mm are used to measure the diffusion constant of these impurities. The specimens are heated for 1 hour at 1017°C and qunenched at the rate of about 800°C/min. Resistivity is measured as a function of the depth from the surface, and the penetration of the surface impurities into the specimen is estimated from the decreased hole density. The distribution of the diffused impurities with the depth from the surface is shown in Fig. 3, where solid line is calculated value obtained by assuming error function for diffusion process and diffusion coefficient $=1\times10^{-5}$ cm²/sec. It is seen that the penetration of the surface impurities nearly agrees with the calculated one. It is noticed that the surface impurities diffuse with large diffusion coefficient such as 1×15^{-5} cm²/sec, and that as shown in Fig. 3 the concentration of heat treatment center near the surface is larger than that in the interior where the diffused centers have a plateau distribution.

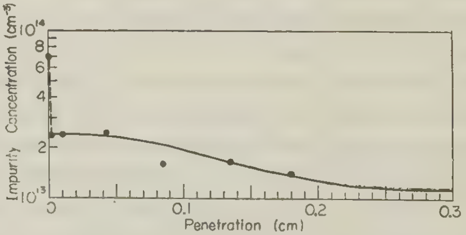

Fig. 3. Penetration curve of surface impurity at 1017°C.

Similar experiments were also performed at 1106°C, and it was seen that the diffusion coefficient at its temperature was greater than 1×10^{-5} cm²/sec. The distribution of the duffused centers shown in Fig. 3 indicates that two species of diffused centers may be present:

a more slowly diffusing species for the shallow penetration with a high surface concentration and a faster diffusing species for the deep penetration.

On the faster diffusing species, the diffusion coefficient is extremely large at the temperatures above 1000°C such as $1\times10^{-5}\,\mathrm{cm^2/sec}$ or more. Therefore, it seems that the diffused impurity in thin specimens distributes uniformly for about 60 min. Then, the plateau in the curve for 1017°C in Fig. 3 measures the surface concentration of a faster diffusing species. Fig. 4 shows the variation of heat treatment center density with the temperature at which the specimens were treated. The specimens of 1 mm thickness with the resistivity of 10 to 200 Ω cm are heated for 2 hours at the temperature range of 1000 to 1265°C and then quenched. The changes of resistivity are measured at 50 μ below the surface, and the diffused center density is obtained. As shown in Fig. 4, the logarithm of the diffused center density varies linearly with the reciprocal of the treating temperature, showing the slope of about 1.8 eV.

It is experienced that the decrease in hole density by heat treatment at high temperatures is larger in the center of pulled crystals than at the edge[3]. Similar results are also obtained in present work. Specimens of 1 mm thickness are prepared by slicing perpendicularly to the pulled axis of crystal. After heating at 1060 and 1200°C, the changes in resistivity are measured along the diameter. Fig. 5 shows the variations of the concentration of heat treatment center along the diameter. It is seen that the concentrations of the diffused center at the edge of the slices are less than those at the center where dislocation density is expected to be small. On the other hand, the concentration of the diffused center depends on the rate at which the specimens are cooled from high temperatures. For example, after the specimens of 200 Ω cm resistivity were heated for 1 hour at 1050°C, the specimens were cooled at the rate of 2°C/min from the treating temperature to 500°C and then rapidly to room temperature. Results obtained from the resistivity measurements show that the diffused centers are nearly zero in the slowly cooled specimens.

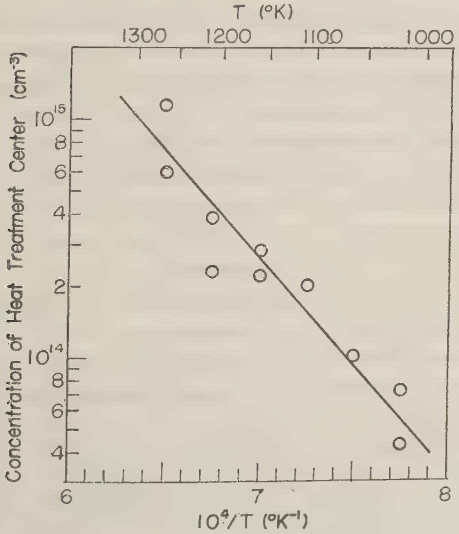

Fig. 4. Solubility of a faster diffusing species *vs* reciprocal temperature.

§ 4. Discussion

G. Bemski[1] has pointed out that the concentration of carrier in both p- and n-type silicon decreases by heating at high temperatures, and that these decreases result from the introduction of gold as a heat treatment center which has both donor and acceptor levels in silicon. In this work, while the hole density in p-type silicon decreases by the heat treatment at high temperatures, the heat treatment on high resistivity n-type silicon shows no changes in resistivity except the decrease of donor density due to the annihilation of oxygen[6]. Reduction of the hole density in p-type silicon may be explained by an assumption that the heat treatment does not introduce into silicon any deep acceptor levels, but some donor levels. In the elements investigated so far in silicon, the element which has two deep donor levels is only iron, of which the donor levels lie at 0.40 eV above the valence band and at 0.55 eV below the conduction band.[7] If it is permited to assume that one of the impurities of the heat treatment centers is originated from iron, the results obtained in preceeding section may be nearly explained. In Fig. 1, the activation energies 0.43 and 0.51 eV obtained from curve 3 and 4, respectively, are nearly in agreement with the values on iron, but the value obtained from curve 2 is very small compared with 0.40 eV. This discrepancy may be understood as follows: when the amount of the introduced heat treatment centers is small in comparison with the hole density in the initial p-type specimen, the Fermi level will be located below the deep donor level for such centers.

Since the concentration of heat treatment center is proportional to the surface-to-volue ratio, it may be reasonable to assume that the heat treatment centers are originated from the impurities on the surface of specimen. These impurities have a large diffusion constant such as 1×10^{-5} cm²/sec at 1017°C. In the elements investigated so far in silicon, the elements which have such a large diffusion constant are Li, Cu, Au, Zn, Fe,[8] and Ni[9]. Since the heat treatment centers will not have any acceptor levels, it seems that the above mentioned elements are not probable except iron as the impurity of the heat treatment center. The diffusion constant of iron which has been measured by C. B. Collins[7] is 5×10^{-6} cm²/sec at 1000 to 1115°C. It may be noticed that the diffusion constant of iron shows also the good aggreement with the value obtained for the heat treatment centers. As shown in Fig. 4, the activation energy of the surface concentration is about 1.8 eV and much smaller in comparison with the value obtained from the data of C. B. Collins for iron.[7] It seems that this discrepancy may be probably due to the difference in the degree of crystal defect, for the properties of the heat treatment center are very structure sensitive as shown in Fig. 5. The initial surface concentration of the impurity may be roughly estimated from the faster diffusing species as follows; in Fig. 2, the number of diffused center per unit surface-to-volume ratio is about 1.5×10^{12} cm^{-2} at 1050°C. It will be resonable to consider that these amount of the impurities can be supplied on the surface of silicon during the etching process or from argon as a gas ambient.

Heat treatment centers are not observed in the specimens which are cooled slowly from high temperatures. This result is suggestive of the precipitation of the impurity. It seems that the heat treatment centers diffused at high temperature precipitate or aggregate in the site, such as dislocations, having a low potential energy in the course of cooling. This mechanism will agree with the results shown in Fig. 5 that the reduction of hole concentration by heat treatment increases at the center of the slice where the dislocation density is small compared with that at the edge.

It is known that some concentrations of heat treatment center in silicon have a deleterious effect on the lifetime of minority carriers.[1-3] For iron in silicon, the recombination cross section for holes, A, is 3×10^{-16} cm² and for electrons, A_n, is greater than 1.5×10^{-15} cm².[7] In consideration of the diffusion mechanism, energy levels, and recombination properties on the heat treatment centers, it will be reasonable to consider that one of the impurities from which the heat treatment centers in this work originate is probably iron atoms.

The author wishes to thanks Dr. T. Momota for his continual encouragement, and Dr. M. Shibuya for helpfull discussions.

On the Energy of the Interstitial Atom in Graphite

By Tadao IWATA, F.Eiichi FUJITA and Hideji SUZUKI

Japan Atomic Energy Research Institute
Tōkai-mura, Ibaraki-ken

(Received September 16, 1960)

Self- and migration energies associated with interstitial carbon and xenon atoms in graphite are calculated, taking account of the relaxation around the interstitials. Assuming that the graphite lattice consists of thin elastic plates held together by the weak interaction forces and subjected to the transverse force by the interstitial atom, the strain form is obtained by solving the equations for the bending plates. Then, employing a suitably chosen interaction potential between the interstitial and all other atoms, the relaxation and the energies associated with the interstitials are calculated. In case of the carbon atom, the self-energy is 2.5 ev, the migration energy 0.016 ev and the ratio of strain energy to the total self-energy 0.49, and in case of xenon, they are 15.1 ev, 0.03 ev and 0.79 respectively.

§ 1. Introduction

Lattice defects in graphite have been investigated since the development on the first nuclear reactor[1]. Dienes[2] was the first to study the mechanism for self-diffusion in graphite using a simple but pertinent theory: He estimated the energies associated with vacancy, interstitial and direct interchange of atoms, and concluded from these values that either of the vacancy mechanism and the interstitial mechanism may be not always favourable for self-diffusion as compared with the direct interchange. The experiment on the diffusion of carbon stoms in natural graphite was done by Kanter[3], and it was found that the diffusion process can be expressed by $D=40f^2\exp(-163000/RT)$ where f is a constant depending on the crystal shape. He compared this experimental value of activation energy for self-diffusion with the theoretical values obtained by Dienes and revised by him, but didn't find what mechanism actually takes place in self-diffusion in graphite because of the discrepancies between the experimental and theoretical values. It should be noted that the above investigators took no account of the relaxation of atoms around the point defects in their calculations, which would substantially change the above theoretical values.

On the other hand, recent development in the radiation damage experiments seems to emphasize the importance of migration and self-energies of vacancies and interstitials formed by the incident high energy particles[4,5]. Although there are few fundamental irradiation experiments on graphite, it is possible to predict rough values for the energies of the defects; for instance, the self-energies of vacancy and interstitial are probably several electron volts (presumably 3~8 ev), the migration energy of vacancy a few electron volts (3~4 ev), and the migration energy of interstitial very low (of the order 0.1 ev). Actually, Dienes[2] estimated the migration energy of vacancy as 3.1 ev, which seems to be fairly reasonable. However, all other kinds of energies associated with the defects appear to remain not accurately calculated. Therefore, it is quite necessary to do more such calculations using appropriate theoretical methods as well as to do more fundamental experiments.

Another problem concerning the radiation effects on graphite arise from a new development of the nuclear reator; that is the diffusion of fission products such as xenon atoms in graphite. Xenon atoms produced by fission of uranium will migrate in graphite in such a fuel element as the "semi-homogeneous", and their diffusibility sometimes could determine the fundamental design of the reactor. This problem may be treated by a theory similar to that of the migration of the carbon interstitial atoms.

In this paper, we report on the migration and self-energies of the interstitial atoms of carbon and xenon in graphite. It is well known that graphite has a layer structure of hexagonal planes weakly held together by van der Waals forces. The bonds within the planes are very strong covalent bonds, the length of which is 1.42 Å. The inter-layer distance, in which the weak van der Waals interaction is taking place, is 3.35 Å. Accordingly, it may be reasonable to assume the graphite crystal lattice to be a system of thin elastic plates separated at a constant distance by the very weak interaction forces, so far as the lattice can be treated by the elasticity theory.

§ 2. Relaxation of Lattice around an Interstitial Atom

2.1 *Strain form in the layer structure*

There arise two kinds of extra energy increases when an interstitial atom is put into the graphite lattice; namely, (1) the strain energy arising from the change of atomic distances and bond angles as a result of bending of the hexagonal layers around the interstitial, and (2) the interaction energy between the interstitial atom and all other atoms in the crystal lattice. We can treat the former elastically without taking account of the detailed crystal structure. As mentioned before, this treatment is suggested from the layer structure of graphite, and, in fact, had a good success in the interpretation of the specific heat of graphite[6,7]. The latter energy will be obtained if the interaction potential between atoms is suitably chosen and also the strain form of the bent layers is determined, as will be mentioned later.

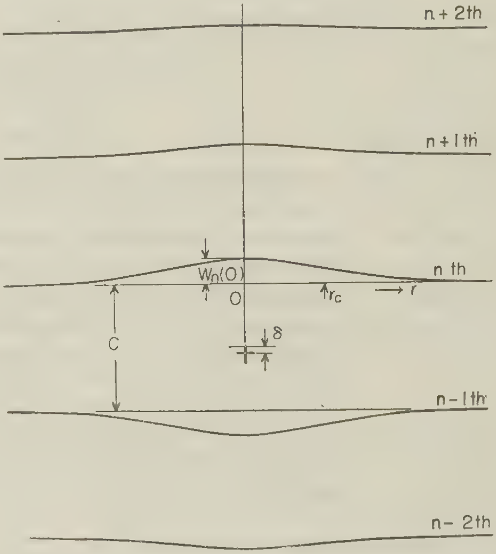

Fig. 1. Relaxation of the graphite lattice around an interstitial.

In this section, we determine the strain form by making the sum of both energy increases minimum. Formally, the latter interaction is introduced as the distribution load on each layer, its strength and distribution form being taken as two parameters in the calculation. The distribution of the load is undoubtedly co-axial as shown in Fig. 1. Therefore, we have the elastic strain energy associated with an interstitial in the form

$$V=\int_0^\infty \sum_{m=-\infty}^{\infty}\left[\frac{1}{2}c\rho\kappa^2\{\nabla^2 w_m(r)\}^2+\frac{1}{2}c\rho\mu^2\{w_{m+1}(r)-w_m(r)\}^2\right]2\pi r dr\,. \tag{1}$$

Here $w_m(r)$ represents the transverse displacement of the m-th layer at a radius r, the displacement parallel to the layer being neglected. c is the distance between the adjacent layers and ρ the volume density. κ^2 and μ^2, each multiplied by $c\rho$, are the bending elastic constant and the Hook's force constant between the neighbouring layers respectively. The first term in the bracket represents the elastic energy in the bent plates, and the second term the interaction energy increase between the neighbouring layers.

We introduce a distribution load $c\rho F_m(r)$ and use the D'Alembert's principle

$$\delta V-\int_0^\infty \sum_{m=-\infty}^{\infty} c\rho F_m(r)\cdot\delta w_m(r)\cdot 2\pi r dr=0 ,$$

in order to find the equations to determine the strain form. Putting the boundary condition that $w_m(r)$ becomes zero as $r\to\infty$, the equation for the strain form of the n-th layer per unit area is obtained[8];

$$-\kappa^2\cdot\nabla^4 w_n(r)+\mu^2\{w_{n+1}(r)+w_{n-1}(r)-2w_n(r)\}=-F_n(r) , \tag{2}$$

where

$$\nabla^2=\frac{d^2}{dr^2}+\frac{1}{r}\frac{d}{dr} .$$

To solve Eq. (2), we assume as following, provided that the interstitial is between the n-th and $(n-1)$-th layer;

$$w_{n-1}(r)=-w_n(r) , \qquad w_{n+1}(r)=\alpha\cdot w_n(r) , \qquad 0\leq\alpha\leq 1 . \tag{3}$$

The former assumption may be quite reasonable as an approximation, unless the crystal structure around the interstitial site is precisely taken into account. The latter assumption is also permissible if $w_m(r)\ll c$ and the region of strain is comparatively small. Thus, the equation to be solved under the above boundary condition is

$$(\nabla^4+h^4)w_n(r)=f_n(r): \quad h=\sqrt[4]{3-\alpha}\cdot\sqrt[2]{\mu/\kappa} , \qquad f_n(r)=F_n(r)/\kappa^2 . \tag{4}$$

To obtain the solution, first we find a Green function $G(r, \xi)$ that is the solution of the equation

$$(\nabla^4+h^4)G(r, \xi)=\frac{\delta(r-\xi)}{2\pi r} \tag{5}$$

and satisfying the boundary condition[9]. The physical meaning of $G(r, \xi)$ is the displacement of the layer at any radius r due to the unit load on the circle of $r=\xi$. By means of the Bessel function representation of δ-function, we have

$$G(r, \xi)=\begin{cases}\dfrac{1}{8h^2}[J_0(\sqrt{i}\,h\xi)\cdot H_0^{(1)}(\sqrt{i}\,hr)-J_0(\sqrt{-i}\,h\xi)\cdot H_0^{(1)}(\sqrt{-i}\,hr)] , & (r>\xi)\\[2ex] \dfrac{1}{8h^2}[J_0(\sqrt{i}\,hr)\cdot H_0^{(1)}(\sqrt{i}\,h\xi)-J_0(\sqrt{-i}\,hr)\cdot H_0^{(1)}(\sqrt{-i}\,h\xi)] , & (r<\xi)\end{cases} \tag{6}$$

where J_0 and $H_0^{(1)}$ are respectively the first and the third kind of Bessel function (Appendix). Thus we can obtain the solution of Eq. (4) by the integration,

$$w_n(r)=\int_0^\infty G(r, \xi)f_n(\xi)2\pi\xi d\xi . \tag{7}$$

By the direct differentiation, it is also possible to verify that Eq. (7) is the solution of Eq. (4). The right hand side of Eq. (7) and therefore Eq. (1) can be obtained analytically, if we assume a step function for $f_n(r)$, that is

$$f_n(r)=\begin{cases}\text{const}: & (0\leq r\leq r_c)\\ 0 \ : & (r_c\leq r) .\end{cases} \tag{8}$$

Then we have

$$\frac{w_n(r)}{w_n(0)}=\begin{cases}\dfrac{1}{C_n}\Big\{1+\dfrac{1}{2}\dfrac{\pi i}{2}\sqrt{i}\,hr_c\cdot H_0'^{(1)}(\sqrt{i}\,hr_c)\cdot J_0(\sqrt{i}\,hr) \\ \qquad +\dfrac{1}{2}\dfrac{\pi i}{2}\sqrt{-i}\,hr_c\cdot H_0'^{(1)}(\sqrt{-i}\,hr_c)\cdot J_0(\sqrt{-i}\,hr)\Big\} & (0\leq r\leq r_c) ,\\[2ex] \dfrac{1}{C_n}\Big\{\dfrac{1}{2}\sqrt{i}\,hr_c\cdot J_0'(\sqrt{i}\,hr_c)\cdot\dfrac{\pi i}{2}H_0^{(1)}(\sqrt{i}\,hr) \\ \qquad +\dfrac{1}{2}\sqrt{-i}\,hr_c\cdot J_0'(\sqrt{-i}\,hr_c)\cdot\dfrac{\pi i}{2}H_0^{(1)}(\sqrt{-i}\,hr)\Big\} & (r_c\leq r) ,\end{cases} \tag{9}$$

$$C_n=\Re\left\{1+\frac{\pi i}{2}\sqrt{i}\,hr_c\cdot H_0'^{(1)}(\sqrt{i}\,hr_c)\right\} ,$$

where $w_n(0)$ is the displacement at $r=0$ of the n-th layer, which is also the maximum value of $w_n(r)$. In spite of the seemingly rough assumption of Eq. (8), the real situation of the lattice strain can be approached by the variation of the parameters, $w_n(0)$ and r_c.

Komatsu and Nagamiya[6] derived the value of μ from data of the force constants between the carbon atoms of benzen molecule and of the compressibility of graphite measured by Bridgeman. Further, they determined κ by fitting their calculated specific heat curve to the observed ones. The results they obtained are; $\mu=1.17\times10^{13}\,\text{sec}^{-1}$ and $\kappa=0.611\times10^{-2}\,\text{cm}^2/\text{sec}$. As will be shown later, α is about 0.30, and h scarcely varies with the change of α. Therefore, we put h as a constant, 0.30 in atomic units.

2.2 *Expression of strain energy in terms of $w_n(r)$*

As mentioned before, the strain energy can be regarded as consisting of the intralayer and the interlayer strain energy, which are represented by the first and the second term in Eq. (1) respectively. Now, extending the assumption of Eq. (3), we assume that the strain form of each layer is similar and has the opposite directions on the upper and lower sides of the interstitial atom. That is,

$$\cdots=\frac{w_{n+2}(r)}{w_{n+2}(0)}=\frac{w_{n+1}(r)}{w_{n+1}(0)}=\frac{w_n(r)}{w_n(0)}=\cdots ,$$

$$w_{n+k}(r)=-w_{n-1-k}(r) . \tag{10}$$

Then, putting

$$\left.\begin{aligned}
&\int_0^\infty\left\{\nabla^2\left(\frac{w_n(r)}{w_n(0)}\right)\right\}^2\cdot 2\pi r dr=2\pi S_1 ,\\
&\int_0^\infty\left(\frac{w_n(r)}{w_n(0)}\right)^2\cdot 2\pi r dr=2\pi S_2 ,
\end{aligned}\right\} \tag{11}$$

we have

$$\begin{aligned}
V=&\frac{1}{2}c\rho\kappa^2\cdot 2\pi S_1\{2w_n^2(0)+2w^2_{n+1}(0)+2w^2_{n+2}(0)+\cdots\}\\
&+\frac{1}{2}c\rho\mu^2\cdot 2\pi S_2\{4w_n^2(0)+2[w_{n+1}(0)-w_n(0)]^2+2[w_{n+2}(0)-w_{n+1}(0)]^2+\cdots\} ,
\end{aligned} \tag{12}$$

where[10]

$$\left.\begin{aligned}
&C_n^2\cdot S_1=\frac{1}{8}h^4r_c^2\cdot s_a-\frac{ih^2}{4}\cdot s_b ,\\
&C_n^2\cdot S_2=\frac{1}{2}r_c^2-\frac{1}{8}r_c^2\cdot s_a+\frac{3i}{4h^2}\cdot s_b ,\\
&s_a=\frac{\pi i}{2}\sqrt{i}\,hr_c\cdot J_0(\sqrt{i}\,hr_c)\cdot H_0'^{(1)}(\sqrt{i}\,hr_c)+\frac{\pi i}{2}\sqrt{i}\,hr_c\cdot J_0'(\sqrt{i}\,hr_c)\cdot H_0^{(1)}(\sqrt{i}\,hr_c)\\
&\qquad+\frac{\pi i}{2}\sqrt{-i}\,hr_c\cdot J_0(\sqrt{-i}\,hr_c)\cdot H_0'^{(1)}(\sqrt{-i}\,hr_c)\\
&\qquad+\frac{\pi i}{2}\sqrt{-i}\,hr_c\cdot J_0'(\sqrt{-i}\,hr_c)\cdot H_0^{(1)}(\sqrt{-i}\,hr_c) ,\\
&s_b=\frac{\pi i}{2}(\sqrt{i}\,hr_c)^2\cdot J_0'(\overline{i}\,hr_c)\cdot H_0'^{(1)}(\sqrt{i}\,hr_c)\\
&\qquad-\frac{\pi i}{2}(\sqrt{-i}\,hr_c)^2\cdot J_0'(\sqrt{-i}\,hr_c)\cdot H_0'^{(1)}(\sqrt{-i}\,hr_c) .
\end{aligned}\right\} \tag{13}$$

2.3 *Interaction energy between the interstitial and all other atoms in the lattice*

First, in case of the carbon interstitial we will determine the interaction potential between the interstitial and all other atoms in the stacking layers. This potential is considered to have two terms, repulsive and van der Waals, and have no possibility of the covalent bond. Therefore, the interaction in question can be regarded as additive of interstitial-lattice site atom pairs.

Brennan[11] calculated the interaction potential between the neighbouring layers of the graphite lattice: He obtained the repulsive term quantum-mechanically, and found the van der Waals term by making the potential minimum at the observed value of c. In order to estimate the elastic constant for shearing c_{44}, Komatsu[7] calculated the interaction potential between two atoms on the neighbouring layers by a method similar to that employed by Brennan, with appropriate modifications and corrections.

We use Komatsu's potential for the interaction between the interstitial and any atom in the layers. This potential seems to be accurate when the distance between two atoms is near to or larger than the c-spacing, but it becomes unreasonably attractive due to the dominant van der Waals term when they approach nearer, as is often the case with the interstitial atom. Therefore, this potential is not applicable in the vicinity of the interstitial. There seems no calculation for the potential in this short-distance region.

Dienes[2] found a solid relation between bond strengths and equilibrium interatomic distances in the C—C bond, the benzen bond and the C=C bond, and, by extrapolating it to the range of interatomic distance between the C—C covalent bond distance and the c-spacing in graphite, he constructed a repulsive potential term of Born-Mayer type. Its physical foundation is recognizable as follows: It is empirically well-known that the nature of the covalent bond can be represented approximately by the Morse potential $U=D\{\exp[-2a(r-r_0)]-2\exp[-a(r-r_0)]\}$. It is likely that, at the equilibrium distance, the bond energy D in this potential is equal to the repulsive energy in magnitude. Therefore, the bond strengths in Dienes' relation can be regarded as the repulsive energies too. On the other hand, the potential we need to construct consists mainly of the repulsive term in the range considered. Consequently, we can employ the repulsive term of the carbon-carbon covalent bond to obtain the necessary potential.

Table I.

	C—C	Benzen	C=C
r_0	1.54	1.39	1.33 Å
D	58.6	86.0	100.0 kcal/mol.

In Table I[12] are shown the bond lengths and the bond stregths, from which the relation $\log D=Ar_0+B$ can be expected as Dienes pointed out, that leads to the potential of Born-Mayer type. We extrapolate the covalent bond data after Dienes' method so as to smoothly connect with Komatsu's potential in the vicinity of c-spacing. Thus, finally, the potentials to be used in our calculation are

$$\varphi_{C-C}(r)=\begin{cases}\exp(1.652-1.386r): & (r\leq 5.56)\\ -\dfrac{309.3}{r^6}+0.5153\exp(-0.2223r-0.07951r^2): & (r\geq 5.56)\end{cases} \tag{14}$$

in atomic units. The minimum interatomic distance to which the former potential will be applied in the present calculation is about 2.2 Å (or 4.1 a.u.). The latter is Komatsu's potential.

In the second, we will determine the interaction potential in case of Xe-interstitial atom in graphite by averaging arithmetically the potential of carbon-carbon and that of xenon-xenon. In spite of lacking in strict verification, this procedure may give a reasonable tendency as in the case of covalent bonds. Komatsu's potential is adopted for this purpose, because, due to the large strain in case of Xe-interstitial, we need not to take account of the potential in the short distance range. After Whalley and Schneider[13], who investigated intermolecular potentials of xenon etc. using the second virial coefficients and the crystal properties at 0°K, we adopt the xenon-xenon potential,

$$\varphi_{\mathrm{Xe-Xe}}(r)=\varepsilon\left\{\left(\frac{r_m}{r}\right)^{12}-2\left(\frac{r_m}{r}\right)^{6}\right\}, \qquad (\varepsilon=7.135\times10^{-4}\,\mathrm{a.u.},\quad r_m=8.630\,\mathrm{a.u.})\,, \tag{15}$$

Thus, the interaction potential between the Xe-interstitial atom and any carbon atom in the graphite lattice is

$$\varphi_{\mathrm{C-Xe}}(r)=\frac{1}{2}\{\varphi_{\mathrm{C-C}}(r)+\varphi_{\mathrm{Xe-Xe}}(r)\}\,. \tag{16}$$

Now, by means of these potentials, we can calculate the interaction energy between an interstitial atom and all other carbon atoms in the strained layers of graphite, the strain form of which is determined by Eq. (9) for given values of parameters, $w_n(0)$ and r_c. This calculation is performed by summing the energies for the atoms of $r\leq 11$ a.u. on the n-th and $(n-1)$-th layers, and then replacing it by the integration for all other atoms. We express the interaction energy ultimately in the form of the quadratic equation of $w_n(0)$ around the equilibrium atate;

$$U=B_1(r_c)\cdot w_n^2(0)+B_2(r_c)\cdot w_n(0)+B_3(r_c) \tag{17}$$

where the coefficients B_1 etc. depend upon the parameter r_c.

2.4 *Determinatian of the strain and the self-energy of interstitial*

The total extra energy increase due to the introduction of an interstitial atom into the lattice from the infinity is given by the sum of Eq. (12) and Eq. (17). We have to find the minimum value of the total extra energy, which is the self-energy of the interstitial atom, varying $w_n(0)$ and r_c. First, in order to vary $w_n(0)$ with r_c fixed, we rewrite the total extra energy W in the form,

$$\begin{aligned}W=&(A_1+B_1)w_n^2(0)+B_2w_n(0)+B_3\\&+A_2\{w_{n+1}^2(0)+w_{n+2}^2(0)+w_{n+3}^2(0)+\cdots\}\\&-A_3\{w_n(0)\cdot w_{n+1}(0)+w_{n+1}(0)\cdot w_{n+2}(0)+w_{n+2}(0)\cdot w_{n+3}(0)+\cdots\}\end{aligned} \tag{18}$$

where

$$A_1=2\pi c\rho\kappa^2S_1+6\pi c\rho\mu^2S_2\,,\qquad A_2=2\pi c\rho\kappa^2S_1+4\pi c\rho\mu^2S_2\,,\qquad A_3=4\pi c\rho\mu^2S_2\,.$$

S_1, S_2, B_1, B_2, B_3, A_1, A_2 and A_3 in the equation are the functions of r_c. In the real crystal the total extra energy increase should have the minimum value with respect to the variation of any one of the parameters $w_{n+1}(0)$, $w_{n+2}(0)$ etc. As it is considered that the real situation is represented by the above calculation in good approximation, we may put the partial derivatives of W with respect to $w_{n+1}(0)$, $w_{n+2}(0)$, etc. equal to zero to eliminate them. Using the above relations and the conditions, $w_{n+m+2}(0)\ll w_{n+m}(0)$ where m is zero or a positive integer, we have

$$w_{n+m}(0)=\alpha^m\cdot w_n(0)\,,\qquad \alpha=\frac{A_3}{2A_2} \tag{19}$$

and

$$W=B_1'\cdot w_n^2(0)+B_2\cdot w_n(0)+B_3=B_1'\left\{w_n(0)+\frac{B_2}{2B_1'}\right\}^2+B_3-\frac{B_2^2}{4B_1'} \tag{20}$$

where

$$B_1'=A_1+B_1-\frac{A_2A_3^2}{4A_2^2-A_3^2}\,.$$

In Eq. (20), W becomes the minimum when $w_n(0)=-B_2/2B_1'$ for a given r_c. Moreover, by varying r_c to minimize W, the self-energy of the interstitial atom can be obtained as is shown in Fig. 2.

§ 3. Migration Energy of Interstitials

Two super-imposed hexagonal networks above and below an interstitial atom are shown in Fig. 3. A and B indicate the interstitial sites, corresponding to the equilibrium point and the saddle point respectively. The migration energy of the interstitial atom is given by the difference between the energies at A and B, that is, $W_B - W_A$. According to the crystal symmetry in regard to the interstitial site, B is located just in the middle of the two layers above and below it. On the other hand, the A site is considered to have a small shift δ in the direction perpendicular to the layers. The total energy increases at B and A configuration are then represented in terms of the interaction energy U and the elastic energy V as follows;

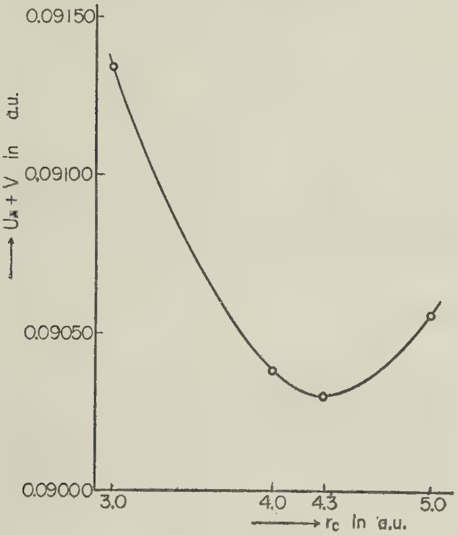

Fig. 2. U_A+V vs. r_c curve for carbon interstitial atom.

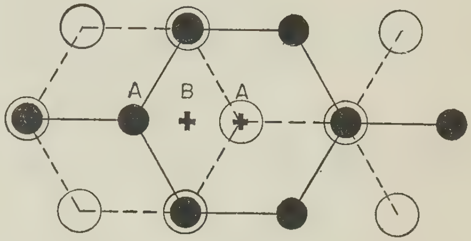

Fig. 3. A and B site for interstitial atom in graphite.

$$\left.\begin{aligned} W_B &= U_B\{w_{nB}(0), r_{cB}, 0\} + V\{w_{nB}(0), r_{cB}\} \\ W_A &= U_A\{w_{nA}(0), r_{cA}, \delta_A\} + V\{w_{nA}(0), r_{cA}\} \end{aligned}\right\} \tag{21}$$

The parameters $w_{nB}(0)$ and r_{cB} in B configuration can be determined after the procedure mentioned in the preceding section, while in A configuration we must determine δ_A to minimize W_A. This is done under the assumption that the strain in A configuration is the same with that in B configuration. δ_A and W_A in this case are denoted as δ_A' and W_A'. Hence,

$$W_A' = U_A\{w_{nB}(0), r_{cB}, \delta_A'\} + V\{w_{nB}(0), r_{cB}\}\ . \tag{22}$$

Now, we expand W_A in the Taylor series around $w_{nB}(0)$, r_{cB} and δ_A'. The result is

$$\begin{aligned} W_A = W_A' &+ \left(\frac{\partial(U_A+V)}{\partial w_n}\right)_{w_{nB}} (w_{nA}-w_{nB}) + \left(\frac{\partial(U_A+V)}{\partial r_c}\right)_{r_{cB}} (r_{cA}-r_{cB}) \\ &+ \frac{1}{2}\left(\frac{\partial^2(U_A+V)}{\partial w_n^2}\right)_{w_{nB}} (w_{nA}-w_{nB})^2 + \frac{1}{2}\left(\frac{\partial^2(U_A+V)}{\partial r_c^2}\right)_{r_{cB}} (r_{cA}-r_{cB})^2 \\ &+ \left(\frac{\partial^2(U_A+V)}{\partial w_n \partial r_c}\right)_{w_{nB}, r_{cB}} (w_{nA}-w_{nB})(r_{cA}-r_{cB}) \\ &+ \frac{1}{2}\left(\frac{\partial^2(U_A+V)}{\partial \delta_A}\right)_{\delta_A'} (\delta_A-\delta_A')^2 + \cdots\ . \end{aligned} \tag{23}$$

Further, if we eliminate $(w_{nA}-w_{nB})$ and $(r_{cA}-r_{cB})$ of the first order terms in the equation by putting $\partial W_A/\partial w_{nA}$ and $\partial W_A/\partial r_{cA}$ equal to zero, the migration energy in the first order approximation can be obtained in the form,

$$W_B - W_A = U_B\{w_{nB}(0), r_{cB}, 0\} - U_A\{w_{nB}(0), r_{cB}, \delta_A'\} + \frac{1}{(ac-b^2)}\{ag^2 - 2bgf + cf^2\} \qquad (24)$$

where

$$a = \left(\frac{\partial^2(U_A+V)}{\partial w_n^2}\right)_{w_{nB}}$$

$$b = \left(\frac{\partial^2(U_A+V)}{\partial w_n \partial r_c}\right)_{w_{nB}, r_{cB}}$$

$$c = \left(\frac{\partial^2(U_A+V)}{\partial r_c^2}\right)_{r_{cB}}$$

$$f = \left(\frac{\partial(U_A+V)}{\partial w_n}\right)_{w_{nB}} = \left(\frac{\partial(U_A-U_B)}{\partial w_n}\right)_{w_{nB}}$$

$$g = \left(\frac{\partial(U_A+V)}{\partial r_c}\right)_{r_{cB}} = \left(\frac{\partial(U_A-U_B)}{\partial r_c}\right)_{r_{cB}} .$$

Table II. Numerical results from the present calculations.

Interstitial atom	$w_{nB}(0)$	r_{cB}	δ_A'	α	Ratio of strain energy to self-energy	Self-energy	Formation energy	Migration energy
C	0.48 Å	2.29 Å	0.04 Å	0.30	0.49	2.5 ev	9.9 ev	0.016 ev
Xe	1.50 Å	2.47 Å	0.003 Å	0.31	0.79	15.1 ev		0.03 ev

§ 4. Discussion

We calculated the self-energies, the migration energies etc. associated with the carbon and xenon interstitial atoms in graphite, taking account of the lattice relaxation. In Table 2 are shown the numerical results obtained.

In case of the carbon interstitial, our calculation might have a slight inaccuracy because of the ambiguity in the interaction potential used in the close-distance region. On the other side, in case of xenon while the potential is rather reliable, the displacement of layers becomes to be not perpendicular to them on account of large strain and will make the strain energy calculation inaccurate. Nevertheless, the calculation of migration energy may be enough reliable, for it is the energy difference which varies with respect to changes of the potential, strain etc. more slowly than the energy itself. The values of migration energy calculated suggest that interstial atoms in graphite are very mobile even at extremely low temperatures. The formation energy is defined as the the sum of the self-energy and the sublimation energy, which is required to move an atom from the crystal surface to the infinity. We adopted the experimental value of the sublimation energy of graphite, 170 kcal/mol.[14] to obtain the formation energy of carbon interstitial in the table. Finally, it should be noted that our result for the self-energy of carbon interstitial is considerably smaller than that obtained by Dienes, 12.9 ev, suggesting the importance of the consideration for the lattice relaxation. In fact, the ratio of the strain energy to the self-energy amounts to 0.49 even in case of the carbon interstitial as cited in Table II.

Acknowledgement

The authors wish to express their hearty thanks to Dr. Y. Takagi for his kind encouragement and interest, and to Prof. T. Inui for his valuable discussions in mathematics.

Appendix

Calculation of Green Function[9]

In order to get Green function which satisfies Eq. (5), we employ the integral representation of the δ-function,

$$\frac{\delta(r-\xi)}{r} = \int_0^\infty kJ_0(kr)\cdot J_0(k\xi)dk . \qquad (25)$$

According to this representation, we assume $G(r, \xi)$ as follows;

$$G(r, \xi)=\int_0^\infty kg(k)\cdot J_0(kr)\cdot J_0(k\xi)dk\,. \qquad (26)$$

Substituting both Eqs. (25) and (26) for Eq. (5), $g(k)$ can be determined. Hence,

$$G(r, \xi)=\frac{1}{2\pi}\int_0^\infty \frac{k}{k^4+h^4}J_0(kr)\cdot J_0(k\xi)dk\,.$$

When $r>\xi$, this is modified in the form,

$$G(r, \xi)=\frac{1}{4\pi}\int_{-\infty}^\infty \frac{k}{k^4+h^4}H_0^{(1)}(kr)\cdot J_0(k\xi)dk\,.$$

Carrying out the complex integration in the upper half of k-plane by virtue of the theorem of residues, finally we have

$$G(r, \xi)=\frac{i}{2}\{\mathrm{Res}\,(\sqrt{i}\,h)+\mathrm{Res}\,(\sqrt{-i}\,h)\}\,,$$

which leads to Eq. (7). When $r<\xi$, the calculation can be performed by either doing in a similar way or using the principle of reciprocity.

Electric Conduction of Ferrites containing Fe^{2+}-ions

By Nahonori MIYATA

Department of Physics, Yokohama National University, Yokohama

(Received October 20, 1960)

The D.C. electric conductivity was measured between 100°K and 300°K for the ferrite solid solution $(MeFe_2O_4)_{1-y}$-$(Fe_3O_4)_y$, where Me=Mn, Ni, Mn-Ni or Zn. Above 120°K the specific conductivity of each specimen depends on temperature as $\sigma=A\cdot\exp(-\varepsilon/kT)/T$. The activation energy ε is $(5\sim8)\times10^{-2}$ eV. A depends on the concentration, y, of Fe_3O_4 as $A=(6.5\pm2.5)\times10^4(y/1-y)$ degree/Ωcm. The analysis of these experimental expressions shows that the dependence of the mobility on temperature for each specimen can be fitted by the expression, $\mu=\mu_0\cdot\exp(-\varepsilon/kT)/T$ and the dependence on the Fe^{2+}-ion concentration, y, by $\mu_0=(3.0\pm1.2)\times10^1(1/1-y)$ degree (cm²/volt sec). μ_0 is independent of the kind and distribution of Me^{2+}-ions.

§ 1. Introduction

The electric resistivity of ferrites at room temperature ranges from about 10^{-2} Ωcm to higher than 10^{11} Ωcm depending on the chemical composition. It has long been known that low resistivities are caused in particular by the simultaneous presence of ferrous and ferric ions on equivalent lattice sites (octahedral sites). Recently, the electric conduction mechanism of ferrites containing Fe^{2+}-ions came to be understood as the hopping motion of electrons between Fe^{2+} and Fe^{3+} on the B-sites (octahedral sites) of the spinel lattice[1]. From the study on the $(MeFe_2O_4)$-(Fe_3O_4) solid solution system, it may be possible to make clear the effect of Me^{2+} or Fe^{2+} on the B-sites on the electric conduction. Previously, the author and his collaborators[2] have reported the conductivity of $MnFe_2O_4$-Fe_3O_4 system. Here the study is extended to the case of Me=Ni, Mn-Ni or Zn, where Ni and Zn are elected on account of the tendency of their preferred occupation of B-site and A-site, respectively. The method of analysis of the experimental results and some conclusions about the ionic distribution mentioned in the previous short note[2] are corrected in this paper.

§ 2. Specimens

Specimens, 3×3×7 mm, were cut from a single crystal or a coarse-grained ingot grown in the Pt-crucible by the Bridgman method in the air atmosphere. The main cations were chemically analysed. The analysis could not determine the excess or deficiency of the oxygen compared with the stoichiometric composition more accurately than ±5% of the oxygen content. The stoichiometry of oxygen will be estimated rather from the electric conductivity. The crystal structure was investigated by the X-ray analysis. All specimens reported here had the spinel type and their lattice constants depended linearly on the concentration of cations. The details of the preparation and structure of specimens will be described in a later other paper[3].

§ 3. Experimental Method

The D.C. specific electric resistance was measured between the temperature range from 100°K to 300°K by the four-probe method with two In-amalgam electrodes on both sides of the specimen for the current flow and two brass electrodes, 4 mm apart, for measuring the potential between them.

§ 4. Results

(a) *Dependence of the electric resistance on the temperature*

Above about 120°K, where a *knick* is observed for almost all specimens, experimental values of the temperature dependence of the specific electric resistance, ρ, are represented by the expression

$$\sigma=1/\rho=A\cdot\exp(-\mathcal{E}/kT)/T^n\,, \tag{1}$$

where A is a constant, $\mathcal{E}$ is the activation energy, T is the absolute temperature and n is a constant which is about unity. An example for a few specimens is shown in Fig. 1, where circle and square represent the observed values and the solid curves show the equation (1) with the suitable choice of the values of A and $\mathcal{E}$.

(b) *Dependence of A and $\mathcal{E}$ on Fe^{2+} concentration*

Two constants in the equation (1), A and $\mathcal{E}$, are determined for each specimen under the assumption $n=1$ and plotted as a function of molar ratio y of $(MeFe_2O_4)_{1-y}$-$(Fe_3O_4)_y$ system in Fig. 2 and 3, respectively. $\mathcal{E}$'s are $(5\sim8)\times10^{-2}$ eV. $A(y)$ is expressed by the relation

$$A=(6.5\pm2.5)\times10^4(y/1-y)\text{degree}/\Omega\text{cm} . \qquad (2)$$

The solid curve and two dotted curves show Eq. (2) together with its dispersion. As the conductivity is very sensitive to the excess or deficiency of oxygen content, the dispersion of the observed value is unavoidable to some extent. It should rather be noticed that, as seen in Fig. 2, equation (2) is common to all ferrite solid solution systems independent of the kind of Me^{2+}-ion.

§ 5. Discussion

Generally, the electric conductivity is given by

$$\sigma=en\mu , \qquad (3)$$

where e is the charge, n the number and μ the mobility, of the charge carrier. The conduction mechanism of ferrites such as those described here is considered as the hopping motion of electrons between Fe^{2+} and Fe^{3+} on the B-site of the spinel lattice[1]. n is now equal to the number of Fe^{2+} and independent of temperature for each specimen.

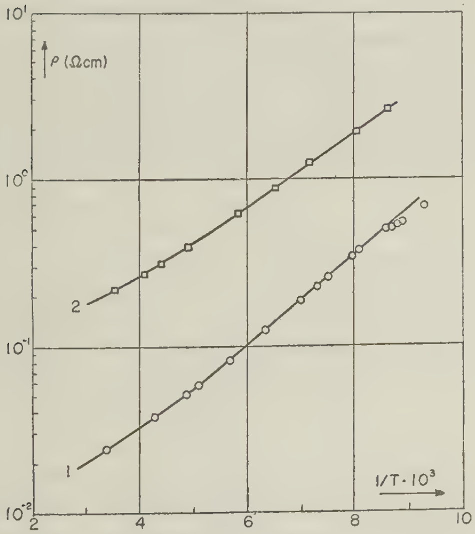

Fig. 1. A few examples of the temperature dependency of the electric resistance (log ρ *vs.* $1/T$).

Composition	Observed values	Solid curves mean $1/\rho=A\cdot\exp(-\varepsilon/kT)/T$ with
$(Zn_{0.3}Fe_{0.7})Fe_2O_4$	○	1; $A^{-1}=6.0\times10^{-6}$ Ωcm/degree $\varepsilon=6.6\times10^{-2}$ eV
$(Mn_{0.85}Fe_{0.15})Fe_2O_4$	□	2; $A^{-1}=7.5\times10^{-5}$ Ωcm/degree $\varepsilon=5.8\times10^{-2}$ eV

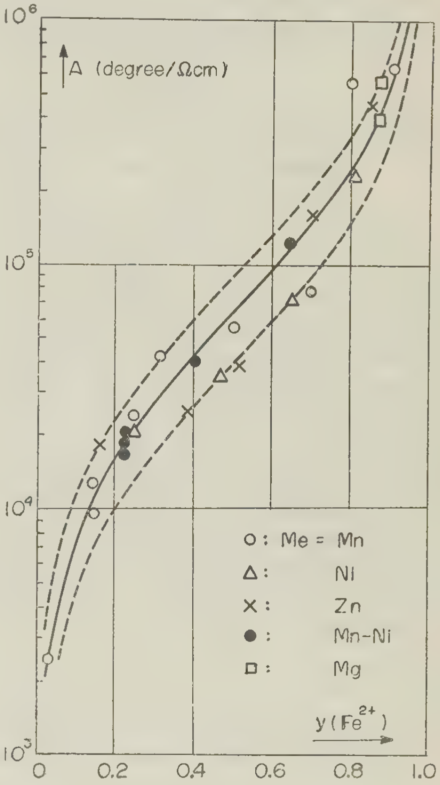

Fig. 2. (A *vs.* y) of $(MeFe_2O_4)_{1-y}$-$(Fe_3O_4)_y$. A solid curve and dotted ones show a center and width of the equation $A=(6.5\pm2.5)\times10^4(y/1-y)$ degree/Ωcm.

As the lattice constant is about 8.4A and there are eight molecules in a unit cell, $n=1.35\times10^{22}\cdot y\,\text{cm}^{-3}$. The cause of the factor proportional to y in equation (2) is understood as the proportionality of n to y. (1) and (3) show that the mobility depends upon temperature as

$$\mu=\mu_0\cdot\exp(-\mathcal{E}/kT)/T , \qquad \mu_0=A/en . \qquad (4)$$

Next, from (2) and (4) with $e=1.60\times10^{-19}$ coulomb and $n=1.35\times10^{22}\cdot y\,\text{cm}^{-3}$,

$$\mu_0=(3.0\pm1.2)\times10^1(1/1-y)\,\text{degree}(\text{cm}^2/\text{volt sec}). \qquad (5)$$

Also, from the usually used equation,

$$\mu=\frac{ea^2}{kT}W \quad \text{and} \quad W=\nu\cdot\exp(-\mathcal{E}/kT)\ ,$$

where a is taken as the distance between nearest B-sites, the jumping frequency, W, is obtained as

$$W=\frac{(2.9\pm1.1)\times10^{12}}{(1-y)}\cdot\exp(-\mathcal{E}/kT)\cdot\mathrm{sec}^{-1}\ . \qquad (6)$$

These relations, (4), (5) or (6), are independent of the kind and distribution of Me^{2+} (Zn^{2+} and Ni^{2+} prefer A-site and B-site, respectively) as seen by the experiment, and show that the mobility, or the transition probability of electrons between Fe^{2+} and Fe^{3+}, becomes large, inversely proportional to $(1-y)$, with the increase of magnetite concentration, y. The theoretical explanation of these relations is not known at present but these facts may provide an important evidence for the hopping mechanism.

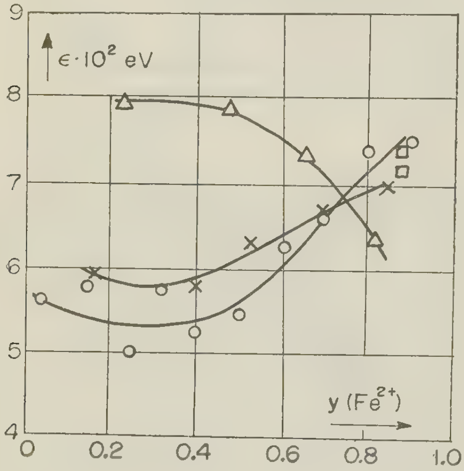

Fig. 3. (ε vs. y) of $(MeFe_2O_4)_{1-y}$-$(Fe_3O_4)_y$. Symbols are the same as in Fig. 2.

Here the experimental results are analysed by the use of (1) with $n=1$. It should be added that for specimens of low magnetite concentration the dependence of σ on temperature is expressed rather by (1) with $n\cong0$, though the reason is not clearly understood.

Dislocations and Fine Lines in Rochelle Salt Crystal

Terutaro NAKAMURA and Kikuo OHI

Department of Physics, Ochanomizu University, Otsuka, Tokyo

(Received November 4, 1960)

Etch pits on c-face of rochelle salt were observed and it was concluded that they correspond to points where dislocations parallel to c-axis emerge on c-face. Some of the dislocations were found to be longer than several millimeters.

Fine lines parallel to c-axis, called *sudaré* among Japanese researchers, were observed to be distributed in quite the same manner as dislocation etch pits are. *Sudarés* are observed at the deepest points of some etch pits.

If surface energy of the interface between rochelle salt and its decomposed products be low, dislocation core may be opened and filled with the decomposed products. It seems likely that this open-cored dislocation may grow into the *sudaré*.

§ 1. Introduction

It has been pointed out that dislocations in ferroelectric crystals have interesting interactions with ferroelectric behaviors[1)-3)]. Screw dislocations in c-direction of rochelle salt crystal were shown to anchor small domains, which will act as nuclei of growing domains.[2)] Shape of the anchored domain was calculated with an electronic computer[3)]. The formation of the anchored domain was shown to stabilize array of parallel screw dislocation lines.[3)] Recently observations of dislocations in ferroelectric GASH[4),5)] and ferroelectric glycine sulfate[6)] have been reported.

The present paper describes observations of etch pits on c-face of rochelle salt crystal, which lead us to the conclusion that these pits correspond to points where dislocations emerge on c-face, and that these dislocations are parallel to c-direction and longer than several millimeters.

It is known that a rochelle salt crystal includes a number of fine lines parallel to c-direction, of $1\mu \sim 10\mu$ in diameter, from tens to several hundreds of microns in length[7)], called *sudaré*.* The *sudarés* are included even in very good crystal which has been grown in the best conditions, while *veils*** are included only in parts which have experienced too rapid crystal growth. These two ideas must be kept separate one from another. Informations heretofore reported about *sudaré* are as follows. They are not visible in the crystal, when the growth has just been completed, but become visible when the days roll on[8)]. Distribution of *sudarés* seems to be related to crystallographic direction[9)]. They increase by irradiation with X- or γ-ray[10),11)].

It was pointed out by Frank[10)] that there exists a state of equilibrium in which a dislocation core is opened if energy of strain at the core is larger than surface energy of created boundary surface. It has been suggested earlier that *sudaré* may be closely related with open-cored dislocation[2)], and this view is supported experimentally by the present work.

§ 2. Dislocation Etch Pits on c-Face

A c-plate crystal of rochelle salt is cut out from a large good crystal by means of a wet

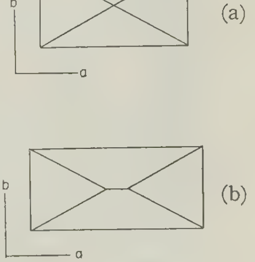

Fig. 1. Etch figures on a c-surface of rochelle salt crystal.

---

* Among Japanese researchers this kind of imperfection is usually called *sudaré*, because these fine lines are distributed forming a wall, which looks like a "*sudaré*", a kind of blind, made of fine bamboo tubes arranged to form a wall.

** Word *veil* is used as a macroscopic imperfection, caused by too rapid crystallization, composed of many small spherical holes.

thread, and carefully polished. This c-cut plate is rubbed lightly with a wet filter paper, and observed under a microscope.

Quadrangular pyramidal etch pits as shown in Photo. 1 are observed. Longer side parallel to a-axis is about 100μ and shorter side parallel to b-axis is about 50μ. Some etch pits have a shape of pointed pyramid as Fig. 1a, while some have shape of hip roof as Fig. 1b*. Experimental results described below lead us to the conclusion that these etch pits correspond to the emergence points of dislocation lines.

(1) There is an imperfect cleavage parallel to c-plane of rochelle salt crystal. Matched cleavage faces parallel to c-plane are etched. Every etch pit on both faces corresponds perfectly to each other as shown in Photo. 1a and b.

(2) By rubbing a crystal with a wet filter paper, water acts not only as an etchant but also as a chemical polisher and dislocations can be followed. Photo. 2 show that etched pattern remains unchanged for about 1 mm, apart from fine details.

(3) The etch pits on the top and the bottom surfaces of one crystal piece even about 5 mm thick are sometimes observed to correspond to each other (Photo. 3). This is the case especially in a sub-grain boundary, most of which are observed to lie parallel to a-, b-, or m-plane.

(4) It is observed that etch pits are nucleated by mechanical stresses which are given by contact with a pin-point or by dropping a steel bar (Photo. 4). Pits caused by the mechanical shock can be followed by chemically polishing for about $50\mu\sim300\mu$, but in the chemical polishing process they become round-bottomed and finally disappear (Photo. 4a and b).

(5) The pit density ranges from 10^3 to $10^4/\text{cm}^2$, but it reaches a value larger than $10^5/\text{cm}^2$ at probably imperfect portions, where some *veils* are found nearby.

§ 3. *Sudaré* and Dislocation Etch Pits

A cube of about $(0.5\,\text{mm})^3$ is cut out from a large rochelle salt crystal by means of a wet thread, so that its faces are nearly perpendicular to a-, b-, and c-axis respectively, and the faces are polished carefully.

Sudaré can be observed through a- or b-faces, under a microscope by dark field illumination, as bright lines shown in Photo. 5.

Observed through c-faces, *sudarés* appear to be fine bright spots under dark field illumination (Photo. 6a), while they appear as fine dark spots under bright field illumination. Immediately after observing *sudarés* through c-face, this c-face is etched by means of the technique shown above in § 2. Some of dislocation etch pits are then ascertained to correspond to *sudarés*. (Photo. 6a and b)

In the process of dissolution of c-surface by water, some spots are observed, which can be identified with emergence points of *sudarés*, at the deepest points of some of the etch pits.

It has been reported by Sakisaka that *sudarés* are always found not to be isolated, but to form walls. Some walls are parallel to a-, b-, or m-face, but some are not plane but form cylindrical surfaces. Photo. 7a shows an arrangement of *sudaré* walls, which was photographed by throwing a parallel ray at a certain angle of incidence (oblique illumination). Photo. 7b shows an arrangement of etch pits, which was obtained by etching the surface of Photo. 7a. Photo. 7a and b clearly indicate that the *sudarés* are distributed quite in the same manner as dislocation etch pits are.

These experimental results seem to be enough to conclude that *sudaré* and dislocation are closely related with each other, and that *sudaré* may be open-cored dislocations proposed by Frank, as discussed below.

§ 4. Discussion

It has been reported that there exist two types of domain structure; i.e. some crystals consist of laminated domains parallel to a–b plane (b-domain crystal), and some consist of laminated domains parallel to a–c plane (c-domain crystal). It was reported that b-domain crystal is obtained only by crystallization in the ferroelectric range, and shows tendency to change into c-domain crystal[2]. In explaining this phenomenon, it was pointed out that screw dislocation parallel to c-axis accompanies strained region having y_z which must anchor small domain at the dislocation[2]. The shape

---

* Similar figures are found in Cady's book[12]. The figures are, however, remarked to be "etch hills" in contradiction with our experimental result which has ascertained them to be "etch pits".

of the anchored domain was calculated, and it was also pointed out that the array of parallel screw dislocations will be stabilized by formation of anchored domains which relax stresses around dislocation lines, otherwise parallel screw dislocations cannot exist stably[3].

The present experiments revealed that the dislocations in rochelle salt are parallel to *c*-direction and seem to run in parallel straight lines through very long distance by observing both ends of dislocations of about several millimeters (Photo. 3). This fact is rather striking, because dislocations in alkali halides or GASH are reported to form loops when

(Correspondence in left and right end parts looks to be unsatisfactory, owing to lighting condition.)

chemically polished about a few hundred microns. On the present step we cannot distinguish whether the etch pits correspond to edge or screw dislocations, but our experimental results do not show any contradiction with the previously proposed image that a number of screw dislocations run in straight lines parallel to *c*-axis, and anchor nucleus domains.

Our experiment has shown that etch pits are identified with dislocation emergence points and that *sudarés* are distributed in quite the same manner as dislocation etch pits are, and *sudaré* is observed at the deepest point of a pit. These results are leading us to the previously proposed assumption that the *sudaré* may be identified with open-cored dislocation first proposed by Frank. Consider a screw dislocation in a material with isotropic elastic constants. If a strained part near the dislocation core become empty tube of radius r, free energy per unit length increases by

$$\Delta F=\int_0^r 2\pi\gamma\, dr-\int_0^r \frac{\mu b^2}{8\pi^2 r^2}2\pi r\, dr \qquad (1)$$

where γ, μ and b denote specific surface energy, rigidity modulus and Burgers vector respectively. There is an equilibrium when

$$r=\mu b^2/8\pi^2\gamma \qquad (2)$$

for which ΔF takes minimum value. This is Frank's hollow dislocation.. For occurence of open-cored dislocation, large Burgers vector or low specific surface energy is required. Since the lattice constant in *c*-direction of rochelle salt is $c=6.17$Å according to Beevers-Hughes, very large Burgers vector is not expected. However, very low specific surface energy may be expected, since *sudaré* can be conceived not to be empty but to probably contain decomposed products of rochelle salt.* The radius of equilibrium of the tube given by Eq. (2) is conceived to be much smaller than the magnitude which can be observed by an optical microscope. The open-cored tube, however, likely grows up to observable *sudaré* when some additional energy is supplied, for instance thermal energy, irradiation energy of X or γ ray, etc. This supposed process is in agreement with facts reported[8),9),10)].

§ 5. Summary and Conclusion

Etch pits on *c*-face of rochelle salt were observed and concluded to be identified with points where dislocations parallel to *c*-axis emerge on *c*-face. It is rather striking that dislocations are ascertained to be several millimeters long.

Fine lines parallel to *c*-axis, called *sudaré* among Japanese researchers, were observed to be distributed in quite the same manner as dislocation etch pits are. *Sudarés* are observed at the deepest points of some etch pits.

It is proposed that *sudaré* is what is formed by the process that some parts of a dislocation become open-cored, as Frank's hollow dislocation, being filled with decomposed products, and grows gradually when thermal, radiant and other kind of energy are supplied.

Observation of Lattice Defects in Graphite by Electron Microscopy, Part I

By F. Eiichi FUJITA and Kazuhiko IZUI

Japan Atomic Energy Research Institute
Tokai-mura, Ibaraki-ken, Japan

(Received September 7, 1960)

In Part I, lattice defects which can *a priori* exist in graphite crystals and be observed by means of electron microscopy, mainly dislocations, are reported. Four kinds of dislocations and their combination predicted from the crystal structure are observed through the diffraction contrast and the disturbances in the moiré pattern such as the extra terminating half lines and the line shift. Their network arrangements and movement are also found. The line grating model reveals the relation between the line shift of the moiré fringes and the Burgers vector of the glissile dislocations. New origins of extra terminating half lines are considered too.

§1. Introduction

In recent years, the study of lattice defects in crystals by means of transmission electron microscopy has been developped mainly in three ways; 1) direct resolution of crystal lattices in such as platinum phthalocyanine[1], and of super lattices in such as antigorite[2] and surpentine[3], 2) direct observation of dislocation lines and stacking faults through the diffraction contrast associated with them in metals including aluminium[4], gold[5] and stainless steel[6], and 3) detection of dislocations by means of moiré patterns from overlapping crystals of copper sulfide[7], gold-paradium[8], etc.

Among these methods, the first one has an advantage that the direct imaging of the crystal lattices is given and dislocations passing through the crystal film and having a component of the Burgers vector perpendicular to the lattice planes manifest in the image as extra terminating half lines. However, its application is limited to the crystals with lattice spacings larger than 6 Å, which is the resolution limit of the present-day electron microscopes. Therefore, many of the substances we want to study lie beyond the reach of this method.

The second method is useful for examining the density, configuration and motion of dislocation lines and is not severely confined by the direction of the lines and the Burgers vectors as in the case of the first method. It would be, however, difficult to determine the Burgers vector by this method even if the selected area electron diffraction method was used in parallel or a careful analysis of the relation between the Burgers vector and the diffraction contrast of the image was performed.

The third method using the moiré pattern is more or less similar to that of the first one, for it reveals dislocations as extra terminating half lines in the moiré pattern. Consequently, the limitation of this method detect the lattice defects is not so different from that of the first method, although in this method indirect resolution of crystal planes of even less than 1 Å in spacing can be obtained and the two dimentional analysis of the Burgers vector is practically possible by using two sets of moiré patterns.

The first attempt to apply both of the second and the third methods in closer relation to the study of lattice defects in graphite has been put into practice by the authors, since various types of disturbances in the moiré pattern from graphite were observed by one of the authors[9]. There have been relatively few number of works of electron microscopy on the lattice defects in graphite such as observation of spiral growth in small particles of graphite by T. Tsuzuku[10], observation of moving dislocations by A. Grenall[11], study of moiré dislocations in synthetic graphite by I. M. Dawson and E. A. C. Follett[12], and observation of sessile dislocation rings in quenched graphite by S. Amelinckx[13]. The present paper reports various kinds of dislocations and stacking faults in graphite crystals predicted and observed through the diffraction contrast as well as by means of the moiré pattern, which enable the determination of the direction of dislocation lines and the Burgers vectors. Various modes of network arrangements of dislocations and the motion of dislocation lines are also observed. The relation between the line shift of moiré fringes across the dislocation lines and their Burgers vectors is discussed, and identification of sessile and glissile, full and half dislocations and their combinations is found to be possible. Origins of extra terminating half lines in the moiré pattern, other than the dislocations passing from the top to the bottom surface of the crystal film, are also discussed.

§ 2. Experimental Procedure

Three kinds of graphite powder were used in the present experiment: Natural graphite powder of SP-1 grade (spectroscopically pure) was supplied by the National Carbon Co., U. S. A. Graphite powder obtained by the reduction from silicon carbide powder by means of high temperature chlorine gas reaction was kindly offered by Dr. Y. Sasaki of the chemistry division of this institute. X-ray and electron diffraction measurements and electron microscopy revealed that the crystallites of this powder of synthetic graphite are as perfect as those of SP-1 natural graphite in respect to the crystal structure. On the other hand, ground powder of artificial graphite supplied by the Showa Denko Co. for the JRR-3 reactor of our institute was found to be rather imperfect, and therefore not used in the present experiment except observation of irradiation effect.

Graphite powder of these kinds was ground between two glass plates with a small amount of distilled water and ether, floated on distilled water, meshed and then dried. This process enables the powder to have a dispersed state suitable for electron diffraction and microscopy, and would also give the crystals appreciable mechanical deformation to produce dislocations, stacking faults, and possibly relative rotations of overlapping crystallite flakes.

In parallel with the observation of unirradiated powder, some irradiation experiments were done which will be mentioned in Part II.

The electron microscopes used in the present observation were of Hitachi HU-10 type with the resolution of 10 Å which has the double condensers in the illumination system and is operated at 75 KV, and of Hitachi HS-5 type with the resolution of 25 Å operated at 50 KV. Electron diffraction study was done by using the same equipments. About 500 pictures were taken at direct magnifications between 10,000 and 30,000, in which many remarkable phenomena were found as illustrated in the following paragraphs.

§ 3. Experimental Results

In general, graphite powder consists of laminar stacking of small crystallite flakes several hundreds angstroms in thickness, a few microns wide in lateral dimensions. This aspect can be seen in Photo. 1. In some areas of the photograph we can see moiré patterns in patches, which indicate the extent of nearly perfect crystal regions or the size of crystallite flakes. Electron diffraction patterns from such areas sometimes show satellites in hexagonal distribution around normal spots as are seen in Photo. 2, indicating that the moiré pattern is arising from interferrence of the direct beam and the doubly diffracted beam from two overlapping crystals with a slight relative rotation around the axis perpendicular to the crystallite planes or *c*-atomic planes of the crystals. In case of the dark field image, the moiré pattern still remains and is considered to be produced by the interference of two primary diffracted beams from two overlapping crystals as pointed out by J. F. Goodman[14]. Some of the moiré patterns observed are formed by three or more overlapping crystals. For example, in Photo. 3 a set of moiré lines with a fine spacing of 50 Å is modulated with a large spacing of 300 Å. A simple geometrical consideration reveals that such a feature of moiré pattern is a result of overlapping of three crystals two of which are rotated by a relatively small angle of the order of 10^{-2} with respect to each other and the rest one by an angle about 6 times larger with respect to the other two. Much more complicated moiré patterns were frequently observed, some of which are apparently highly affected by the Bragg extinction contours or the extinction of equal inclination and some are probably modulated by densely distributed crystal imperfections such as a group of dislocation lines. These features of moiré patterns will be partly discussed in the following paragraph.

Extra terminating half lines in moiré patterns are sometimes observed, as are seen in Photos. 4 (a), (b) and 5. It is generally known that a dislocation having an extra half plane among the crystal planes to form the moiré pattern and passing through the crystal film will give rise to an extra terminating line in the moiré pattern[7,15]. This was further extended to the case of general dislocation by

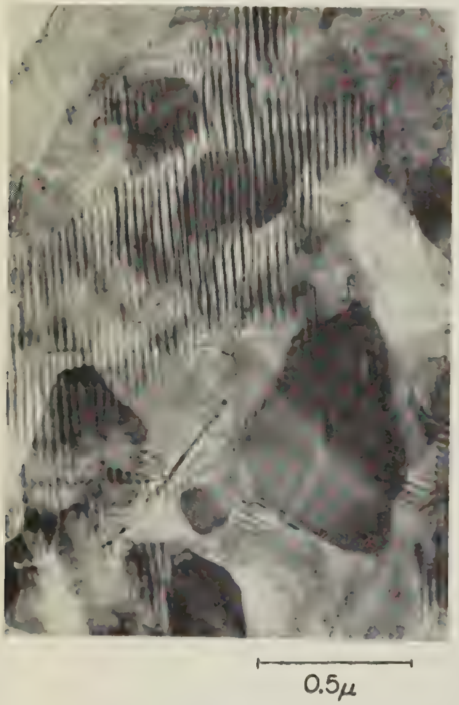

Photo. 1. General aspect of natural graphite powder.

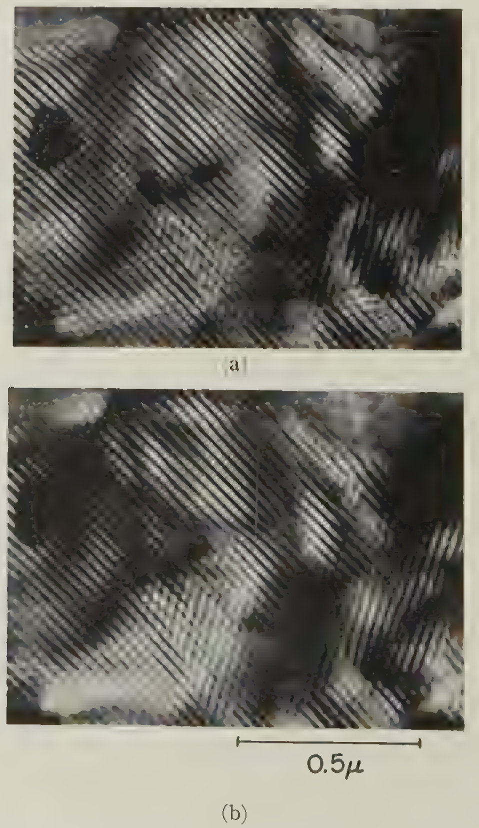

Photo. 4. Extra terminating half lines in moiré pattern and their movement due to the change of illmination condition.

G. A. Bassett, J. W. Menter and D. W. Pashley[8] as discussed later. On the other hand, it was realized that even in absence of a real dislocation such structure in the moiré pattern can be produced by certain kind of contamination of the specimen film[16] and possibly by local distortion of the film. In the present case, when the focus of the objective lens is changed, most of such extra terminating lines are not displaced. While, when changing the angle and the intensity of illumination, many of them are observed to disappear or be displaced as shown in Photos. 4 (a) and (b) which are taken in otherwise the same condition. These facts are apt to lead to a conclusion that most of the observed extra terminating half lines in moiré patterns are not arising from contamination or dislocation lines normal to the *c*-atomic planes. There are, however, a few exceptions in which extra half lints are not displaced and have very clear contrast as shown in Photo. 5, likely indicating the real existence of such dislocations.

Disturbances of moiré patterns along some curved lines are frequently observed as shown in Photos. 6, 7, and 8. As will be mentioned later, these curved lines were verified to be dislocation lines lying in basal or *c*-atomic planes of the crystal. A direct evidence for that seems to be given by Photo. 7, on the left-hand side of which are seen dislocation lines due to the diffraction contrast associated with them like those in metal crystals, while on the right-hand side are the same lines disturbing the moiré pattern in a manner similar to those seen in Photos. 6 and 8. In Photo. 6, two sets of moiré patterns appear in

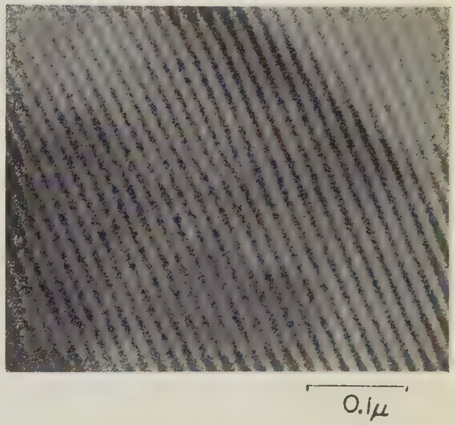

Photo. 5. Extra terminating half line in moiré pattern presumably arising from a dislocation.

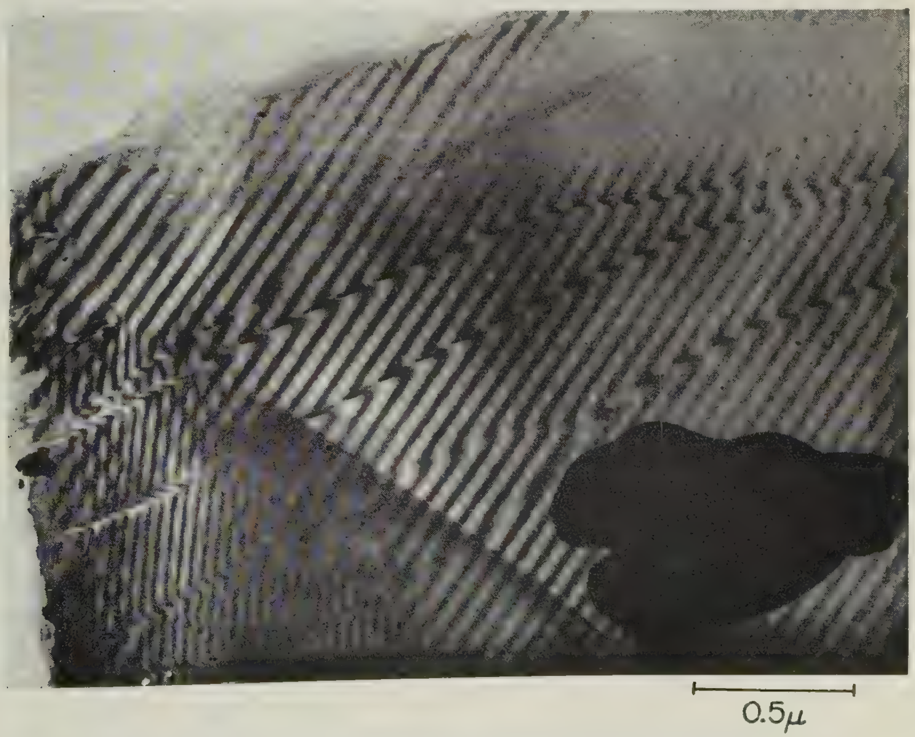

Photo. 6. Disturbance of moiré pattern due to dislocations lying in *c*-plane.

somewhat different ways probably due to the difference in the inclination of crystal; one, parallel to the direction *A*, is predominant in most of the field of the micrograph, and the other, parallel to the direction B, appears only on the lower left-hand side of the picture. We call the former the {100} moiré pattern and the latter the {110} moiré pattern henceforth, since by a closer examination they proved to be arising from double diffraction from the {100} and {110} planes respectively in the hexagonal crystal structure of graphite as shown in Fig. 3. It is noteworthy that, as are seen in this micrograph and Fig. 1 which is a schematical representation of the micrograph, while across the lines such as *ac*, *gh* and *kl* the line shifts of the {100} moire pattern and the {110} pattern take place by just

one and two moiré spacings respectively, across the lines such as *ab*, *jk* and *mk* the shift of the two patterns are about a half and just one moiré spacing respectively. This suggests that the nature, presumably the Burgers vector, of the dislocation lines such as *ac*, *gh* and *kl* is different from that of the lines such as *ab*, *jk* and *mk*. It should also be noted that across five curved lines seen in Photo. 8 the moiré lines shift by the amount of about one third of the moiré spacing, and that generally the line shift takes place gradually across the dislocation line, presumably exhibiting the breadth of the dislocation in the basal plane. By a geometrical analysis based on the kinematical theory a full interpretation of such behaviours of the disturbance of moiré patterns due to dislocation lines as mentioned above can be given, to which we shall refer in the following paragraph.

Apart from the disturbance of moiré pat-

terns, dislocation lines which lie in the basal planes can be directly observed on account of their diffraction contrast. Generally speaking, their appearances and behaviour are similar to those of dislocations observed by many investigators in metal crystals[4,6,17]. In the following are the remarkable features of dislocations in graphite thus observed in the present experiment.

Apparently there are two kinds of dislocations, as are inferable from their difference in the image contrast and mobility, namely one which has sharp, clear contrast and is immobile as shown in Photos. 7 and 9, and the other which has rather obscure, broad contrast and is very mobile as shown in Photos. 10, 11 and 14. As will be discussed later, the Burgers vector of the former is considered to have the main component perpendicular to the basal plane and that of the latter must be in the basal plane. Sometimes paired dislocations which may be the result of split of unit dislocations into their partials are observed. In some cases, such that the thickness of the observed crystal is inadequate or the orientation is not proper for diffraction conditions, it is difficult to identify the kinds of dislocations, unless their motion is observable in the microscope. Moreover, in an extreme case, one cannot distinguish an array of dislocations from a moiré pattern, which will be discussed later on too.

Various types of dislocation networks are observed as well as their random distribution, which are shown in Photos. 9, 10, 11, 12 and 13: Photos. 9 and 13 exhibit parallel arrays of dislocations with the average distance of 1000 Å, a network partly triangular and partly rhombic in appearance is seen in Photo. 10, and a square network in Photo. 12. On the other hand, Photo. 11 shows more or less random distribution of dislocations. Photo. 12 is also remarkable example showing double images of most of the dislocations in the network.

Although many dislocations of various kinds above mentioned are observed in a large number of crystals, there are some crystallites in which no dislocation is observable over several microns in lateral dimensions.

As Grenall[11] first reported, motion of dislocations of the glissile type is easily observed by changing the electron beam current of the microscope. In general, dislocation loops spread from randomly distributed dislocations in certain small area or from a source situated at the periphery of a crystal, move rapidly and more or less discontinuously interacting with other dislocations, and finally form a stable network. Especially the triangular network of about 2000 Å in meshes as shown in Photo. 10 seems to be very stable as a final configuration. Photos. 14 (a) and (b), which were successively taken at the same field in the electron microscope, show the spreading dislocation loops at the initial stage of motion.

§ 4. Discussions

A) *Dislocations in graphite structure*

Dislocations conceivable in the graphite crystal structure are of four kinds as are listed in Table I and schematically shown in Fig. 2 (a), (b), (c) and (d).

Table I. Four kinds of fundamental dislocations in the graphite structure.

Kind	Burgers vector	Line direction	Type
1	// to *c*-plane, a [100]	⊥ to *c*-plane	edge
2	⊥ to *c*-plane, c [001]	⊥ to *c*-plane	screw
3	// to *c*-plane, a [100]	// to *c*-plane	edge and screw
4	⊥ to *c*-plane, c [001]	// to *c*-plane	edge

As is well known[7,15] a dislocation of kind 1 may produce an extra terminating half line or so-called a moiré dislocation such as shown in Photos. 4 (a), (b) and 5, if it actually

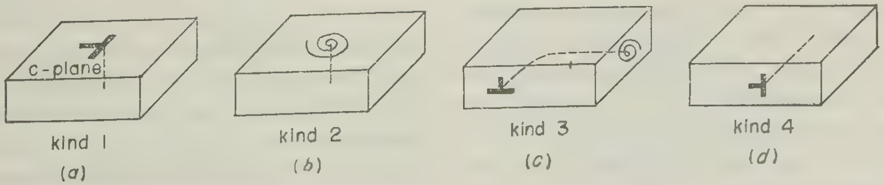

Fig. 2. Schematic representations of four kinds of fundamental dislocations in graphite structure.

exists in graphite crystal. From a theoretical consideration that the interaction force or binding between two succesive c-atomic planes is of van der Waals nature which is very weak as compared with the binding forces in the c-planes, and also from the experimental facts that extraordinarily thin flakes can easily made from a crystal by peeling off c-atomic layers and that the crystal is very glissile along c-planes producing c-plane slip and c-axis rotation, it is rather difficult to conceive that this kind of edge dislocation threading every successive c-atomic plane can stably exist. Dawson and Follett[12)] found many extra terminating half lines in the moiré pattern from synthetic graphite, and refered them to real edge dislocations of kind 1. Although we cannot draw a conclusion on the existence of dislocations of this kind at the present stage of the experiment, so far as the results obtained at least in case of natural graphite most of the extra terminating lines in moiré patterns seem to be not arising from real edge dislocations of this kind, but be the so-called ghosts caused by the local distortion or bending of the crystal, or be due to another kind of dislocations lying in the c-atomic plane such as kind 3. The latter two cases will be explained in detail in the following section.

Kind 2 is of screw type threading c-atomic planes like kind 1. In this case, however, its real existence is more thinkable than the kind 1, if we consider the continuous herical structure of successive c-planes around a screw dislocation of this kind. Actually, Tsuzuku[10)] observed such screw dislocations in small penny shaped graphite crystals grown from carbon black particles, which seem to play very important rôle in the growth of crystals. It may be not unreasonable to expect that this kind of dislocations produces an observable image contrast and a disturbance in the moiré pattern at any rate. However, we have not yet observed them in our graphite crystals.

Kind 3 is the most probable to exist in graphite crystals and is undoubtedly responsible for their very glissile nature along c-layers. Most of the observed dislocations which are mobile and have the obscure, broad contrast such as shown in Photos. 10, 11 and 14 may be of this kind. The very weak van der Waals interaction between c-atomic layers would be again an important factor to determine the breadth of these dislocations, which may in turn govern its electron image contrast. The Burgers vectors of unit dislocations of this kind are shown by $\boldsymbol{a}$, $\boldsymbol{a}'$ and $\boldsymbol{a}''$ in Fig. 3 as well as the Burgers vectors of their partials $\boldsymbol{b}$, $\boldsymbol{c}$ and so on. As a hatched parallelogram in the figure shows, the former form the unit cell of the graphite structure together with the c-axis vector perpendicular to them. It is apparent that a unit dislocation can reduce its energy by splitting into two partials with a stacking fault between them on account of the favourable strain energy relation, $a^2 > b^2 + c^2$ and of very low stacking fault energy. The stacking made of c-layers of the graphite structure can be expressed by $ACACAC\cdots$ or $ABABAB\cdots$ if it is perfect. In Fig. 3, the atomic arrangements in the three configurations, A, B, and C shown by solid circles and solid lines, dotted circles and dotted lines, and open circles and double lines respectively. When we displace the A configuration by the displacement vector or slip vector $\boldsymbol{b}$, we have the B configuration, and by the $\boldsymbol{c}$ vector the C configuration.

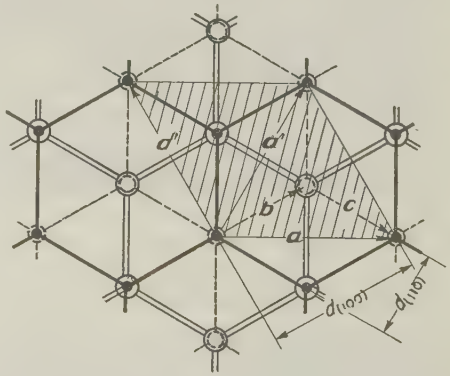

Fig. 3. Three configurations of c-layer stacking and Burgers vectors in c-plane in graphite structure.

It follows that, when a half dislocation of the Burgers vector $\boldsymbol{b}$ moves along a slip plane between a layer of the A configuration and that of the C configuration underneath, a stacking sequence $ACACBABA\cdots$ is obtained behind the dislocation, provided that the lower part of the crystal is fixed for the convenience of understanding. Therefore, if this half dislocation is followed by another half dislocation of the $\boldsymbol{c}$ vector for completion of a unit dislocation, a stacking fault of the *ABCA* type is produced between the two dislocations. This situation is shown in Fig. 4 (a). Similarly, if a half dislocation of the ***c*** vector precedes that of the ***b*** vector, a stacking fault of the *ACCA* type is obtained, which is shown in Fig. 4 (b). The former type of split of a unit dislocation may be more probable than the latter, because the *CC* stacking of the latter type would be associated with a stacking fault energy higher than that of the *ABC* type. Considering, however, that the van der Waals interaction between stacking layers are very weak as compared with the homopolar binding in *c*-atomic layers, well-defined split of a unit dislocation such as in f. c. c. metals seems to be rather difficult to expect in graphite crystals. Actually, among many observed dislocations which can be regarded as kind 3, very few are found clearly splitting in spite of their unmistakably broad contrasts in the direct image or in the moiré pattern. At present we cannot clarify the reason why some dislocations behave themselves like exceptions by clear splitting. Nevertheless, half dislocations of the above types appear to have important rôles in imperfect crystals such as of synthetic graphite or of ground powder of graphite.

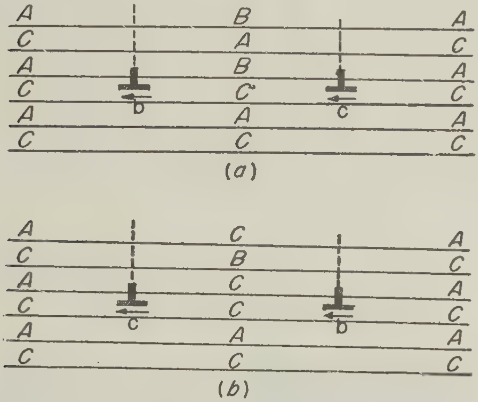

Fig. 4. Partial dislocations of kind 3 and stacking disorders of *c*-layers.

Dislocations of kind 4 are formed at the periphery of *c*-atomic layers inserted in or extracted from the *ACACAC* hexagonal *c*-layer stacking in a crystal as shown in Fig. 5: Unit dislocation, shown by (a), is a result of insertion or missing of two successive layers, and should be associated with a considerabls high strain energy, although it has no stacking fault along the extra or missed planes. Insertion or extraction of a single layer produces a half dislocation with a stacking fault layer of *ABC* type, like (b), or *ACC* type, like (c). A full dislocation (a) would reduce its self energy by splitting into two (c) dislocations if the atomic diffusion can take place in its vicinity, and a (c) dislocation in turn would reduce its stacking fault energy if associated by a glissile half dislocation of kind 3 previously mentioned as shown by Fig. 5 (d). Such behaviours of splitting and association of dislocations seem to be plausible and important, as they can fully account for the disturbances in the moiré pattern by dislocations, which is to be discussed in the next section.

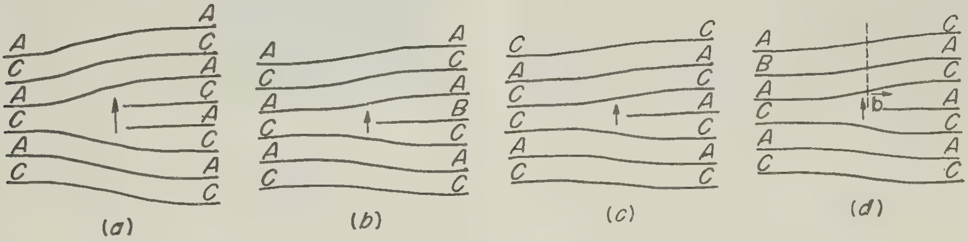

Fig. 5. Dislocations of kind 4.

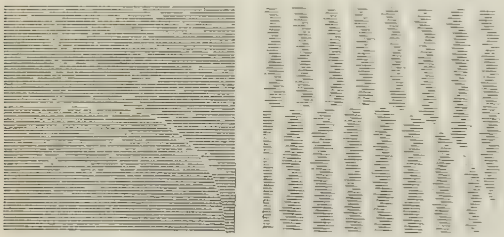
B) *Disturbances in moiré patterns due to dislocations lying in c-atomic layers*

As is mentioned in the preceding paragraph, origins of extra terminating half lines in the moiré pattern have been discussed by many investigators[7,8,15]. Among these discussions, that by Bassett, Menter and Pashley[8] appears to be worthy of note in regards to another kind of disturbance of moiré pattern due to dislocations lying in *c*-atomic layers: They first pointed out that generally a dislocation line, the Burgers vector of which has a component perpendicular to the lattice planes giving rise to the moiré pattern, can be detected as a number of terminating half lines even if it is not perpendicular to the film examined or it is a screw dislocation. Although they didn't treat the case in which a dislocation passes through the film completely in parallel with it or more specifically the case in question in which the slip plane is parallel to the film, their argument may be extended to such cases to interpret the disturbances in moiré patterns as shown in Photos. 6, 7 and 8.

Apart from the method that Bassett et al[8] have used to illustrate their argument, we first begin with treating a simple line greating model[21] which can be regarded as the lattice projection to form moiré patterns. Consider a portion of a line grating bounded by a curved line is displaced by an amount of fraction of the line spacing, d, in the direction normal to the lines as shown in Fig. 6 (a).



(a) (b)

Fig. 6. Line shift of moiré fringes due to a displacement of a part of a line grating.

By superposing this line grating on a perfect line grating making a small angle α with it, a moiré pattern which has a shift of moiré fringes across the boundary line by a fraction of the fringe spacing, $D=d/\alpha$, is formed. It is easily verified that the amount of displacement of the line grating and that of the moiré fringes have the same fraction in respect to their spacings; as a special case, if the displacement of the line grating is just d, the shift of the fringes is just D too.

Such a displacement as mentioned above will actually take place in a crystal lattice by a dislocation with the Burgers vector and slip plane which are parallel with the film plane. Consider a glissile edge dislocation of possitive sign of kind 3 in a graphite thin crystal as shown in Fig. 7. Due to a component of its Burgers vector perpendicular to the crystal planes to form a moiré pattern, contraction of spacings of the crystal planes will be produced along the dislocation line in the uppermost part of the crystal bounded by the slip plane as shown in Figs. 7 and 8 (a). The latter picture is the same as Fig. 6 (a) in such a sense that there is a displacement corresponding to the displacement vector or the Burgers vector between the upper and lower sides of the lattice, only a difference being that in Fig. 8 (a) the displacement is gradual across the breadth of the dislocation line.

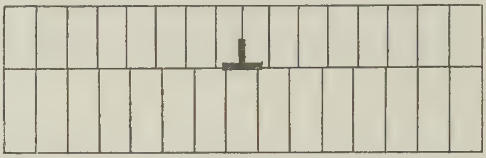


Fig. 7. An edge dislocation of kind 3 and change of lattice spacings in its vicinity.

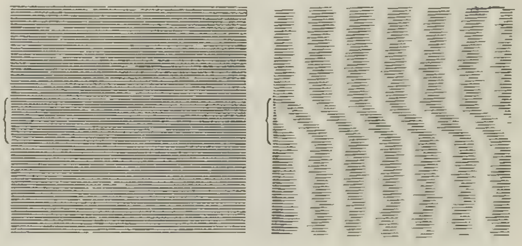

(a) (b)

Fig. 8. Line shift of moiré fringes due to an edge dislocation of kind 3.

Like in the case of Figs. 6 (a) and (b), superposition of Fig. 8 (a) on a perfect line grating produces a curved and shifted moiré pattern as shown in Fig. 8 (b), which can actually be observed very frequently as in Photos. 6, 7 and 8. In the above explanation, we took no account of the lower part of the crystal, which will bear practically the same amount of shift of the moiré fringes in the reverse direction due to the displacement associated with lattice expansion along the dislocation line. In actual observations, therefore, either of the two parts which is thicker or more favourable in the diffraction condition will have a predominant effect on the ultimate image formation.

It is clear from the above model that the breadth of disturbed or curved region of the moiré lines directly gives the width of the dislocation on the slip plane and that the amount of shift of the moiré lines gives the component of Burgers vector perpendicular to the lattice planes concerned. From Photos. 6, 7 and 8, the dislocation width is estimated to be 200 Å or less. This value seems to be much larger than those which are expected for dislocations in metal crystals, but may be not unreasonable if we consider that the difinition of the dislocation width in the present case is different from a usual "half width" difinition, that the very weak interaction between the *c*-atomic layers above and below the slip plane tends to spread the dislocation, and that there is a possibility for a unit dislocation to split into partial dislocations. In fact, a simple calculation following the Peierl's analysis for the isotropic case[18] gives the value of the order of 100 Å which is to be compared with the above observed value. The relation between the Burgers vector and the associated line shift of the moiré pattern in graphite can be predicted by using Fig. 3: Consider a dislocation with the Burgers vector $\boldsymbol{a}$. Since the component of the Burgers vector normal to the (100) lattice planes just corresponds to one lattice spacing, this dislocation will give a relative displacement of this amount to the lattice before and behind it, and therefore will give a full line shift of the (100) moiré fringes. On the other hand, a half dislocation with the Burgers vector $\boldsymbol{b}$ has the normal component of 2/3 of the (100) lattice spacing, and therefore will give the 2/3 line shift of the moiré pattern. Similarly, a half dislocation with the vector $\boldsymbol{c}$ will give 1/3 line shift of the (100) moiré pattern, which is clearly seen in Photo. 8. The same consideration reveals that a dislocation with the Burger $\boldsymbol{a}'$ in Fig. 3 will give the (110) moiré fringes a shift of two line spacings while it gives a full line spacings while it gives a full line shift of the (100) moiré fringes, and that a half dislocation with the vector $\boldsymbol{b}$ will give a full line shift to the (110) moiré fringes. All of these predicted behaviour of dislocations concerning the disturbance on moiré patterns are actually found in Photo. 6 as mentioned in the preceding paragraph. It should also be noted that the Kirchhoff's law in regard to the amounts of line shift is maintained at every junction point of dislocation lines such as *c*, *e*, *h* and *k*, suggesting the preservation of the same low regarding their Burgers vectors.

Two problems seem to remain unsolved: In the first, the line shift of about a half line spacing which is actually observed on dislocation lines such as *ce*, *hi* and *jk* in Photo. 6 cannot be deduced from the above simple line grating model taking account of possible Burgers vectors in the graphite structure. However, careful reexamination of Fig. 7, in which the concerned lattice planes are represented by vertical straight lines even in the vicinity of the dislocation because of the assumption that the crystal film is very thin, will lead to a conclusion that the amount of line shift is determined not only by the Burgers vector of the dislocation but also by some other conditions such as the depth or the distance of crystal part to produce the moiré pattern from the dislocation and possibly the applied stress to the crystal film. For instance, if we assume that the film is very thick, the crystal part far apart from the dislocation underneath or above it has no longer dilatation field and hence no displacement in the lattice planes, so that no line shift will take place in the moiré pattern. Consequently, it is not inconceivable that we could observe a line shift in the moiré pattern the amount of which does not exactly correspond to a Burgers vector possible in the crystal structure. The second problem arises from the fact that two arguments seemingly exclusive to each other are sometimes compatible in one dislocation; one argument is that a sharp, stationry diffraction contrast is due to a sessile dislocation of kind 4 which would not give rise to the line shift of the moiré pattern, and the other that glissile dislocation of kind 3 which produce an obscure contrast can cause the line shift because their Burgers vector have a component normal to the lattice planes to form the moiré pattern. For instance, while several lines on the left-hand side of Photo. 7 have a sharp immobile diffraction contrast peculiar to dislocations of kind 4, the same lines on the right-hand side are associated with the line shift of the moiré pattern which is characteristic of dislocations of kind 3. So far as observed in the present experiment, many dislocations have such an ancipital character. We have, therefore, to draw a conclusion that many dislocations are actually the composite of kind 3 and kind 4. Such association of two kinds of dislocations might arise from two causes, that, as previously mentioned, a dislocation of Fig. 5(c) would reduce its stacking fault energy if associated with a half dislocation of kind 3 as shown in Fig. 5 (d), and that the core energy of either of the two dislocations might be reduced by the association. Recently, Amelinckx[13] observed dislocation rings of kind 4 as a consequence of plane condensation of vacancies in thermally quenched and treated graphite crystals. From their image contrast, he suggested that the dislocation ring is sometimes accompanied by slip on the plane of condensation by a half dislocation to reduce the energy of stacking disorder, which is in good agreement with the above conclusion.

C) *Origins of extra half lines in moiré patterns*

The line grating model in the preceding section for the explanation of the line shift of moiré fringes due to dislocations of kind 3 can easily extended to interpret the occurence of extra terminating half lines in the moiré pattern. Consider a dislocation of kind 3 the Burgers vector of which is such as to produce a full line shift of a moiré pattern. The shift and curvature of the moiré fringes around the edge part of this dislocation is well described by Fig. 8 (b), and is again shown on the left hand side of a schematical representation of Fig. 9. As the dislocation increases its screw component by curving as shown in the latter figure, the curvature of the moiré fringes becomes less sharp although the same amount of line shift still remains as is seen in the middle of the figure. Finally, when the dislocation becomes a pure screw as far as the component of Burgers vector to produce the line shift is concerned, the dislocation line is parallel to the moiré lines and no line shift will be observed. It follows that there must be an extra terminating half line at an end of the pure screw part such as denoted by P in Fig. 9. Such a half line in the moiré pattern, arising from a glissile dislocation of kind 3 lying in the c-plane, may distinctive from that due to a dislocation of kind 1 by its high mobility and anomalous curving of some moiré fringes near the extra terminating half line. Actually, many of the extra half lines observed in the present experiment, for instance those in Figs. 4 (a) and (b), have such characters as above mentioned and therefore seem to arise from this origin.

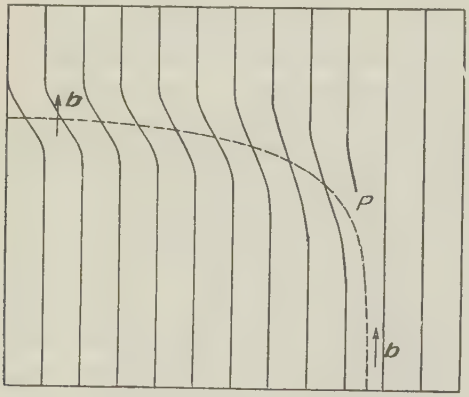

Fig. 9. Extra terminating half line in moiré fringes due to a dislocation of kind 3.

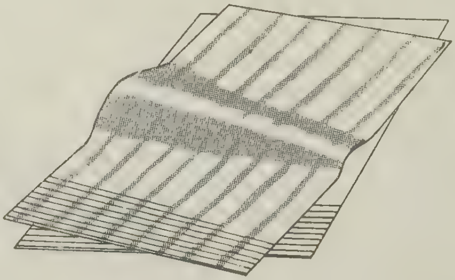

Fig. 10. Small wrinkle on one of two overlapping crystals which can produce an extra half line in the moiré pattern.

Another possible origin for extra half lines in the moiré pattern may be a local distortion of one of the overlapping crystal films otherwise perfect, such as shown in Fig. 10, which would take place especially in case of graphite crystals. An example of this kind of moiré dislocation is given by Photo. 15, in which a distinctive half line is not shown, but instead n half lines are found to meet $n+1$ half lines, n being of the order of 30. As is well known, the spacing of the rotation moiré lines is given by $D=d/\alpha$, where α is the rotation angle and d the spacing of lattice planes to form the moiré lines. α is of the order of 2×10^{-2} rad., when D is about 100 Å. By differenciating the above equation, we have $\delta D/D=-\delta\alpha/\alpha$. Hence, to obtain a value of 1/30 for $\delta D/D$, we may put a value as small as 10^{-3} rad. to $\delta\alpha$, which would easily be produced by a slight wrinkle, as shown in Fig. 10, without extremely disturbing the double diffraction condition there. A wide range disturbance of moiré fringes around the extra half line is characteristic of this kind of moiré dislocation as is seen in Photo. 15.

D) *Diffraction contrast of dislocations in graphite*

P. B. Hirsch, A. Howie and M. J. Whelan[19] treated the electron microscope image contrast of dislocations by a kinematical theory, and clarified that the contrast is essentially phase contrast in the Bragg diffracted beams, the phase difference being due to the displacements of atoms around the dislocations. The theory succeeded in explaining characteristic features of the observed images. Many of such features, for instances, the dependence of the contrast on the Burgers vector of dislocation, the reversal of contrast on bright and dark field images, the invisibility of some dislocations, and the occurrence of double images, are also observed in the present experiment. Especially, as are cited in Table 1, dislocations in graphite have very simple geometrical configurations in spite of the variety in their kinds. Hence, if the dislocation structures, or the atomic displacements around the dislocations, in the graphite lattice were carefully analysed, this would immediately lead to the quantitative verification of the theory and hence to clarifying the problem of the electron image contrast of defects in crystals.

Recently, Y. Kamiya and R. Uyeda[20] found two interesting phenomena concerning the image contrast of dislocations in molybdenite crystals which are also found in our graphite crystals; one is that the diffraction contrast on the crystal film changes abruptly from black to white across a dislocation line as indicated by an arrow in Fig. 9, and the other is that very regular array of dislocations is sometimes indistinguishable from the moiré pattern in their appearences. Kamiya and Uyeda explained the former by taking account of the tilt of the crystal film given by the edge dislocation the Burgers vector of which is parallel to the film. This gives, in our case, an evidence of the association of dislocations of kind 3 and kind 4, because the dislocations in Fig. 9 are regarded as immobile dislocations of kind 4 which would not produce the tilt of the crystal film by themselves. They also explained the latter by replacing the rotation or shear of two overlapping crystals to form the moiré pattern by a twist or shear boundary formed by the cross grating or array of screw dislocations, and concluded the correspondence between the moiré lines and the dislocation lines. This will be again discussed in Part II in regard to the irradiation effect in graphite crystals.

Acknowledgements

The authors wish to express their hearty thanks to Drs. Y. Takagi and K. Motojima for their interest and encouragement in this work, and to Profs. R. Uyeda, T. Suzuki and Dr. H. Suzuki for their valuable discussions. Their thanks are also due to Messrs. H. Ōtsu and Y. Katano for their continued assistance in this work.

A Diffraction Pattern caused by Temperature Diffuse Scattering. I. General Theory

By Yoshiro KAINUMA

Physical Institute, Nagoya University, Nagoya

(Received September 24, 1960)

When diffuse X-rays caused by scattering in a thermally vibrating crystal are scattered again in the same crystal, a new diffraction pattern similar to Kossel-pattern is produced. The properties of the new pattern is discussed by the use of the perturbation theory of X-ray scattering in a crystal. This discussion is similar to that given in the author's theory of Kikuchi-pattern (Acta Cryst. 8 (1955) 247).

According to the present theory, the signs of crystal structure factor can be determined by examining the new pattern produced at an appropriate crystal orientation, provided relative values of elastic constants are available.

§1. Introduction

In the present paper, the diffuse scattering of X-rays which is caused by thermal vibration of crystal lattice has been extensively studied. If the diffuse X-rays are reflected by net planes in the same crystal, a new diffraction pattern, geometrically similar to Kossel-pattern, will appear superposed on the diffuse scattering. This was first pointed out by Grenville-Wells[1)*)]. The intensity formulae of this pattern are derived in what follows, and it is pointed out that there is a possibility of a new approach to the phase problem in X-ray crystal analysis by utilizing this pattern.

Calculation of the intensity consists of two steps. In the first step, the intensity is calculated for a crystal in which the vibrating atoms are frozen at a certain instant of time. This calculation is carried out by the use of of a perturbation method in which a generalized theorem of reciprocity in optics plays an important part. In the second step the calculated intensity of the first step is averaged over an interval of time much longer than the periods of lattice vibrations. The time average is estimated by employing the theory of lattice vibration.

It is shown that the new diffraction pattern is superposed on the ordinary temperature diffuse scattering. The new pattern lies on a certain diffraction cone and can be separated into two parts, one with a symmetrical line profile corresponding to Kikuchi-line, the other with an antisymmetical line profile corresponding to Kikuchi-band. The antisymmetrical part gives a pattern similar to the 'Helldunkellinie' of Kossel-pattern.[**)]

In centro-symmetrical crystals the sign of structure factor may be determined by examining the antisymmetrical line profile produced at an appropriate crystal orientation, provided the relative values of the elastic constants are given.

§2. Perturbation Method

Let a beam of parallel X-rays fall upon a crystal. The electric field of the incident X-rays in vacuum is given by

$$\boldsymbol{E}=\boldsymbol{E}_0 \exp(-2\pi i \boldsymbol{K}_0\cdot\boldsymbol{r})\exp(2\pi ict/\lambda)\ , \qquad (1)$$

where λ and $\boldsymbol{K}_0$ are the wavelength and wave vector respectively of the incident X-rays and all other notations have their usual meanings.

The electromagnetic field of X-rays inside and outside the crystal satisfies the following equations:

$$\left.\begin{array}{l}\mathrm{rot}\,\boldsymbol{E}=-(1/c)\partial\boldsymbol{H}/\partial t\\ \mathrm{rot}\,\boldsymbol{H}=(1/c)\partial\boldsymbol{D}/\partial t\end{array}\right\} \qquad (2)$$

and

$$\boldsymbol{E}=\{1+(e^2/mc^2)(\lambda^2/\pi)\rho(\boldsymbol{r})\}\boldsymbol{D} \qquad (3)$$

where $\rho(\boldsymbol{r})$ is the density of electrons. When

---

[*)] N. Norman (Acta Cryst. **11** (1958) 1) observed similar diffraction phenomena due to Compton scattering of X-rays by a diamond crystal.

[**)] The corresponding phenomena in electron diffraction due to thermal diffuse scattering were studied by S. Takagi (J. Phys. Soc. Japan **13** (1958) 278, 287). Takagi's theoretical approach, however, is different from the present author's treatment.

$\rho(r)$ corresponds to the frozen crystal, $\rho(r)$ has no lattice periodicity. However, the same average of the density $\langle\rho(r)\rangle$ is periodic within the crystal. We will hereafter denote $\langle\rho(r)\rangle$ by $\rho_1(r)$. If the incident beam of X-rays falls upon an imaginary crystal with the density $\rho_1(r)$, the field of X-rays $\boldsymbol{E}_1$, $\boldsymbol{H}_1$ and $\boldsymbol{D}_1$ can be easily calculated by the use of Eqs. (2) and (3) in accordance with the ordinary procedure of dynamical theory.

Let us define $\boldsymbol{E}_2$, $\boldsymbol{H}_2$ and $\boldsymbol{D}_2$ by $\boldsymbol{E}_2=\boldsymbol{E}-\boldsymbol{E}_1$, $\boldsymbol{H}_2=\boldsymbol{H}-\boldsymbol{H}_1$ and $\boldsymbol{D}_2=\boldsymbol{D}-\boldsymbol{D}_1$, respectively. Then $\boldsymbol{E}_2$, $\boldsymbol{H}_2$ and $\boldsymbol{D}_2$ describe the diffuse scattering caused by thermal vibration*, including the new pattern besides the ordinary temperature diffuse scattering (§ 3). $\boldsymbol{E}_2$, $\boldsymbol{H}_2$ and $\boldsymbol{D}_2$ satisfy Eq. (2) while Eq. (3) is written

$$\boldsymbol{E}_2=\{1+(e^2/mc^2)(\lambda^2/\pi)\rho_1(r)\}\boldsymbol{D}_2 + (e^2/mc^2)(\lambda^2/\pi)\rho_2(r)\boldsymbol{D}_1\ , \tag{4}$$

where $\rho_2(r)$ is the difference between instantaneous electron density and averaged electron density, i.e. $\rho_2(r)=\rho(r)-\rho_1(r)$. In the derivation of Eq. (3) we neglected a small quantity $(e^2/mc^2)(\lambda^2/\pi)\rho_2(r)\boldsymbol{D}_2$.

We must calculate the electromagnetic wave field with the suffix 2 at a point A which lies far from the crystal. If a radiation of the same wavelength λ, which is emitted from the point A, falls upon the imaginary crystal of an electron density $\rho_1(r)$, the electromagnetic field satisfies the equations

$$\left.\begin{aligned}&\operatorname{rot}(\overline{\boldsymbol{E}}-\overline{\boldsymbol{E}}_e)=-(1/c)\partial\overline{\boldsymbol{H}}/\partial t\\&\operatorname{rot}\overline{\boldsymbol{H}}=(1/c)\partial\overline{\boldsymbol{D}}/\partial t\end{aligned}\right\} \tag{5}$$

and

$$\overline{\boldsymbol{E}}=\{1+(e^2/mc^2)(\lambda^2/\pi)\rho_1(r)\}\overline{\boldsymbol{D}}\ , \tag{6}$$

where $\overline{\boldsymbol{E}}_e$ in Eq. (5) is an external electromotive force present at the singular point A and is given by

$$\overline{\boldsymbol{E}}_e=\overline{\boldsymbol{p}}\exp(2\pi ict/\lambda)\delta(\boldsymbol{r}-\boldsymbol{r}_A)\ , \tag{7}$$

where $\overline{\boldsymbol{p}}$ is a constant dipole moment and $\delta(\boldsymbol{r}-\boldsymbol{r}_A)$ is the delta-function. Hereafter, we call the electromagnetic wave expressed by $\overline{\boldsymbol{E}}$, $\overline{\boldsymbol{H}}$ and $\overline{\boldsymbol{D}}$ the reciprocal wave. By the help of the reciprocal wave we can calculate $\boldsymbol{D}_2$ at the point A by a generalized theorem of reciprocity, which is expressed as follows:

$$\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\overline{\boldsymbol{p}}\exp(2\pi ict/\lambda) = -(e^2/mc^2)(\lambda^2/\pi)\int\rho_2\boldsymbol{D}_1\cdot\overline{\boldsymbol{D}}\,d\boldsymbol{r}\ . \tag{8}$$

The proof of Eq. (8) is similar to that of the ordinary theorem of reciprocity in optics[2),3)], and is given in Appendix 1.

If the incident radiation does not excite any Bragg reflection, we have the expression for $\boldsymbol{D}_1$ inside the crystal as follows:

$$\boldsymbol{D}_1=\boldsymbol{E}_0\exp(-2\pi i\boldsymbol{k}_0\cdot\boldsymbol{r})\exp(2\pi ict/\lambda)\ , \tag{9}$$

where $\boldsymbol{k}_0$ is the wave vector of the incident wave in the crystal. If the reciprocal wave is reflected by a single net plane $\boldsymbol{G}$, then according to the formula of dynamical theory[4)] we have the following expression for $\overline{\boldsymbol{D}}$ inside the crystal;

$$\overline{\boldsymbol{D}}=\sum_h\sum_s\overline{\boldsymbol{D}}_h{}^s\exp(-2\pi i\overline{\boldsymbol{k}}_h{}^s\cdot\boldsymbol{r})\exp(2\pi ict/\lambda)\ , \tag{10}$$

where $\sum_h$ is a summation over the reciprocal lattice points $\boldsymbol{O}$ (the origin) and $\boldsymbol{G}$, and $\sum_s$ is that over the wave points P' and P'' (Fig. 3).

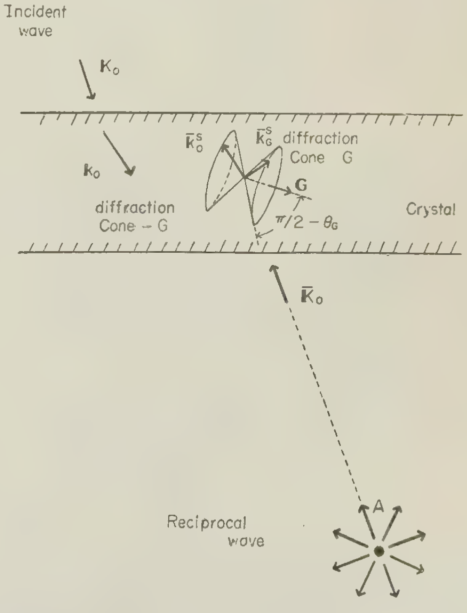

Fig. 1. Incident wave and reciprocal wave in Laue case (transmission pattern).

---

* The total scattering intensity is poportional to the time average $\langle|\boldsymbol{E}|^2\rangle=\langle|\boldsymbol{E}_1|^2\rangle+\langle|\boldsymbol{E}_2|^2\rangle+\langle\boldsymbol{E}_1\cdot\boldsymbol{E}_2{}^*\rangle+\langle\boldsymbol{E}_1{}^*\cdot\boldsymbol{E}_2\rangle$. $\langle|\boldsymbol{E}_1|^2\rangle$ represents the incident wave and Bragg reflections, and thus it vanishes in all directions except the directions of the incident beam and of Bragg reflections. On the other hand, $\langle|\boldsymbol{E}_2|^2\rangle$ vanishes in the exact directions of the incident beam and of Bragg reflections. Therefore, in the above equation the cross terms $\langle\boldsymbol{E}_1\cdot\boldsymbol{E}_2{}^*\rangle$ and $\langle\boldsymbol{E}_1{}^*\cdot\boldsymbol{E}_2\rangle$ vanish in all directions and $\langle|\boldsymbol{E}_2|^2\rangle$ represents diffuse scattering caused by thermal vibration.

$\overline{\boldsymbol{D}}_h{}^s$ is the amplitude of the plane wave with the wave vector $\overline{\boldsymbol{k}}_h{}^s$, where $\overline{\boldsymbol{k}}_G{}^s=\overline{\boldsymbol{k}}_0{}^s+\boldsymbol{G}$. Eq. (10) is derived by the use of the approximation that the reciprocal wave outside the crystal can be regarded as a plane wave at the position of the crystal and given by

$$\overline{\boldsymbol{E}}=\overline{\boldsymbol{E}}_0\exp(-2\pi i\overline{\boldsymbol{K}}_0\cdot\boldsymbol{r})\exp(2\pi ict/\lambda)\,, \tag{11}$$

where

$$\overline{\boldsymbol{E}}_0=-(\pi/R)\{\overline{\boldsymbol{K}}_0\times(\overline{\boldsymbol{K}}_0\times\boldsymbol{p})\}\exp(-2\pi iR/\lambda)\,, \tag{12}$$

where R is the distance between the point A and the crystal, and $\overline{\boldsymbol{K}}_0$ is the wave vector of the plane wave (Fig. 1). $\overline{\boldsymbol{D}}_h{}^s$ in Eq. (10) is given by the fundamental equations and boundary conditions in the dynamical theory of diffraction*.

Introducing unit vectors $\overline{\boldsymbol{e}}_\perp$ and $\overline{\boldsymbol{e}}_{||}$ we have

$$|\boldsymbol{D}_2(\boldsymbol{r}_A)|^2=|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\overline{\boldsymbol{e}}_\perp|^2+|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\overline{\boldsymbol{e}}_{||}|^2\,, \tag{13}$$

where $\overline{\boldsymbol{e}}_\perp$ and $\overline{\boldsymbol{e}}_{||}$ are perpendicular to each other and both are perpendicular to the wave vector $\overline{\boldsymbol{K}}_0$, and $\overline{\boldsymbol{e}}_\perp$ is, in addition, perpendicular to the reciprocal lattice vector $\boldsymbol{G}$. Therefore $\overline{\boldsymbol{e}}_\perp$ is approximately perpendicular, and $\overline{\boldsymbol{e}}_{||}$ is parallel, to the plane which includes both wave vectors $\overline{\boldsymbol{k}}_0{}^s$ and $\overline{\boldsymbol{k}}_G{}^s$.

§ 3. The time average

The observed intensity at the point A is given by the average

$$J_2(\boldsymbol{r}_A)=(c/8\pi)\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)|^2\rangle. \tag{14}$$

Eq. (14) can be obtained by averaging two terms in Eq. (13) and by multiplying a constant factor $(c/8\pi)$. The averaging is worked out by employing the theory of lattice vibration similar to that in the kinematical treatment of temperature diffuse scattering.

The further treatment differs by the conditions of Laue case and Bragg case. It should be noted that the distinction between Lause case and Bragg case is related to the reciprocal wave but not to the incident wave. In Laue case both vectors $\overline{\boldsymbol{k}}_0{}^s$ and $\overline{\boldsymbol{k}}_G{}^s$ direct inward within the crystal (Figs. 1 and 2a); in Bragg case $\overline{\boldsymbol{k}}_0{}^s$ directs outward while $\overline{\boldsymbol{k}}_G{}^s$ directs inward (Fig. 2b). In Laue case we treat both transmission and reflection patterns; in Bragg case, however, we treat only reflection pattern.

(I) *Laue case*. By substituting $\overline{\boldsymbol{p}}=|\overline{\boldsymbol{p}}|\boldsymbol{e}_{\perp,||}$ into Eqs. (8) and (12) and by the help of Eqs. (9), (10) and (11) we have for non-absorbing crystal the relation

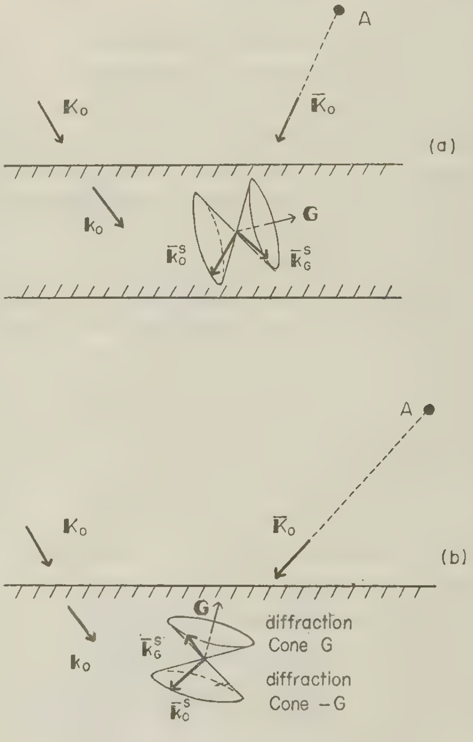

Fig. 2. Incident wave and reciprocal wave.
(a) Laue case (reflection pattern).
(b) Bragg case (reflection pattern).

$$\begin{aligned}\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\overline{\boldsymbol{e}}_{\perp,||}|^2\rangle&=NkT(1/R^2)(e^2/mc^2)\\&\times[S_{00}|\boldsymbol{E}_0\cdot\overline{\boldsymbol{e}}_{\perp,||}|^2+\{S_{GG}(\gamma_0/\gamma_G)|\boldsymbol{E}_0\cdot\overline{\boldsymbol{e}}_{\perp,G||}|^2-S_{00}|\boldsymbol{E}_0\cdot\overline{\boldsymbol{e}}_{\perp,||}|^2\}1/2(1+W^2_{\perp,||})\\&+\{S_{0G}F_{-G}+S_{G0}F_G\}(1/|F_G|)\sqrt{\gamma_0/\gamma_G}\,(\boldsymbol{E}_0\cdot\overline{\boldsymbol{e}}_{\perp,||})(\boldsymbol{E}_0{}^*\cdot\overline{\boldsymbol{e}}_{\perp,G||})(C_{\perp,||}/|C_{\perp,||}|)\\&\times W_{\perp,||}/2(1+W^2_{\perp,||})]\,.\end{aligned} \tag{15}$$

In Eq. (15), the derivation of which is given in Appendix 2, F_G is the crystal structure factor,

---

* $\overline{\boldsymbol{D}}_h{}^s$ is given by Eq. (A26), (A27), (A28) and (A29) in appendix 2 and by Eqs. (A38), (A39) and (A40) in Appendix 3.

T is the absolute temperature, k is Boltzmann's constant, N is the total number of unit cells, γ_0 and γ_G are respectively the cosines of the angles Θ_0 and Θ_G (Fig. 3). The parameter $W_{\perp,\parallel}$ determines the direction of $\bar{K}_0$ and is given by

$$W_{\perp,\parallel}=\eta/\{2|F_G|\cdot|C_{\perp,\parallel}|(e^2/mc^2)(\lambda^2/\pi)\sqrt{|\gamma_G/\gamma_0|}\,(1/v_a)\}\,, \tag{16}$$

where

$$\eta=2(\theta-\theta_G)\sin 2\theta_G-(e^2/mc^2)(\lambda^2/\pi)F_0\{1-(\gamma_G/\gamma_0)\}(1/v_a)\,, \tag{17}$$

where θ is the glancing angle of $\bar{K}_0$ on the net plane $\boldsymbol{G}$, and θ_G is the Bragg angle. We have $W_{\perp,\parallel}\gtrless 0$ and $\eta\gtrless 0$ for $\theta\gtrless\theta_G$. The quantity $C_{\perp,\parallel}$ in Eqs. (15) and (16) is given by

$$C_{\perp}=1 \tag{18}$$

and

$$C_{\parallel}=\cos 2\theta_G \tag{19}$$

v_a in Eqs. (16) and (17) is the volume of a unit cell. S_{00}, S_{GG}, S_{0G} and S_{G0} in Eq. (15) are given by

$$S_{hg}\approx\sum_k\sum_l(4\pi^2/\sqrt{m_k m_l})g_k(-\boldsymbol{b}_h)g_l(-\boldsymbol{b}_g)\exp\{-2\pi i(\boldsymbol{b}_h\cdot\boldsymbol{X}^k-\boldsymbol{b}_g\cdot\boldsymbol{X}^l)\}$$
$$\times\{\boldsymbol{b}_h\cdot\boldsymbol{\chi}_{kl}(\boldsymbol{\tau})\cdot\boldsymbol{b}_g\}\,, \tag{20}$$

where

$$\boldsymbol{b}_0=\boldsymbol{k}_0+\bar{\boldsymbol{k}}_0 \tag{21}$$

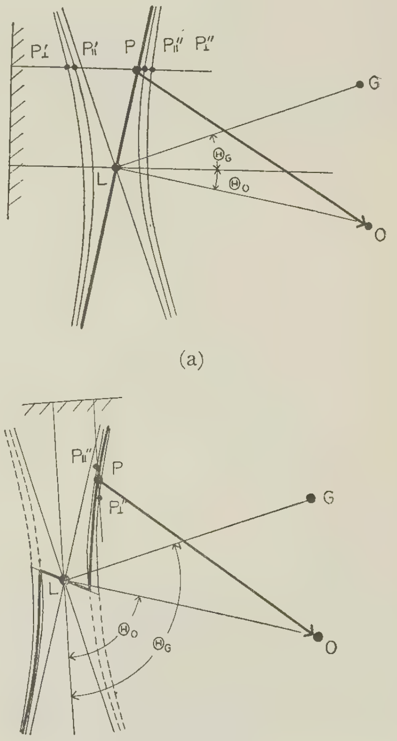
and

$$\boldsymbol{b}_G=\boldsymbol{b}_0+\boldsymbol{G}\,. \tag{22}$$

The wave vector $\bar{k}_0$ is the weighted mean of $\bar{k}'_{0\perp}$ with the weight $|\bar{D}'_{0\perp}|$ and $\bar{k}_0''$ with the weight $|\bar{D}''_{0\perp}|$. Then $\bar{k}_0$ coincides with the weighted mean of $\bar{k}'_{0\parallel}$ with the weight $|\bar{D}'_{0\parallel}|$ and $\bar{k}''_{0\parallel}$ with the weight $|\bar{D}''_{0\parallel}|$. We have $PO=LO$ for any η (Fig. 3). The effective atomic scattering factor of the kth atom in the unit cell g_k is given by

$$g_k(-\boldsymbol{b}_h)=f_k(-\boldsymbol{b}_h)\exp\{-M_k(-\boldsymbol{b}_h)\}\,, \tag{23}$$

where f_k is the ordinary atomic scattering factor and $\exp\{-M_k(-\boldsymbol{b}_h)\}$ is the temperature factor. m_k is the mass of the kth atom. The vector $\boldsymbol{X}^k$ denotes the position of the kth atom in a unit cell relative to the lattice point. $\boldsymbol{\chi}_{kl}$ is the tensor used by Zachariasen in the kinematical treatment of temperature diffuse scattering and related to the elastic constants of the crystal. The wave vector $\boldsymbol{\tau}$ is given by $\boldsymbol{\tau}=\boldsymbol{b}_0-\boldsymbol{I}$, where $\boldsymbol{I}$ is the reciprocal-lattice-point vector nearest to the vector $\boldsymbol{b}_0$. By the help of Eqs. (13), (14) and (15) we have the intensity of diffraction pattern $J_2(\boldsymbol{r}_A)$ as follows:



(a)

(b)

Fig. 3. (a) The locus of P in Laue case, where $\overrightarrow{PO}=\bar{K}_0$. (b) The locus of P in Bragg case, where $\overrightarrow{PO}$=mean of the real parts of $\bar{k}^s_{0\perp}$ and $k^s_{0\parallel}$.

$$
\begin{aligned}
J_2(\boldsymbol{r}_A)=NkT[I_eS_{00}+\{&I_e^{\perp}(S_{GG}(\gamma_0/\gamma_G)-S_{00})(1/2(1+W_{\perp}^2))\\
&+I_{eGG}^{||}S_{GG}(\gamma_0/\gamma_G(-I_e^{||}S_{00})(1/2(1+W_{||}^2))\}\\
&+(S_{0G}F_{-G}+S_{G0}F_G)(1/|F_G|)\sqrt{\gamma_0/\gamma_G}\\
&\times(I_e^{\perp}(W_{\perp}/2(1+W_{\perp}^2))+I_{eG}^{||}(W_{||}/2(1+W_{||}^2))\cos 2\theta_G/|\cos 2\theta_G|)]\ ,
\end{aligned}
\tag{24}
$$

For unpolarized incident radiation, we have

$$I_e=I_0(1/R^2)(e^2/mc^2)^2(1+\cos^2\phi_0)/2\ , \tag{25}$$

$$I_e^{\perp}=I_0(1/R^2)(e^2/mc^2)^2(1/2\sin^2 2\theta_G)(\cos^2\phi_0+\cos^2\phi_G-2\cos\phi_0\cos\phi_G\cos 2\theta_G)\ , \tag{26}$$

$$
\begin{aligned}
I_e^{||}=I_0(1/R^2)(e^2/mc^2)^2[&((1+\cos^2\phi_0)/2)\\
&-(1/\sin^2 2\theta_G)(\cos^2\phi_0+\cos^2\phi_G-2\cos\phi_0\cos\phi_G\cos 2\theta_G)]\ ,
\end{aligned}
\tag{27}
$$

$$
\begin{aligned}
I_{eGG}^{||}=I_0(1/R^2)(e^2/mc^2)^2[&((1+\cos^2\phi_G)/2)\\
&-(1/\sin^2 2\theta_G)(\cos^2\phi_0+\cos^2\phi_G-2\cos\phi_0\cos\phi_G\cos 2\theta_G)]\ ,
\end{aligned}
\tag{28}
$$

and

$$
\begin{aligned}
I_{eG}^{||}=I_0(1/R^2)(e^2/mc^2)^2[&(\cos 2\theta_G-\cos\phi_0\cos\phi_G)/2\\
&-(1/\sin^2 2\theta_G)\{\cos 2\theta_G(\cos^2\phi_0+\cos^2\phi_G)-2\cos\phi_0\cos\phi_G\}]\ ,
\end{aligned}
\tag{29}
$$

where I_0 is the intensity of the incident radiation, ϕ_0 is the angle $\angle(\boldsymbol{k}_0, -\bar{\boldsymbol{k}}_0)$ and ϕ_G is $\angle(\boldsymbol{k}_0, -\bar{\boldsymbol{k}}_G)$.

The right-hand side of Eq. (24) can be regarded as the summation of three terms. The first term is the ordinary diffuse scattering around the reciprocal lattice point $-\boldsymbol{I}$. The second term is an even function of η and the third termtan odd function, both amounting to considerable values near the diffraction cone of index G. The second and the third terms correspond to Kikuchi-lines and Kikuchi-band[3] respectively (Fig. 4). In practice, the line

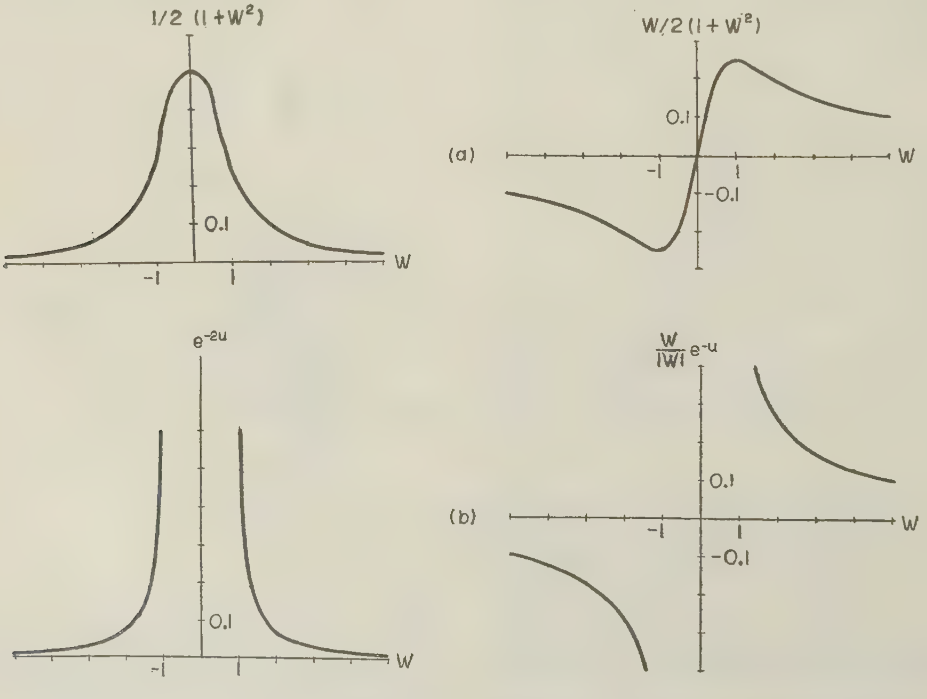


Fig. 4. The line profiles of the symmetric line and the antisymmetric line. (a) Laue case. (b) Bragg case.

corresponding to the superposition of the second and the third terms is observed only when the cone G passes through the diffuse spot $-I$. Hereafter we treat only such cases. Under the influence of the third term, the line on diffraction cone shows a feature similar to ‘Helldunkellinie’ of Kossel-pattern. While in a broad sense, the intensity of Kossel-pattern is independent of the direction of incident electrons or incident X-rays, the intensity of our pattern depends remarkably on the direction of the incident X-rays.

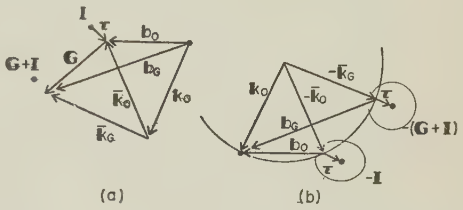

Fig. 5. The geometrical relations between wave vectors.
(a) The definitions in the text.
(b) The same vectors in the Ewald construction.

It is to be noted that in Laue case if $G+I\neq 0$ and the diffraction cone G passes through the diffuse spot $-I$, there appears in the same pattern another diffuse spot $J=-(G+I)$ through which the diffraction cone $-G$ passes. This implies that the direction of the incident beam is near the direction exciting simultaneous reflections $-I$ and J. The above-mentioned geometrical relation occurs because we have $k_0+\bar{k}_G-(G+I)=\tau$ in addition to $k_0+\bar{k}_0-I=\tau$ as shown in Fig. 5.

(II) *Bragg case.* If the crystal is thick enough and not prefectly non-absorbing, the expression for the intensity of our pattern $J_2(r_A)$ becomes very simple. Outside the region of total reflection, $|W_{\perp,||}|>1$, we have

$$\begin{aligned} J_2(r_A)=kT[&(A_\perp I_e{}^\perp+A_{||}I_e{}^{||})S_{00}\\ &+(A_\perp I_e{}^\perp \exp(-2u_\perp)+A_{||}I^{||}_{eGG}\exp(-2u_{||}))S_{GG}|\gamma_0/\gamma_G|\\ &+(A_\perp I_e{}^\perp(C_\perp/|C_\perp|)(W_\perp/|W_\perp|)\exp(-u_\perp)+A_{||}I^{||}_{eG}(C_{||}/|C_{||}|)(W_{||}/|W_{||}|)\exp(-u_{||}))\\ &\times(S_{0G}F_{-G}+S_{G0}F_G)(1/|F_G|)\sqrt{|\gamma_0/\gamma_G|}]\,, \end{aligned} \tag{30}$$

where $|W_{\perp,||}|=\cosh u_{\perp,||}$ and $u_{\perp,||}>0$. Inside the region of total reflection, $|W_{\perp,||}|<1$, we have

$$\begin{aligned} J_2(r_A)=kT\Bigg[&(A_\perp I_e{}^\perp+A_{||}I_e{}^{||})S_{00}\\ &+(A_\perp I_e{}^\perp+A_{||}I^{||}_{eGG})S_{GG}|\gamma_0/\gamma_G|\\ &+\Bigg\{A_\perp I_e{}^\perp(C_\perp/|C_\perp|)\left(S_{0G}F_{-G}\exp i\left(v_\perp+\frac{\pi}{2}\right)+S_{G0}F_G\exp -i\left(v+_\perp\frac{\pi}{2}\right)\right)\\ &+A_{||}I^{||}_{eG}(C_{||}/|C_{||}|)\left(S_{0G}F_{-G}\exp i\left(v_{||}+\frac{\pi}{2}\right)+S_{G0}F_G\exp -i\left(v_{||}+\frac{\pi}{2}\right)\right)\Bigg\}\\ &\times(1/|F_G|)\sqrt{|\gamma_0/\gamma_G|}\Bigg]\,, \end{aligned} \tag{31}$$

where $W_{\perp,||}=\sin v_{\perp,||}$. The derivations of Eqs. (30) and (31) are given in Appendix 3. The factors $A_{\perp,||}$ in Eqs. (30) and (31) represent the effect of primary extinction and of absorption and $A_{\perp,||}$ is a function of η as given by Eq. (A35)*. The factors S_{00}, S_{GG}, S_{0G} and S_{G0} are given by Eq. (20). However it should be noted that in Bragg case b_0 in Eq. (20) is not given by Eq. (21) but is defined as the mean of the real parts of $b^s_{0\perp}$ and $b^s_{0||}$. In Eq. (20) b_G is given by Eq. (22). In Bragg case, PO becomes asymptotically equal to LO as the value $|\eta|$ increases (Fig. 3).

The factors $A_\perp$ and $A_{||}$ become very small in a region of total reflection, especially when $|\eta|$ is near zero. Thus we always have a defect line. Apart from the effect of $A_\perp$ and $A_{||}$ the general feature of the intensity distribution of our pattern in Bragg case resembles that in Laue case (Fig. 4). The intensity of our pattern can be regarded as a summation of three terms similar to those in Laue case. Outside the regions of total reflection, the factors $A_{\perp}$ and $A_{||}$ change slowly if the X-rays are not strongly absorbed.

---

* η is given by Eq. (17) also in Bragg case.

It is noteworthy that in Bragg case even when the diffraction cone G passes through the diffuse spot $-I$ the diffuse spot J does not usually appear in reflection pattern because the cone $-G$ which passes through the diffuse spot J does not cut the reflection pattern (Fig. 2).

§ 4. Possibility of the Determination of the Sign of Struncture Factor

Let us examine the case where the direction of the incident radiation is slightly deviated from the condition of the simultaneous reflections made by two net planes $-I$ and J. Then the diffuse spot $-I$ is cut by both diffraction cones $-I$ and G in both Laue and Bragg cases*. We will examine the line profile of the diffraction cone at the position corresponding to a small value of $|\tau|$. Then the contribution of the acoustic vibrations to the intensity of the pattern predominates over the contribution of the optical vibrations if F_{-I} and F_J are not zero. Thus we have at higher temperatures

$$(1/\sqrt{m_k m_l})\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}) \approx \boldsymbol{\Omega}^{-1}(\boldsymbol{\tau})/(4\pi^2\boldsymbol{\tau}^2 v_a) , \tag{33}$$

where $\boldsymbol{\Omega}^{-1}(\boldsymbol{\tau})$ is a tensor expressed in terms of the elastic constants of the crystal[6)].

Since we have $\boldsymbol{b}_0 \sim \boldsymbol{I}$, $\boldsymbol{b}_G \sim \boldsymbol{I}+\boldsymbol{G}=-\boldsymbol{J}$ and $F_J=\sum_k g_k(\boldsymbol{J}) \exp(2\pi i\boldsymbol{J}\cdot\boldsymbol{X}^k)$, the term $\{S_{0G}F_{-G}+S_{G0}F_G\}$ in Eqs. (24), (30) and (31) reduces to

$$\begin{aligned}\{S_{0G}F_{-G}+S_{G0}F_G\} \approx\ & (\lambda^2/\pi)^2(e^2/mc^2)^2(1/v_a)\{\boldsymbol{I}\cdot\boldsymbol{\Omega}^{-1}(\boldsymbol{\tau})\cdot(\boldsymbol{G}+\boldsymbol{I})\} \\ & \times(1/\boldsymbol{\tau}^2)|F_I|\cdot|F_J|\cdot|F_G|\cdot 2\cos\varphi_I+\varphi_J+\varphi_G) ,\end{aligned} \tag{34}$$

where φ_h is the phase of structure factor

$$F_h=|F_h| \exp(i\varphi_h) . \tag{35}$$

There are three degrees of freedom in the determination of the phase of structure factor corresponding to the three degrees of freedom in selection of the coordinate origin. The value $(\varphi_G+\varphi_I+\varphi_J)$ is invariant for any selection of the origin under the condition that $\boldsymbol{G}+\boldsymbol{I}+\boldsymbol{J}=0$**. In the phase problem we must determine the invariant value of $(\varphi_G+\varphi_I+\varphi_J)$.

Therefore, if the new pattern is observed and if its line profile is measured, then the value of $\cos(\varphi_G+\varphi_I+\varphi_J)$ may be calculated by Eqs. (24), (30) and (34), provided the tensor $\boldsymbol{\Omega}^{-1}(\boldsymbol{\tau})$ is given. Since it would be difficult to measure the line profile, we treat here only a centro-symmetrical crystal where $\cos(\varphi_G+\varphi_I+\varphi_J)$ reduces to ± 1. It would be easy to distinguish whether the antisymmetric line is black-white or white-black. Then by Eqs. (24) and (34) in Laue case or by Eqs. (30) and (34) in Bragg case, we can determine the value of $(\varphi_G+\varphi_I+\varphi_J)$ provided the sign of $\{\boldsymbol{I}\cdot\boldsymbol{\Omega}^{-1}(\boldsymbol{\tau})\cdot(\boldsymbol{G}+\boldsymbol{I})\}$ is given. For the determination of elastic constants, which are necessary to evaluate $\boldsymbol{\Omega}^{-1}(\boldsymbol{\tau})$, the temperature diffuse scattering may be used[7)].

It may be suitable to choose combinations of $\boldsymbol{G}$, $\boldsymbol{I}$ and $\boldsymbol{J}$ where the structure amplitude $|F_G|$ is large, because the width of the line is proportional to $|F_G|$ (Fig. 4 and Eqs. (16) and (17)) and thus the antisymmetrical structure of line would be clearly observed. Generally, Laue case is more suitable for the present purpose. In Bragg case, the antisymmetrical structure of line would be difficult to observe since the effect of extinction, which is expressed by the factor A, is so remarkable that the antisymmetrical structure is likely to be overlooked.

---

* If the cone $-\boldsymbol{I}$ passes through the centre of diffuse spot $-\boldsymbol{I}$, the incident beam excites the Bragg reflection $-\boldsymbol{I}$. In such a case, $\boldsymbol{D}_1$ given by Eq. (9) can not be adopted because Eq. (9) was derived under the assumption that the incident wave is not reflected by any net plane.

** F_h is given by $F_h=\int\rho_1{}^L(X)\exp(2\pi i\boldsymbol{h}\cdot X)\,dX$, where $\rho_1{}^L(X)$ is the averaged electron density and the integration extends over a unit cell. If the lattice point is shifted from O_L to O_L' where $\overrightarrow{O_L O_L'}=\boldsymbol{s}$, $\rho_1{}^{L'}(\boldsymbol{X}')$ is given by $\rho_1{}^{L'}(\boldsymbol{X}')=\rho_1{}^L(\boldsymbol{X}'+\boldsymbol{s})$ and F_h' is given by $F_h'=F_h\exp(-2\pi i\boldsymbol{h}\cdot\boldsymbol{s})$. Thus we have $\varphi_h'=\varphi_h-2\pi i\boldsymbol{h}\cdot\boldsymbol{s}$ If $\boldsymbol{G}+\boldsymbol{I}+\boldsymbol{J}=0$, we have $\varphi_G'+\varphi_I'+\varphi_J'=\varphi_G+\varphi_I+\varphi_J$ for any $\boldsymbol{s}$.

§ 5. Discussions

Booth[8] suggested in 1946 a solution of phase problem according to which the phase of structure factor can be determined in principle by observing whether two diffuse spot ares joined by a diffuse streak or not. His method was criticized by Stokes[9]. Booth paid no attention to the fact that the phase of structure factor has three degrees of freedom (§ 4.). Booth's method takes into consideration the region of large $|\tau|$ where the optical vibrations contribute to the temperature diffuse scattering much more than the acoustic vibrations. On the other hand, the region of small $|\tau|$ is used here. Thus our method is free from the difficulty found in Booth's method.

The calculation in this article was carried out by assuming an ideally perfect crystal although real crystals are not ideally perfect. However, our result of calculation, in the main, are likely to hold for fairly perfect real crystals, if adequate corrections are made for increased intensity and increased breadth due to the mosaic structure of real crystals.

It is assumed that the radiation is almost unabsorbed by the crystal. If the absorption is strong and the effect of absorption is taken into account, remarkable changes will occur in the line profile of the pattern. In Kikuchi-bands it was found that the antisymmetrical line profile is reversed by the effect of absorption[10]. In a phase determination by the present method, the use of a strongly absorbed radiation should be avoided.

The author expresses his deep appreciation to Prof. Ryozi Uyeda for his guidance throughout this work. This research is supported in part by Kagaku Kenkyu Hi, the Science Research Fund established by the Ministry of Education, Japan.

Appendix 1

Here we prove Eq. (8), a generalized theorem of reciprocity. By the use of the well-known formula of vector analysis we have

$$\operatorname{div}(\boldsymbol{E}_2\times\overline{\boldsymbol{H}})=\overline{\boldsymbol{H}}\cdot\operatorname{rot}\boldsymbol{E}_2-\boldsymbol{E}_2\cdot\operatorname{rot}\overline{\boldsymbol{H}}\,.$$

Since $\boldsymbol{E}_2$ and $\boldsymbol{H}_2$ satisfy Eq. (2) and $\overline{\boldsymbol{H}}$ and $\overline{\boldsymbol{D}}$ satisfy Eq. (5) we have

$$\operatorname{div}(\boldsymbol{E}_2\times\overline{\boldsymbol{H}})=\overline{\boldsymbol{H}}\cdot(-1/c)\partial\boldsymbol{H}_2/\partial t-\boldsymbol{E}_2\cdot(1/c)\partial\overline{\boldsymbol{D}}/\partial t\,,$$

which is rewritten

$$\operatorname{div}(\boldsymbol{E}_2\times\overline{\boldsymbol{H}})=(-2\pi i/\lambda)(\overline{\boldsymbol{H}}\cdot\boldsymbol{H}_2+\boldsymbol{E}_2\cdot\overline{\boldsymbol{D}})\,. \tag{A1}$$

By a similar procedure we have

$$\operatorname{div}\{(\overline{\boldsymbol{E}}-\overline{\boldsymbol{E}}_e)\times\boldsymbol{H}_2\}=(-2\pi i/\lambda)(\boldsymbol{H}_2\cdot\overline{\boldsymbol{H}}+\overline{\boldsymbol{E}}\cdot\boldsymbol{D}_2-\overline{\boldsymbol{E}}_e\cdot\boldsymbol{D}_2)\,. \tag{A2}$$

Subtracting Eq. (A2) from Eq. (A1) and integrating with respect to $\boldsymbol{r}$ over the whole space, by the help of Green's theorem, we have

$$\int\{(\boldsymbol{E}_2\times\overline{\boldsymbol{H}})_n-(\overline{\boldsymbol{E}}\times\boldsymbol{H}_2)_n\}dS=(-2\pi i/\lambda)\int(\boldsymbol{E}_2\cdot\overline{\boldsymbol{D}}-\overline{\boldsymbol{E}}\cdot\boldsymbol{D}_2+\overline{\boldsymbol{E}}_e\cdot\boldsymbol{D}_2)d\boldsymbol{r}\,. \tag{A3}$$

In the derivation of the left-hand side of Eq. (A3) we use Eq. (7). Since the left-hand side of Eq. (A3) vanishes, we have

$$\int\overline{\boldsymbol{E}}_e\cdot\boldsymbol{D}_2d\boldsymbol{r}=-\int(\boldsymbol{E}_2\cdot\overline{\boldsymbol{D}}-\overline{\boldsymbol{E}}\cdot\boldsymbol{D}_2)d\boldsymbol{r}\,. \tag{A4}$$

By the use of Eqs. (4), (6), (7) and (A4) we have Eq. (8).

Appendix 2

Here we derive Eq. (15) which holds in Laue case. By the help of Eq. (8) and the definition of $\rho_2(\boldsymbol{r})$, as given in § 2., we have

$$\begin{aligned}\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\bar{\boldsymbol{e}}_{\perp,||}|^2\rangle &= (e^2/mc^2)^2(\lambda^2/\pi)^2(1/|\bar{\boldsymbol{p}}|^2)\\ &\times\left\{\iint\langle\rho(\boldsymbol{r})\rho(\boldsymbol{r}')\rangle(\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r}))(\boldsymbol{D}_1{}^*(\boldsymbol{r}')\cdot\bar{\boldsymbol{D}}^*(\boldsymbol{r}'))\,d\boldsymbol{r}d\boldsymbol{r}'\right.\\ &\left.-\left|\int\langle\rho(\boldsymbol{r})\rangle\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r})\,d\boldsymbol{r}\right|^2\right\}.\end{aligned}\tag{A5}$$

If the Nordheim's assumption of rigid-atoms[11)] is adopted, i.e. if the electron clouds around atoms are not deformed when nuclei oscillate, the electron density $\rho(\boldsymbol{r})$ is given by

$$\rho(\boldsymbol{r})=\sum_n\sum_k\rho_k(\boldsymbol{r}-\boldsymbol{r}_n{}^k-\boldsymbol{u}_n{}^k)\,,\tag{A6}$$

where $\rho_k(\boldsymbol{\xi})$ is the electron density which is due to the kth atom in the unit cell and is expressed as a function of $\boldsymbol{\xi}$ $(=\boldsymbol{r}-\boldsymbol{r}_n{}^k-\boldsymbol{u}_n{}^k)$ i.e. the coordinate relative to the nucleus of the kth atom. $\boldsymbol{r}_k{}^n$ and $\boldsymbol{u}_k{}^n$ are the equilibrium position and the displacement from equilibrium position, respectively, of the kth atomic nucleus in the nth unit cell.

By the help of Eqs. (9), (10) and (A6), we have

$$\begin{aligned}\int\rho(\boldsymbol{r})\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r})d\boldsymbol{r} &= \sum_h\sum_s\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s\sum_n\sum_k\int\rho_k(\boldsymbol{\xi})\exp(-2\pi i\boldsymbol{b}_h{}^s\cdot\boldsymbol{\xi})d\boldsymbol{\xi}\\ &\times\exp\{-2\pi i\boldsymbol{b}_h{}^s\cdot(\boldsymbol{r}_n{}^k+\boldsymbol{u}_n{}^k)\}\exp(4\pi ict/\lambda)\,.\end{aligned}\tag{A7}$$

By the use of well-known relation:

$$f_k(\boldsymbol{b})=\int\rho_k(\boldsymbol{\xi})\exp(2\pi i\boldsymbol{b}\cdot\boldsymbol{\xi})d\boldsymbol{\xi}\,,\tag{A8}$$

Eq. (A7) is rewritten

$$\begin{aligned}&\int\rho(\boldsymbol{r})\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r})d\boldsymbol{r}\\ &=\sum_h\sum_s(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)\sum_n\sum_k f_k(-\boldsymbol{b}_h{}^s)\exp\{-2\pi i\boldsymbol{b}_h{}^s\cdot(\boldsymbol{r}_n{}^k+\boldsymbol{u}_n{}^k)\}\exp(4\pi ict/\lambda)\,.\end{aligned}\tag{A9}$$

By the use of Eq. (A9) we have

$$\begin{aligned}&\int\langle\rho(\boldsymbol{r})\rangle(\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r}))d\boldsymbol{r}\\ &=\sum_h\sum_s(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)\sum_n\sum_k g_k(-\boldsymbol{b}_h{}^s)\exp(-2\pi i\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_n{}^k)\exp(4\pi ict/\lambda)\,,\end{aligned}\tag{A10}$$

where g_k is given by Eq. (23). M_k in Eq. (23) is given by

$$M_k(-\boldsymbol{b}_h{}^s)=2\pi^2\langle(\boldsymbol{b}_h{}^s\cdot\boldsymbol{u}_n{}^k)^2\rangle\,.\tag{A11}$$

By a similar procedure, we have

$$\begin{aligned}&\iint\langle\rho(\boldsymbol{r})\rho(\boldsymbol{r}')\rangle(\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r}))(\boldsymbol{D}_1{}^*(\boldsymbol{r}')\cdot\bar{\boldsymbol{D}}^*(\boldsymbol{r}')\,d\boldsymbol{r}d\boldsymbol{r}'\\ &=|\sum_h\sum_s(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)\sum_n\sum_k g_k(-\boldsymbol{b}_h{}^s)\exp(-2\pi i\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_n{}^k)|^2\\ &+\sum_{h,g}\sum_{s,t}(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}^*{}_g{}^t)\sum_{k,l}g_k(-\boldsymbol{b}_h{}^s)g_l(-\boldsymbol{b}_g{}^t)\\ &\times\sum_{n,m}P_{kl}^{nm}(\boldsymbol{b}_h{}^s,\ \boldsymbol{b}_g{}^t)\exp\{-2\pi i(\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_n{}^k-\boldsymbol{b}_g{}^t\cdot\boldsymbol{r}_m{}^l)\}\,,\end{aligned}\tag{A12}$$

where

$$P_{kl}^{nm}(\boldsymbol{b}_h{}^s,\ \boldsymbol{b}_g{}^t)=4\pi^2\langle(\boldsymbol{b}_h{}^s\cdot\boldsymbol{u}_n{}^k)(\boldsymbol{b}_g{}^t\cdot\boldsymbol{u}_m{}^l)\rangle\ . \tag{A13}$$

By the use of Eqs. (A5), (A9) and (A12), we have

$$\begin{aligned}\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\bar{\boldsymbol{e}}_{\perp,\,||}|^2\rangle&=(e^2/mc^2)^2(\lambda^2/\pi)^2(1/|\bar{\boldsymbol{p}}|^2)\sum_{h,g}\sum_{s,t}(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_g{}^{*t})\\&\quad\times\sum_{k,l}g_k(-\boldsymbol{b}_h)g_l(-\boldsymbol{b}_g)\sum_{n,m}P_{kl}^{nm}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)\exp\{-2\pi i(\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_n{}^k-\boldsymbol{b}_g{}^t\cdot\boldsymbol{r}_m{}^l)\}\ .\end{aligned} \tag{A14}$$

In the derivation of Eq. (A14) the following approximations are used.

$$g_k(-\boldsymbol{b}_h{}^s)\approx g_k(-\boldsymbol{b}_h) \tag{A15}$$

and

$$P_{kl}^{nm}(\boldsymbol{b}_h{}^s,\ \boldsymbol{b}_g{}^t)\approx P_{kl}^{nm}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)\ , \tag{A16}$$

where $\boldsymbol{b}_h$ is the mean vector given by Eqs. (21) and (22).

By the application of the theory of lattice vibration, we have

$$P_{kl}^{nm}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)=(4\pi^2kT/N\sqrt{m_km_l})(\boldsymbol{b}_h\cdot\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g)\exp\{2\pi i\boldsymbol{\tau}_p\cdot(\boldsymbol{n}-\boldsymbol{m})\}\ , \tag{A17}$$

where the tensor $\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}_p)$ is given by

$$\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}_p)=(1/kT)\sum_j U_{kj}(p)U_{lj}^*(p)\{Q_j(p)/\omega_j{}^2(p)\}\ . \tag{A18}$$

If the suffix l is replaced by suffix k', Eq. (A18) becomes the same as Eq. (4. 109a) in Zachariasen's textbook[12]. The definitions for $U_{kl}(p)$, $Q_j(p)$ and $\omega_j(p)$ are found in the same textbook. By the help of Eq. (A17), the factor $\sum_{n,m}P\cdots\exp\{\cdots\}$ in Eq. (A14) turns out to be

$$\begin{aligned}&\sum_{n\ m}P_{kl}^{nm}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)\exp\{-2\pi i(\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_n{}^k-\boldsymbol{b}_g{}^t\cdot\boldsymbol{r}_m{}^l)\}\\&\quad=(4\pi^2kT/N\sqrt{m_km_l})(\boldsymbol{b}_h\cdot\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g)\exp\{-2\pi i(\boldsymbol{b}_h\cdot\boldsymbol{r}_0{}^k-\boldsymbol{b}_g\cdot\boldsymbol{r}_0{}^l)\}\\&\quad\quad\times\sum_n\exp\{2\pi i(\boldsymbol{\tau}_p-\boldsymbol{b}_h{}^s)\cdot\boldsymbol{n}\}\sum_m\exp\{-2\pi i(\boldsymbol{\tau}_p-\boldsymbol{b}_g{}^t)\cdot\boldsymbol{m}\}\ .\end{aligned} \tag{A19}$$

In the derivation of Eq. (A19) the following approximation is used: $\exp(-2\pi i\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_0{}^k)\approx\exp(-2\pi i\boldsymbol{b}_h\cdot\boldsymbol{r}_0{}^k)$. If we assume that the crystal is large enough in all directions, Eq. (A19) almost vanishes except when both $\boldsymbol{\tau}_p-\boldsymbol{b}_h{}^s$ and $\boldsymbol{\tau}_p-\boldsymbol{b}_g{}^t$ simultaneously become reciprocal lattice vectors. Since it is not likely that $\boldsymbol{b}_0{}'-\boldsymbol{b}_0{}''$ is equal to any reciprocal lattice vector, the condition for non-vanishing of Eq. (A19) is the simultaneous holding of equations

$$\boldsymbol{\tau}_p-\boldsymbol{b}_h{}^s=-\boldsymbol{h}-\boldsymbol{I} \tag{A20}$$

and

$$\boldsymbol{\tau}_p-\boldsymbol{b}_g{}^t=-\boldsymbol{g}-\boldsymbol{I}\ , \tag{A21}$$

where $\boldsymbol{I}$ is the reciprocal lattice vector nearest both $\boldsymbol{b}_0{}'$ and $\boldsymbol{b}_0{}''$. Eqs. (A20) and (A21) can be satisfied simultaneously only when we have $s=t$. When Eq. (A19) does not vanish, we have

$$\sum_n\exp\{2\pi i(\boldsymbol{\tau}_p-\boldsymbol{b}_h{}^s)\cdot\boldsymbol{n}\}=\sum_m\exp\{-2\pi i(\boldsymbol{\tau}_p-\boldsymbol{b}_g{}^t)\cdot\boldsymbol{m}\}=N\ . \tag{A22}$$

By the help of Eqs. (A19), (A20), (A21) and (A22), we have

$$\begin{aligned}&\sum_{n,m}P_{kl}^{nm}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)\exp\{-2\pi i(\boldsymbol{b}_h{}^s\cdot\boldsymbol{r}_n{}^k-\boldsymbol{b}_g{}^t\cdot\boldsymbol{r}_m{}^l)\}\\&\quad=\delta_{st}NkT(4\pi^2/\sqrt{m_km_l})(\boldsymbol{b}_h\cdot\boldsymbol{\chi}_{kl}(\boldsymbol{\tau})\cdot\boldsymbol{b}_g)\exp\{-2\pi i(\boldsymbol{b}_h\cdot\boldsymbol{X}^k-\boldsymbol{b}_g\cdot\boldsymbol{X}^l)\}\\&\quad\times\exp\{-2\pi i(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{r}_0\}\ ,\end{aligned} \tag{A23}$$

where $\delta_{st}=1$ if $s=t$, $\delta_{st}=0$ if $s\neq t$, $\boldsymbol{\tau}=\boldsymbol{b}_0-\boldsymbol{I}$, and $\boldsymbol{r}_0{}^k=\boldsymbol{r}_0+\boldsymbol{X}^k$. In the derivation of Eq. (A23) the following approximation is used:

$$\chi_{kl}(\boldsymbol{\tau}^s)\approx\chi_{kl}(\boldsymbol{\tau}) \tag{A24}$$

where $\boldsymbol{\tau}^s=\boldsymbol{b}_0{}^s-\boldsymbol{I}$. The approximation is good except when $|\boldsymbol{\tau}^s|$ becomes very small*.

By the help of Eqs. (A14) and (A23), we have

$$\begin{aligned}\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\bar{\boldsymbol{e}}_{\perp,\parallel}|^2\rangle=&(e^2/mc^2)^2(\lambda^2/\pi)^2(1/|\bar{\boldsymbol{p}}|^2)\\ &\times\sum_{hg}\sum_s(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_g{}^{*s})\exp\{-2\pi i(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{r}_0\}NkTS_{hg}\,,\end{aligned} \tag{A25}$$

where S_{hg} is given by Eq. (20).

Let us next evaluate the factor $\sum_s(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_g{}^{*s})$ in Eq. (A25) by the use of the formula of dynamical theory of diffraction[4]. When $\bar{\boldsymbol{p}}=|\bar{\boldsymbol{p}}|\bar{\boldsymbol{e}}_\perp$, we have

$$\bar{\boldsymbol{D}}_h{}^s=\bar{\boldsymbol{e}}_\perp\bar{D}^s_{h\perp}\,. \tag{A26}$$

When $\bar{\boldsymbol{p}}=|\bar{\boldsymbol{p}}|\bar{\boldsymbol{e}}_\parallel$, we have

$$\bar{\boldsymbol{D}}_0{}^s=\bar{\boldsymbol{e}}_\parallel\bar{D}^s_{0\parallel} \tag{A27}$$

and

$$\bar{\boldsymbol{D}}_G{}^s=\bar{\boldsymbol{e}}_{G\parallel}\bar{D}^s_{G\parallel}\,, \tag{A28}$$

where the unit vector $\bar{\boldsymbol{e}}_{G\parallel}$ is perpendicular to wave vector $\bar{\boldsymbol{k}}_G$ and $\bar{\boldsymbol{e}}_{G\parallel}$ is parallel to a plane including both wave vectors $\bar{\boldsymbol{k}}_0$ and $\bar{\boldsymbol{k}}_G$. If the origin of coordinate is assumed to lie on the surface through which the reciprocal wave enters into the crystal, the amplitudes $\bar{D}^s_{h\perp,\parallel}$ in Eqs. (A26), (A27) and (A28) are given by

$$\left.\begin{aligned}&\bar{D}'_{0\perp,\parallel}=(1/2)\{1-(W/\sqrt{1+W^2})\}\bar{E}_0\,,\\ &\bar{D}''_{0\perp,\parallel}=(1/2)\{1+(W/\sqrt{1+W^2})\}\bar{E}_0\,,\\ &\bar{D}'_{G\perp,\parallel}=(-1/2\sqrt{1+W^2})(F_G/|F_G|)\exp(2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)\sqrt{\gamma_0/\gamma_G}(C_{\perp,\parallel}/|C_{\perp,\parallel}|)\bar{E}_0\,,\\ &\text{and}\\ &\bar{D}''_{G\perp,\parallel}=(1/2\sqrt{1+W^2})(F_G/|F_G|)\exp(2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)\sqrt{\gamma_0/\gamma_G}(C_{\perp,\parallel}/|C_{\perp,\parallel}|)\bar{E}_0\,,\end{aligned}\right\} \tag{A29)**$$

where the quantities found in the right-hand sides of Eq. (A29) are given in the text of this article.

By the help of Eqs. (A26), (A27), (A28), (A29), (11) and (12), we have

---

* If $|\boldsymbol{\tau}^s|$ becomes very small, we have $-\bar{\boldsymbol{k}}_0{}^s-\boldsymbol{k}_0\approx-\boldsymbol{I}$, which is the condition of excitation of the Bragg reflection $-\boldsymbol{I}$. Then the assumtion under which Eq. (9) was derived can not be used.

** The averaged electron density can be expressed as $\rho_1{}^L(\boldsymbol{X})$, a function of the coordinate $\boldsymbol{X}$. The coordinate $\boldsymbol{X}$ denotes the relative position to zero-th lattice point. Thus we have $\boldsymbol{r}-\boldsymbol{r}_0=\boldsymbol{X}$ and $\rho_1{}^L(\boldsymbol{X})=\rho_1(\boldsymbol{r})$. As well-known we have

$$\rho_1{}^L(\boldsymbol{X})=(1/v_a)\sum_h F_h\exp(-2\pi i\boldsymbol{h}\cdot\boldsymbol{X})$$

and

$$F_h=\int_{\text{unit cell}}\rho_1{}^L(\boldsymbol{X})\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{X})d\boldsymbol{X}\,.$$

Thus we have

$$\rho(\boldsymbol{r})=(1/v_a)\sum_h\{F_h\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{r}_0)\}\exp(-2\pi i\boldsymbol{h}\cdot\boldsymbol{r})\,.$$

This is the reason that the factor $F_G\exp(2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)$ appears in the expressions of $D'_{G\perp,\parallel}$ and $D''_{G\perp,\parallel}$ in Eqs. (A29).

$$\left.\begin{aligned}
&\sum_s (\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_0{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_0{}^{*s})=|\boldsymbol{E}_0\cdot\bar{\boldsymbol{e}}_{\perp,\parallel}|^2\{1-(1/2(1+W^2_{\perp,\parallel}))\}(1/R^2)(\pi/\lambda^2)^2|\bar{\boldsymbol{p}}|^2\,,\\
&\sum_s (\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_G{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_G{}^{*s})=|\boldsymbol{E}_0\cdot\bar{\boldsymbol{e}}_{\perp,\parallel}|^2(1/2(1+W^2_{\perp,\parallel}))(\gamma_0/\gamma_G)(1/R^2)(\pi/\lambda^2)^2|\bar{\boldsymbol{p}}|^2\,,\\
&\text{and}\\
&\sum_s (\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_0{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_G{}^{*s})=(\boldsymbol{E}_0\cdot\bar{\boldsymbol{e}}_{\perp,\parallel})(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{e}}_{\perp,G\parallel})(W_{\perp,\parallel}/2(1+W^2_{\perp,\parallel}))\\
&\qquad\times(F_{-G}/|F_G|)\exp(-2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)(C_{\perp,\parallel}/|C_{\perp,\parallel})\sqrt{\gamma_0/\gamma_G}(1/R^2)(\pi/\lambda^2)^2|\bar{\boldsymbol{p}}|^2\,.
\end{aligned}\right\}\qquad \text{(A30)}$$

Substituting Eq. (A30) into Eq. (A25), we have Eq. (15) of the text.

Appendix 3

Here we derive Eqs. (30) and (31), which hold in Bragg case. In Bragg case we can also prove Eqs. (A5), (A6) and (A7) which are derived in Laue case. It must be noted that Eq. (A8) is valid only when $\boldsymbol{b}$ is a real vector. In Bragg case $\boldsymbol{b}_h{}^s$ is a complex vector in the region of total reflection. Since we have assumed that the crystal is not perfectly non-absorbing, $\boldsymbol{b}_h{}^s$ has a small imaginary part even outside the region of total reflection. Thus we have the following equations instead of Eqs. (A10) and (A12) in Laue case.

$$\begin{aligned}
&\int\langle\rho(\boldsymbol{r})\rangle\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r})d\boldsymbol{r}\\
&\quad\approx\sum_h(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)\sum_n\exp\{2\pi I(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n\}\sum_k g_k(-R(\boldsymbol{b}_h{}^s))\exp\{-2\pi iR(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n{}^k\}\exp(4\pi ict/\lambda)\,,
\end{aligned}\qquad\text{(A31)}$$

and

$$\begin{aligned}
&\iint\langle\rho(\boldsymbol{r})\rho(\boldsymbol{r}')\rangle(\boldsymbol{D}_1(\boldsymbol{r})\cdot\bar{\boldsymbol{D}}(\boldsymbol{r}))\,(\boldsymbol{D}_1{}^*(\boldsymbol{r}')\cdot\bar{\boldsymbol{D}}^*(\boldsymbol{r}'))d\boldsymbol{r}d\boldsymbol{r}'\\
&\quad\approx|\sum_h(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)\sum_n\exp\{2\pi J(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n\}\sum_k g_k(-R(\boldsymbol{b}_h{}^s))\exp\{-2\pi iR(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n{}^k\}|^2\\
&\quad+\sum_{h,g}(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_g{}^{*s})\sum_{n,m}\exp2\pi\{I(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n+I(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m\}\\
&\quad\times\sum_{k,l}g_k(-R(\boldsymbol{b}_h{}^s))g_l(-R(\boldsymbol{b}_g{}^s))P^{nm}_{kl}(R(\boldsymbol{b}_h{}^s),\ R(\boldsymbol{b}_g{}^s))\\
&\quad\times\exp\{-2\pi i(R(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n{}^k-R(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m{}^l)\}\,,
\end{aligned}\qquad\text{(A32)}$$

where $R(\boldsymbol{b})$ and $I(\boldsymbol{b})$ denote the real part and the imaginary part respectively of vector $\boldsymbol{b}=R(\boldsymbol{b})+iI(\boldsymbol{b})$. In Eqs. (A31) and (A32) $\sum_s$ and $\sum_{s,t}$ are removed because either of the pairs $\bar{\boldsymbol{D}}_0{}'$ and $\bar{\boldsymbol{D}}_G{}'$ or $\bar{\boldsymbol{D}}_0{}''$ and $\bar{\boldsymbol{D}}_G{}''$ are negligibly small in Bragg case if the crystal is thick enough and is not perfectly non-absorbing[13]. By the use of Eqs. (A31) and (A32) we have the following equation instead of Eq. (A14).

$$\begin{aligned}
\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\bar{\boldsymbol{e}}_{\perp,\parallel}|^2\rangle&=(e^2/mc^2)^2(\lambda^2/\pi)^2(1/|\bar{\boldsymbol{p}}|^2)\sum_{h,g}(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_g{}^{*s})\\
&\times\sum_{k,l}g_k(-\boldsymbol{b}_h)g_l(-\boldsymbol{b}_g)\sum_{n,m}\exp2\pi\{I(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n+I(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m\}P^{nm}_{kl}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)\\
&\times\exp\{-2\pi i(R(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n{}^k-R(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m{}^l)\}\,,
\end{aligned}\qquad\text{(A33)}$$

where $\boldsymbol{b}_h$ is a real mean vector defined in the text. By the help of Eq. (A17) the factor $\sum_{n,m}\exp2\pi\{\cdots\}P\cdots\exp\{-2\pi i\cdots\}$ in Eq. (A33) turns out to be

$$\begin{aligned}
&\sum_{n,m}\exp2\pi\{I(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n+I(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m\}P^{nm}_{kl}(\boldsymbol{b}_h,\ \boldsymbol{b}_g)\exp\{-2\pi i(R(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n{}^k-R(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m{}^l)\}\\
&\quad=(4\pi^2kT/N\sqrt{m_km_l})\sum_p(\boldsymbol{b}_h\cdot\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g)\sum_{n,m}\exp2\pi\{I(\boldsymbol{b}_h{}^s)\cdot\boldsymbol{r}_n+I(\boldsymbol{b}_g{}^s)\cdot\boldsymbol{r}_m\}\\
&\quad\times\exp\{2\pi i(\boldsymbol{\tau}_p-R(\boldsymbol{b}_h{}^s))\cdot\boldsymbol{n}\}\exp\{-2\pi i(\boldsymbol{\tau}_p-R(\boldsymbol{b}_g{}^s))\cdot\boldsymbol{m}\}\\
&\quad\times\exp\{-2\pi i(\boldsymbol{b}_h\cdot\boldsymbol{X}^k-\boldsymbol{b}_g\cdot\boldsymbol{X}^l)\}\exp\{-2\pi i(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{r}_0\}
\end{aligned}$$

$$
\begin{aligned}
&= (4\pi^2 kT/\sqrt{m_k m_l})\, v_a \int (\boldsymbol{b}_h\cdot\boldsymbol{\chi}_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g) \\
&\quad\times |\sum_n \exp\{2\pi i(\boldsymbol{\tau}_p-R(\boldsymbol{b}_0{}^s))\cdot\boldsymbol{n}\}\exp\{2\pi I(\boldsymbol{b}_0{}^s)\cdot\boldsymbol{r}_n\}|^2 d\boldsymbol{\tau}_p \\
&\quad\times \exp\{-2\pi i(\boldsymbol{b}_h\cdot\boldsymbol{X}^k-\boldsymbol{b}_g\cdot\boldsymbol{X}^l)\}\exp\{-2\pi i(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{r}_0\}\,,
\end{aligned}
\tag{A34}
$$

where the integration is over a unit cell of reciprocal lattice. In Eq. (A34) we use the approximation $\sum_p = Nv_a\int d\boldsymbol{\tau}_p$. Let us put

$$
\begin{aligned}
&\int (\boldsymbol{b}_h\cdot\chi_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g)|\sum_n \exp\{2\pi i(\boldsymbol{\tau}_p-R(\boldsymbol{b}_0{}^s))\cdot\boldsymbol{n}\}\exp\{2\pi I(\boldsymbol{b}_0{}^s)\cdot\boldsymbol{r}_n\}|^2 d\boldsymbol{\tau}_p \\
&\qquad = (A/N)\int (\boldsymbol{b}_n\cdot\chi_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g)|\sum_n \exp\{2\pi i(\boldsymbol{\tau}_p-R(\boldsymbol{b}_0{}^s))\cdot\boldsymbol{n}\}|^2 d\boldsymbol{\tau}_p\,.
\end{aligned}
\tag{A35}
$$

Then we have

$$
\int (\boldsymbol{b}_h\cdot\chi_{kl}(\boldsymbol{\tau}_p)\cdot\boldsymbol{b}_g)|\sum_n \exp\{2\pi i(\boldsymbol{\tau}_p-R(\boldsymbol{b}_0{}^s))\cdot\boldsymbol{n}\}\exp\{2\pi I(\boldsymbol{b}_0{}^s(\cdot\boldsymbol{r}_n\}|^2 d\boldsymbol{\tau}_p = (A/v_a)(\boldsymbol{b}_h\cdot\chi_{kl}(\boldsymbol{\tau})\cdot\boldsymbol{b}_g)\,,
\tag{A36}
$$

where $\tau-\boldsymbol{b}_0=-\boldsymbol{I}$. Although we can not give the factor A in any simpler expression than Eq. (A35), it can be seen from Eq. (A35) that the factor A has the properties mentioned near the end of § 3 of the text.

By the help of Eqs. (A33), (A34), (A35) and (19) we have

$$
\begin{aligned}
\langle|\boldsymbol{D}_2(\boldsymbol{r}_A)\cdot\bar{e}_{\perp,\parallel}|^2\rangle &= (e^2/mc^2)^2(\lambda^2/\pi)^2(1/|\boldsymbol{p}|^2) \\
&\quad\times\sum_{h,g}(\boldsymbol{E}_0\cdot\boldsymbol{D}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\boldsymbol{D}_g{}^{*t})\exp\{-2\pi i(\boldsymbol{h}-\boldsymbol{g})\cdot\boldsymbol{r}_0\}AkTS_{hg}\,.
\end{aligned}
\tag{A37}
$$

Let us next evaluate the magnitude of $\bar{\boldsymbol{D}}_h{}^s$ in the factor $(\boldsymbol{E}_0\cdot\bar{\boldsymbol{D}}_h{}^s)(\boldsymbol{E}_0{}^*\cdot\bar{\boldsymbol{D}}_g{}^s)$ in Eq. (A37). Eqs. (A26), (A27) and (A28) are also valid in Bragg case, while Eq. (A29) must be rewritten as follows.

(i) If $W<-1$, we have

$$
\begin{aligned}
&\bar{D}'_{0\perp,\parallel}=\bar{E}_0\,, \\
&\bar{D}'_{G\perp,\parallel}=\sqrt{|\gamma_0/\gamma_G|}\exp(-u)(F_G/|F_G|)\exp(2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)(C_{\perp,\parallel}/|C_{\perp,\parallel}|)\bar{E}_0
\end{aligned}
\tag{A38}
$$

and

$$
\bar{D}''_{0\perp,\parallel}=\bar{D}''_{G\perp,\parallel}=0\,,
$$

where $W=-\cosh u$ and $u>0$.

(ii) If $-1<W<1$, we have

$$
\begin{aligned}
&\bar{D}'_{0\perp,\parallel}=\bar{D}'_{G\perp,\parallel}=0\,, \\
&\bar{D}''_{0\perp,\parallel}=\bar{E}_0
\end{aligned}
\tag{A39}
$$

and

$$
\bar{D}''_{G\perp,\parallel}=-i\sqrt{|\gamma_0/\gamma_G|}\exp(-v)(F_G/|F_G|)\exp(2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)(C_{\perp,\parallel}/|C_{\perp,\parallel}|)\,\bar{E}_0
$$

where $W=\sin v$.

(iii) If $W>1$, we have

$$
\begin{aligned}
&\bar{D}'_{0\perp,\parallel}=\bar{D}'_{G\perp,\parallel}=0\,, \\
&\bar{D}''_{0\perp,\parallel}=\bar{E}_0
\end{aligned}
\tag{A40}
$$

and

$$
\bar{D}''_{G\perp,\parallel}=-\sqrt{|\gamma_0/\gamma_G|}\exp(-u)(F_G/|F_G|)\exp(2\pi i\boldsymbol{G}\cdot\boldsymbol{r}_0)(C_{\perp,\parallel}/|C_{\perp,\parallel}|)\,\bar{E}_0
$$

where $W=\cosh u$ and $u>0$.

Outside the region of total reflection, by the help of Eqs. (11), (12), (13), (14), (A37), (A38) and (A40), we have Eq. (30) of the text. Within the region of total reflection, by the help of Eqs. (11), (12), (13), (14), (A37) and (A39), we have Eq. (31) of the text.

Inelastic Scattering of Thermal Neutrons by Paramagnetic Ions

By Soichiro TOSIMA
Faculty of Science Kyusyu University

(Received July 9, 1960)

For the magnetic scattering of thermal neutrons by paramagnetic ions with discrete energy levels, Trammell's theory is extended to include the inelastic scattering. And the scattering cross section of Eu^{3+}, Sm^{3+}, Co^{2+} in oxide and fluoride and Fe^{2+} in oxide are estimated. In these ions, the cross sections appreciably include the inelastic parts, and depend on the temperature and the energy of the incident neutrons, that is, the cross sections suddenly increase when the energy of the neutron exceeds the level separations.

§ 1. Introduction

The orbital effect on the magnetic scattering of slow neutrons by the rare earth ions, has been discussed by Trammell[1], whose result has proved to explain some features in the magnetic scattering by Nd^{3+} and Er^{3+} [2]. Such an orbital effect is generally small in the iron group compounds, because the orbital angular momentum of the iron group ions is largely quenched by the crystalline field in compounds. On the other hand, in the compounds with the rare earth ion, the electrons in the incomplete 4f shell are deeply buried within the ion and less affected by the crystalline field. However, in some particular compounds, for example CoO and FeO, a large orbital angular momentum surviving under the cubic field brings out a large effect on the neutron diffraction, which Nagamiya and Motizuki[3] have discussed with particular reference to CoO.

These studies are principally concerned with the elastic scattering. But, in some ions, Eu^{3+}, Sm^{3+} on the one hand and Co^{2+}, Fe^{2+} in oxides on the other, the lowest excited level arising from the spin-orbit coupling is rather close to the ground level and the level separation is comparable with kT at room temperature and the energy of the neutrons used in the diffraction experiments. We may therefore expect an appreciable portion of neutrons inelastically scattered, which come from the two processes: the one in which the energy of the incident neutron decreases and the scattering ion goes to the higher energy state, and the other in which the energy of the neutron increases and the ion goes to the lower state. In the present work, we will extend Trammell's theory in order to include such processes of inelastic scattering by the magnetic ion with discrete energy levels.

The cross section of the magnetic scattering is roughly proportional to the square of the effective Bohr magneton number of the magnetic ion. It is, therefore, expected that the cross section has a considerable temperature dependence, because the effective Bohr magneton number of the ion concerned now depends on the temperature. The inelastic scattering process in which the ion goes to the higher energy state can take place only when the energy of the neutron is larger than the level separation, since the total energy of the ion and the neutron must be conserved. Therefore, it is also expected that the cross section increases when the energy of the neutron exceeds the level separation.

As is well-known, L, S and J of the magnetic ion are good quantum numbers in the Russell-Saunders scheme, where L and S are respectively the quantum number of the total oribital angular momentum $\boldsymbol{L}$ and that of the total spin angular momentum $\boldsymbol{S}$ and J the quantum number of $\boldsymbol{J}=\boldsymbol{L}+\boldsymbol{S}$. This scheme remains unaltered for the rare earth ions in compounds, and the situations are similar for Co^{2+} and Fe^{2+} in oxides. For, the orbital angular momentum $\boldsymbol{L}$ for these ions can be replaced by an effective orbital angular momentum $\boldsymbol{L}'$ with $L'=1$ within the lowest orbital manifold under the cubic field, and the spin-orbit coupling leads to the splitting of the energy levels according to the magnitude of effective total angular momentum $\boldsymbol{J}'=\boldsymbol{L}'+\boldsymbol{S}$. Thus, we shall calculate the magnetic scattering cross section of the rare earth ions, and the above-mentioned cases of the iron group ions will also be discussed.

§ 2. The Differential Cross Section of the Magnetic Scattering

Trammell[1) has derived the expression of the differential cross section of the magnetic scattering in the case when both the spin and the orbital angular momentum are operative, and the elastic scattering by the magnetic ions Nd^{3+} and Er^{3+} in the lowest state was calculated in his theory. We will extend his theory to include the transitions between the states with different J value. Now we denote the initial and final wave vectors of the neutron by k_0 and k, and the orbital and the spin angular momentum of the k-th electron in the incomplete shell by $\boldsymbol{l}_k$ and $\boldsymbol{s}_k$. Following his expression, we define the vector $\boldsymbol{P}$ by

$$\boldsymbol{P}=\sum_k\left[\tfrac{1}{2}(\boldsymbol{l}_k f(\boldsymbol{\kappa}\cdot\boldsymbol{r}_k)+f(\boldsymbol{\kappa}\cdot\boldsymbol{r}_k)\boldsymbol{l}_k)+2\boldsymbol{s}_k\exp(i\boldsymbol{\kappa}\cdot\boldsymbol{r}_k)\right], \tag{1}$$

where

$$f(\boldsymbol{\kappa}\cdot\boldsymbol{r})=\frac{1}{(i\boldsymbol{\kappa}\cdot\boldsymbol{r})^2}\int_0^{i\kappa\cdot\boldsymbol{r}}x\,e^x\,dx\ ,$$

$$\boldsymbol{\kappa}=\boldsymbol{k}-\boldsymbol{k}_0$$

For unpolarized incident neutron the differential cross section per magnetic ion, $d\sigma/d\Omega$, is given by

$$\frac{d\sigma}{d\Omega}=\left(\frac{e^2\gamma}{2mc^2}\right)^2\sum_m\sum_n\rho_m\frac{k}{2k_0}\{|(m\,|\,P_+\,|\,n)|^2+|(m\,|\,P_-\,|\,n)|^2\} \tag{2}$$

where γ is the nuclear magneton number of the neutron, ρ_m the statistical weight of the initial state m, $P_\pm=P_x\pm iP_y$, and the z-axis is chosen to be parallel to $\boldsymbol{\kappa}$.

In the Russell-Saunders scheme, the wave function Ψ_{JM} for n electrons in the incomplete shell is the taken to be of the from

$$\Psi_{JM}(\boldsymbol{r}_1,\boldsymbol{r}_2,\cdots,\boldsymbol{r}_n)=\Phi(r_1,r_2,\cdots,r_n)\,\Theta_{l,L,S,J,M},$$

where

$$\Phi(r_1,r_2\cdots,r_n)=\prod_{i=1}^n\varphi_{\alpha l}(r_i)$$

Θ_{lLSJM} is a function of angular and spin variables and $\varphi_{\alpha l}(r_i)$ a radial wave function of the i-th electron.

To calculate the matrix element $(J'\,M'\,|\,P_\pm\,|\,J\,M)$, it is convenient to expand $P_\pm$ in spherical harmonics, thus

$$P_\pm=\sum_{\nu=0}i^\nu(2\nu+1)\sum_k\{f_\nu(\kappa r_k)\tfrac{1}{2}[l_l{}^\pm p_\nu(\theta_k)+p_\nu(\theta_k)l_k{}^\pm]+2g_\nu(\kappa r_k)S_k{}^\pm P_\nu(\theta_k)\}\ , \tag{3}$$

$$g_\nu(x)=(\pi/2)^{1/2}x^{-1/2}\,J_{\nu+1/2}(x)\ ,$$

$$f_\nu(x)=2x^{-2}\int_0^x yg_\nu(y)dy\ ,$$

where θ_k is the angle between the vectors $\boldsymbol{\kappa}$ and $\boldsymbol{r}_k$.

In $(J'\,M'\,|\,P_\pm\,|\,J\,M)$, $g_\nu(\kappa r_k)$ and $f_\nu(\kappa r_k)$ become respectively

$$(\Phi(r_1,r_2,\cdots,r_n)\,|\,g_\nu(\kappa r_k)\,|\,\Phi(r_1,r_2,\cdots,r_n))=(\varphi_{\alpha l}(r_k)\,|\,g_\nu(\kappa r_k)\,|\,\varphi_{\alpha l}(r_k))=G_\nu(\kappa) \tag{4}$$

and

$$(\Phi(r_1, r_2, \cdots, r_n) \mid f_\nu(\kappa r_k) \mid \Phi(r_1, r_2, \cdots, r_n)) \\ =(\varphi_{\alpha l}(r_k) \mid f_\nu(\kappa r_k) \mid \varphi_{\alpha'}(r_k))=F_\nu(\kappa)\ , \qquad (5)$$

which have the same values for all n electrons. In practical calculations, $G_\nu(\kappa)$ and $F_\nu(\kappa)$ are approximated as follows. Expanding $g_\nu(\kappa r)$ in the power series of κr, we have

$$g_\nu(\kappa r)=\frac{2\cdot\nu\,!}{(2\nu+1)!}(\kappa r)^\nu\left(1-\frac{1}{4\nu+6}\kappa^2 r^2+\cdot\right)$$

by which (4) is written as

$$G_\nu(\kappa)=\frac{2\cdot\nu\,!}{2(\nu+1)!}\kappa^\nu\langle r^\nu\rangle\left(1-\frac{1}{4\nu+6}\frac{\langle r^{\nu+2}\rangle}{\langle r^\nu\rangle}\kappa^2+\cdot\right) \\ \doteqdot\frac{2\cdot\nu\,!}{(2\nu+1)!}\kappa^\nu\langle r^\nu\rangle\exp\left[-\frac{1}{4\nu+6}\frac{\langle r^{\nu+2}\rangle}{\langle r^\nu\rangle}\kappa^2\right], \qquad (6)$$

where $\langle r^\nu\rangle$ is defined by

$$\langle r^\nu\rangle=\int_0^\infty \phi_{\alpha l}{}^*\,\phi_{\alpha l}\,r^{\nu+2}dr\ .$$

Similarly

$$F_\nu(\kappa)=\frac{2}{\nu+2}\,\frac{2\cdot\nu\,!}{(2\nu+1)!}\kappa^\nu\langle r^\nu\rangle\exp\left[-\frac{1}{4\nu+6} \times\frac{\nu+2}{\nu+4}\,\frac{\langle r^{\nu+2}\rangle}{\langle r^\nu\rangle}\kappa^2\right]. \qquad (7)$$

The differential cross section has in general a larger value for smaller scattering angle, and those expressions are better approximations for smaller angle.

In order to calculate the angular parts involving the spherical harmonics in $(J'\,M' \mid P_\pm \mid J\,M)$, it is convenient to replace $P_\nu(\theta)$ by the equivalent tensor operator, In the shell with azimuthal quantum number l, the matrix elements of $P_\nu(\theta)$ with odd ν or $\nu>2l$ are zero, and $P_\nu(\theta)$ with even ν are replaced by the tensor operators as follows

$$P_0(\theta)=a_0\times 1=a_0 T_0(l)\ , \qquad (8)$$

$$P_2(\theta)=a_2\left(\frac{3}{2}l_z{}^2-\frac{1}{2}l(l+1)\right)=a_2 T_2{}^0(l)\ , \qquad (9)$$

$$P_4(\theta)=a_4\left(\frac{35}{8}l_z{}^4-\frac{30}{8}l(l+1)_z{}^2\frac{3}{8}l^2(l+1)^2 +\frac{25}{8}l_z{}^2-\frac{6}{8}l(l+1)\right)=a_4 T_4{}^0(l) \qquad (10)$$

and

$$P_6(\theta)=a_6\left(\frac{231}{16}l_z{}^6-\frac{315}{16}l(l+1)l_z{}^4+\frac{735}{16}l_z{}^4 +\frac{105}{16}l^2(l+1)^2 l_z{}^2-\frac{525}{16}l(l+)l_z{}^2+\frac{294}{16}l_z{}^2 -\frac{5}{16}l^3(l+1)^3+\frac{5}{2}l^2(l+1)^2-\frac{15}{4}l(l+1)\right) \\ =a_6 T_6{}^0(l)\ . \qquad (11)$$

The values of a_ν for d- and f-shell are given as follows;

	a_0	a_2	a_4	a_6
d-shell	1	$-2/21$	$-2/63$	
f-shell	1	$-2/45$	$2/495$	$-4/3861$

$P_\nu(\theta)$ with $\nu>4$ in d-shell and $\nu>6$ in f-shell do not appear in our expressions. The product of $T_\nu(l)$ and $l^\pm$ can be expanded in terms of following tensor operators

$$T_1{}^{\pm1}(l)=\frac{1}{\sqrt{2}}l^\pm\ ,$$

$$T_3{}^{\pm1}(l)=\frac{1}{\sqrt{12}}\left\{\frac{15}{4}(l^\pm l_z{}^2+l_z{}^2 l^\pm) -\frac{2}{3}l(l+1)l^\pm-\frac{3}{4}l^\pm\right\}$$

and

$$T_5{}^{\pm1}(l)=\frac{1}{\sqrt{30}}\left\{\frac{315}{16}(l^\pm l_z{}^4+l_z{}^4 l^\pm)-\frac{105}{8}l(l+1) \times(l^\pm l_z{}^2+l_z{}^2 l^\pm)+\frac{15}{8}l^2(l+1)^2 l^\pm -\frac{15}{8}l(l+1)l^\pm+\frac{45}{16}l^\pm\right\}.$$

Using these operators, we have

$$\frac{1}{2}(T_1{}^{\pm1}(l)T_\nu{}^0(l)+T_\nu{}^0(l)T_1{}^{\pm1}(l) \\ =b_\nu T_{\nu-1}{}^{\pm1}(l)+c_\nu T_{\nu+1}{}^{\pm1}(l) \qquad (12)$$

where

$$b_2=\frac{1}{5}\left(\frac{3}{4}-l(l+1)\right), \qquad c_0=1$$

$$b_4=\frac{\sqrt{6}}{9}\left(\frac{15}{4}-l(l+1)\right), \qquad c_2=\frac{\sqrt{6}}{5}$$

$$b_6=\frac{\sqrt{15}}{13}\left(\frac{35}{4}-l(l+1)\right), \qquad c_4=\frac{\sqrt{15}}{9}$$

By use of the relations (8), (9), (10), (11) and (12), $P_\pm$ can be expressed in terms of one-electron tensor operators. In the expression of $P_\pm$, $T_\nu{}^{\pm1}$ with $\nu>2l$ does not appear.

The orbital and spin angular momenta of n electrons are combined to form respectively the resultant total orbital angular momentum $\boldsymbol{L}$ and the total spin angular momentum $\boldsymbol{S}$. It is convenient therefore to rewrite the sum of one-electron tensor operators with respect to $\boldsymbol{L}$ and $\boldsymbol{S}$ as follows

$$\sum_k T_\nu{}^{\pm1}(l_k)=d_\nu T_{\nu\mp}{}^1(L) \qquad (13)$$

and

$$\sum T_1{}^{\pm1}(s_k)T_\nu{}^0(l_k)e_\nu T_1{}^{\pm1}(S)T_\nu{}^0(L)\ . \qquad (14)$$

The values of d_ν and e_ν for Eu^{3+}, Sm^{3+}, Co^{2+} and Fe^{2+}, are given as follows;

	d_1	d_3	d_5	e_0	e_2	e_4	e_6
Eu^{3+}	1	1	1	1	−1/6	−1/6	−1/6
Sm^{3+}	1	0	−1/14	1	−1/15	2/105	1/210
Co^{2+}	1	−1/5		1	−1/5	−1/15	
Fe^{2+}	1	−1		1	1/4	1/4	

By use of (13) and (14) $(J'\,M'\mid P_\pm\mid J\,M)$ is now expressed in terms of tensor operators. Namely

$$\begin{aligned}(J'\,M'\mid P_\pm\mid J\,M)=&\sum_{\mu=0}^{l-1}(-)^\mu\sqrt{2}\,[(4\mu+1)a_{2\mu}\,c_{2\mu}\,d_{2\mu+1}\,F_{2\mu}(\kappa)\\&-(4\mu+5)a_{2\mu+2}\,b_{2\mu+2}\,d_{2\mu+1}\,F_{2\mu+2}(\kappa)](J'\,M'\mid T_{2\mu+1}{}^{\pm1}(L)\mid J\,M)\\&+\sum_{\mu=0}^{l}(-)^\mu 2\sqrt{2}\,(4\mu+1)a_{2\mu}\,e_{2\mu}\,G_{2\mu}(\kappa)(J'\,M'\mid T_1{}^{\pm1}(S)T_{2\mu}{}^0(L)\mid J\,M)\,.\end{aligned}\tag{15}$$

The matrix elements of tensor operators are expressed in terms of the Clebsch-Gorsan coefficients $C(J,\,\nu,\,J';\,M,\,\pm1,\,M')$. From the Wigner-Eckart theorem, the following relations are obtained

$$(J'\,M'\mid T_\nu{}^{\pm1}(L)\mid J\,M)=(J'\,\|\,T_\nu(L)\,\|\,J)C(J,\,\nu,\,J';\,M,\pm1,\,M')\tag{16}$$

and

$$\begin{aligned}(J'\,M'\mid T_1{}^{\pm1}(S)T_\nu{}^0(L)\mid J\,M)&=\sum_{J''}\sum_{M''}(J'\,M'\mid T_1{}^{\pm1}(S)\mid J''\,M'')(J''\,M''\mid T_\nu{}^0(L)\,J\,M)\\&=\sum_{J''}\sum_{\mu}(J'\,\|\,T_1(S)\,\|\,J'')(J''\,\|\,T_\nu(L)\,\|\,J)[(2\mu+1)(2J''+1)]^{1/2}\\&\quad\times W(J\nu J'l;\,J''\,\mu)C(\nu,\,l,\,\mu;\,0,\,\pm1)C(J,\,\mu,\,M,\,\pm1,\,M')\,,\end{aligned}\tag{17}$$

where $W(J\nu J'l;\,J''\mu)$ is the Racah coefficient. The reduced matrix $(J'\,\|\,T_\nu\,\|\,J)$ is not hermitic. For simplicity, we introduce the following coefficient $K_{\mu,\pm}^{\nu}(J',\,J)$

$$\begin{aligned}K_{\mu,\pm}^{\nu}(J',\,J)=&\sum_{J''}(J'\,\|\,T_1(S)\,\|\,J'')(J''\,\|\,T_\nu(L)\,\|\,J)\times[(2\mu+1)(2J''+1)]^{1/2}\\&\times W(J\,\nu\,J'\,l;\,J''\,\mu)C(\nu\,l\,\mu;\,0,\,\pm1).\end{aligned}\tag{18}$$

$K_{\mu,\pm}^{\nu}(J',\,J)$ does not vanish only when two sets of the numbers $\mu,\,l,\,\nu$ and $J',\,\mu,\,J$ respectively from the trigonal relations $\Delta(\mu,\,l,\,\nu)$ and $\Delta(J',\,\mu,\,J)$. And we can easily verify the following relations

$$K_{\nu\pm1,+}^{\nu}(J',\,J)=K_{\nu\pm1,-}^{\nu}(J',\,J)$$

and

$$K_{\nu,+}^{\nu}(J'\,J)=-K_{\nu,-}^{\nu}(J'\,J)$$

Inserting (16) and (17) into (15) and using (18), we obtain

$$\begin{aligned}(J'\,M'\mid P_\pm\mid J\,M)=&\sqrt{2}\sum_{\mu}(-)^\mu F_{2\mu+1}^{\pm}(J'\,J;\,\kappa)C(J,\,2\mu+1,\,J';\,M,\,\pm1,\,M)\\&+\sqrt{2}\sum_{\mu}(-)^\mu F_{2\mu}^{\pm}(J'\,J;\,\kappa)C(J,\,2\mu,\,J';\,M,\,\pm1,\,M')\end{aligned}\tag{19}$$

where

$$\begin{aligned}F_{2\mu+1}{}^{\pm}(J',\,J;\,\kappa)=&\{(4\mu+1)a_{2\mu}\,c_{2\mu}\,d_{2\mu+1}\,F_{2\mu}(\kappa)\\&-(4\mu+5)a_{2\mu+2}\,b_{2\mu+2}\,d_{2\mu+1}\,F_{2\mu+2}(\kappa)\}(J'\,\|\,T_{2\mu+1}(L)\,\|\,J)\\&+2(4\mu+1)a_{2\mu}\,e_{2\mu}\,K_{2\mu+1,\pm}^{2\mu}(J'\,J)G_{2\mu}(\kappa)\\&-2(4\mu+5)a_{2\mu+2}\,e_{2\mu+2}K_{2\mu+1,\pm}^{2\mu+2}(J'\,J)G_{2\mu+2}(\kappa)\end{aligned}\tag{20a}$$

and

$$F_{2\mu}{}^{\pm}(J'\,J;\,\kappa)=2(4\mu+1)a_{2\mu}\,e_{2\mu}K^{2\mu}_{2\mu,\pm}(J'\,J)G_{2\mu}(\kappa)\,. \tag{20b}$$

Among F_ν and G_ν, F_0 and G_0 principally contribute to the scattering amplitude. In the elastic scattering the amplitude is approximately proportional to

$$(J\,||\,T_1(L)\,||\,J)F_0(\kappa)+2K^{0}_{1,\pm}(J',J)G_0(\kappa)=(J\,||\,T_1(L)\,||\,J)F_0(\kappa)+2(J\,||\,T_1(S)\,||\,J)G_0(\kappa)$$

and the ratio x of these two reduced matrices is

$$x=\frac{(J\,||\,T_1(S)\,||\,J)}{(J\,||\,T_1(L)\,||\,J)}=\frac{S(S+1)-L(L+1)+J(J+1)}{L(L+1)-S(S+1)+J(J+1)}\,.$$

For $J=L+S$

$$x=\frac{S}{L}>0$$

and for $J=|L-S|$

$$\begin{aligned} x&=-\frac{S}{L+1}<0 &\qquad &\text{for}\quad L>S\\ &=-\frac{S+1}{L}<0 &\qquad &\text{for}\quad L<S \end{aligned}$$

Therefore, in the ion with more than half-filled shell, the amplitude of the elastic scattering by the ion in the lowest state is approximately proportional to the sum of the orbital and spin contributions, because $J=L+S$ in the lowest state. On the other hand, in the case of the ion with less than half-filled shell, the scattering amplitude is approximately proportional to the difference of the orbital and spin contributions, because $J=|L-S|$ in this case.

Inserting (19) into (2), we have the final expression of the differential cross section

$$\frac{d\sigma}{d\Omega}=\left(\frac{e^2\gamma}{2mC^2}\right)^2\sum_J\sum_{J'}\frac{k}{k_0}(-)^{J'-J}\sqrt{(2J'+1)(2J+1)}\times\sum_\nu\frac{2}{(2\nu+1)}\times F_\nu{}^{+}(J,J';\,\kappa)F_\nu{}^{-}(J'\,J;\,\kappa)\,, \tag{21}$$

with the help of the orthogonal property of the Clebsch-Gordan coefficients

$$\sum_M\sum_{M'}C(J,n,J';\,M,\pm1,M')C(J',n,J;\,M'\mp1,M)=(-)^{J'-J}\frac{1}{2n+1}\sqrt{2(J'+1)(2J+1)}\,\delta_{nn'}\,.$$

In the next section, the magnetic scatterings by various ions with discrete levels are discussed by use of the above expression.

§ 3. The Scattering Cross Sections of Eu^{3+}, Sm^{3+}, Co^{2+} in Oxide and Fluoride and Fe^{2+} in Oxide

The level separations of Eu^{3+}, Sm^{3+}, Co^{2+} in oxide and fluoride and Fe^{2+} in oxide are known to be of the same order of magnitude of kT at room temperature. So we estimate the cross section of the paramagnetic diffuse scattering by these ions.

1) *The rare earth ions* Eu^{3+} *and* Sm^{3+}

In these ions the interactions between the ions and the crystalline fields may be neglected approximately. Then (21) may be applicable in these cases.

The radial wave function $\varphi_{4f}(r)$ is approximated by the hydrogen-like wave function with shielding constant σ of the nuclear charge. Van Vleck[4] has assumed σ to be 34 in order to explain the magnetic susceptibility, and put the numerical value of the spin-orbit coupling parameter λ to be 255 cm^{-1} for Eu^{3+} and 266 cm^{-1} for Sm^{3+}. On the other hand, Gobrecht[5] has found λ to be 355 cm^{-1} and σ to be 32 for Eu^{3+} from the spectroscopic data of $Eu_2(SO_4)_3 8H_2O$.

(a) Eu^{3+} ($L=3$, $S=3$)

The level separations are given bp $E_{J+1}-E_J=(J+1)\lambda$. And the functions $F_\nu^{\pm}(J', J; \kappa)$ for the lowest three states are

$$F_1^{\pm}=(J' \| T_1(L) \| J)(F_0-\frac{1}{2}F_2+A_1^0G_0+A_1^2G_2)\ ,^*$$

$$F_2^{\pm}=(J' \| T_2(L) \|)A_2^2G_2$$

$$F_3^{\pm}=(J' \| T_3(L) \| J)\left(-\frac{2\sqrt{6}}{45}F_2+\frac{\sqrt{6}}{30}F_4+A_3^2G_2+A_3^4G_4\right),$$

where

$$A_1^0=2K_{1,\pm}^{0}/(J' \| T_1 \| J)\ , \qquad A_1^2=-2K_{1,\pm}^{2}/27(J \| T_1 \| J)\ ,$$

$$A_2^2=\mp 2K_{2,\pm}^{2}/(J' \| T_2 \| J)\ , \qquad A_3^2=2K_{3,\pm}^{2}/27(J' \| T_3 \| J)$$

and

$$A_3^4=2K_{3,\pm}^{4}/165(J' \| T_3 \| J)\ .$$

Table I. Coefficients $A_\mu^\nu(J', J)$ for the $J'=0$, 1, 2. $A_\mu^\nu(J', J)$ is symmetric with respect to J and J'. And we define $A_\mu^\nu(J', J)$ to be zero unless the trigonal relations $\Delta(\mu, l, \nu)$ and $\Delta(J', \mu, J)$ be formed.

J'	J	A_1^0	A_1^2	A_2^2	A_3^2	A_3^4
1	0	−2	−0.1667	0	0	0
1	1	2	−0.1333	0	0	0
2	1	−2	−0.5	0.0435	−0.0447	0.0272
2	2	2	−2	0	−0.0163	0.0408

The coefficients $A_\mu^\nu(J', J)$ are tabulated in Table I.

Using these values we can estimate the numerical values of the differential and the total cross sections. The differential cross section, $d\sigma/d\Omega$, monotonously decreases with increasing scattering angle θ as is usual in the paramagnetic scattering. The temperature dependence of $d\sigma/d\Omega$ is shown in Fig. 1, where the wave length of the incident neutron has been taken to be 1.212A. At 300°K, the estimated values of the elastic, inelastic part and the sum of both parts of the total cross section σ are respectively 0.43, 0.74 and 1.17 barns for $\lambda=255\ cm^{-1}$, and 0.36, 0.66 and 1.02 barns for $\lambda=335\ cm^{-1}$. And the elastic, inelastic part and the sum of these parts of the differential cross section $d\sigma/d\Omega(\theta=0)$ are 0.13, 0.27 0.40 barns per steradian for $\lambda=255\ cm^{-1}$, and 0.10, 0.25 and 0.35 barns per steradian for $\lambda=335\ cm^{-1}$. The numerical value of $d\sigma/d\Omega$ in the unit of $2/3(e^2\gamma/2mc^2)^2$ correspond to the square of the effective Bohr magneton number μ_{eff}. For comparison, the curve μ_{eff}^2 vs T is also shown in Fig. 1.

$d\sigma/d\Omega$ and σ depend on the energy ε of the incident neutron, as are shown respectively in Fig. 2 and 3. They suddenly increase when ε exceeds the level separations as were expected previously.

(b) Sm^{3+} ($L=5$, $S=5/2$)

μ_{eff} of Sm^{3+} is about 1/2~1/3 of that of

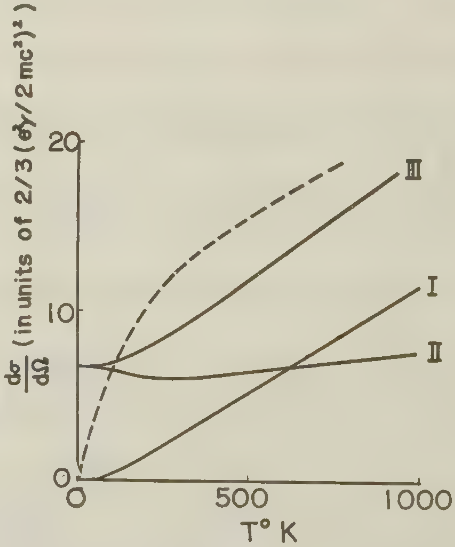

Fig. 1. Temperature dependence of the foreward scattering cross section per ion for $\lambda=255\ cm^{-1}$. Curves I, II and III represent respectively elastic part, inelastic part and the sum of them. The dotted curve represents μ_{eff}^2, where μ_{eff} has been calculated by Van Vleck[4].

---

* The coefficient of F_2 in $F_1^{\pm}$ (J', J) is exactly equal to 1/2 for any ion of the rare earth group. But it is 10.4/20.9 for Er^{3+}, and 8.3/16.3 for Nd^{3+} in Trammell's paper. These are not exact though the numerical values of the cross sections are not affected practically.

Eu^{3+} except at very low temperature, and the cross section is much smaller than that of Eu^{3+}.

2) Co^{2+} *and* Fe^{2+} *in oxide*

Magentic susceptibilities of CoO and FeO have been discussed by Kanamori[6]. According to his theory, L is replaced by $\alpha L'(L'=1; \alpha=-3/2$ for Co^{2+}, and -1 for Fe^{2+}) in the lowest orbital triplet, and the tensor operators are, therefore, replaced by

$$T_1^{\pm1}(L)=-3/2T_1^{\pm1}(L'),$$
$$T_3^{\pm1}(L)=15\sqrt{3}/2\sqrt{2}\,T_1^{\pm1}(L),$$
$$T_2^0(L)=6T_2^0(L)$$

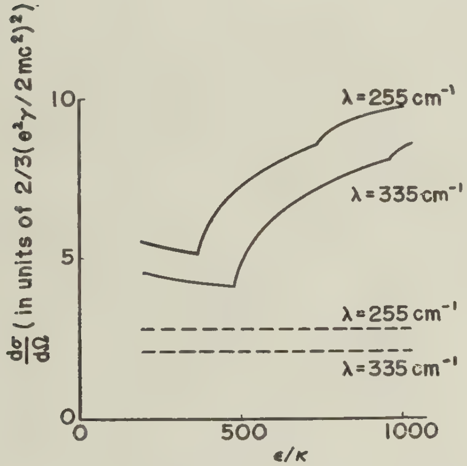

Fig. 2. Dependence of the foreward scattering cross section on the energy ε of the incident neutron. The dotted curve represents the elastic part.

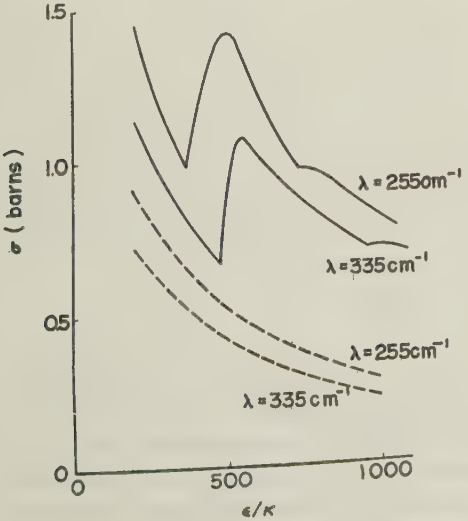

Fig. 3. Variation with ε of the total cross section.

and

$$T_4^0(L)=105/4T_0^0(L')-35/2T_2^0(L')$$

for Co^{2+}. And

$$T_1^{\pm1}(L)=-T_1^{\pm1}(L'),$$
$$T_3^{\pm1}(L)=-3\sqrt{6}/2T_1^{\pm1}(L),$$
$$T_2^0(L)=-3T_2^0(L')$$

and

$$T_4^0(L)=-9/2T_0^0(L')-3T_2^0(L')$$

for Fe^{2+}. The level separations are

$$E_{3/2}-E_{1/2}=405\,\text{cm}^{-1},$$
$$E_{5/2}-E_{3/2}-675\,\text{cm}^{-1}$$

for Co^{2+}, and

$$E_2-E_1=200\,\text{cm}^{-1}$$
$$E_4-E_2=300\,\text{cm}^{-1}$$

In Nagamiya and Motizuki's theory which has discussed the coherent scattering by CoO, the form factor has been calculated by use of the wave functions calculated by Slater[7] and Ariyama et al.[8] On the other hand, the form factor of Co^{2+} in CoF_2 in which the orbital angular momentum is largely quenched has been found experimentally by Erickson[9]. At present, we use the hydrogen-like wave function with shielding constant $\sigma=18.3$, by which we can approximately fit $G_0(\kappa)$ to the form factors by Erickson. The same wave function is approximately used in FeO.

We are not concerned with the short range order effect occuring from the exchange interaction, though the effect is appreciable near room temperature.

(c) Co^{2+} $(L'=1,\ S=3/2)$

The functions $F_\nu^{\pm}(J',\ J)$ for Co^{2+} are

$$F_1^{\pm}=-\frac{3}{2}\left(F_0-\frac{5}{14}F_2-\frac{3}{14}F_4\right)(J'\,||\,T_1(L)\,||\,J)$$
$$+(2G_0-G_4)K_{1,\pm}^{0}(J'\,J)$$
$$-\left(\frac{8}{7}G_2-\frac{2}{3}G_4\right)K_{1,\pm}^{2}(J',J),$$
$$F_2^{\pm}=\left(\frac{8}{7}G_2-\frac{2}{3}G_4\right)K_{2,\pm}^{2}(J'\,J)$$

and

$$F_3^{\pm}=\left(\frac{8}{7}G_2-\frac{2}{3}G_4\right)K_{3,\pm}^{2}(J'\,J)$$

$(J'\,||\,T_4(L')\,||\,J)$ and $K_{\mu,\pm}^{\nu}(J',\ J)$ are tabulated in Table II.

The temperature dependedce of the foreward scattering cross section is shown in Fig. 4. In

Table II. $(J' \| T_1(L') \| J)$ and $K^{\nu}_{\mu,\pm}(J', J)$

J'	J	$(J' \| T_2 \| J)$	$K^{0}_{,1\pm}(J', J)$	$K^{2}_{1,\pm}(J', J)$	$K^{2}_{2\ -}(J', J)$	$K^{2}_{2,\pm}(J', J)$
1/2	1/2	$-1/\sqrt{3}$	$5/2\sqrt{3}$	$-1/4\sqrt{3}$	0	0
3/2	3/2	$2/\sqrt{15}$	$11/2\sqrt{15}$	$17/10\sqrt{15}$	0	$-3\sqrt{14}/5\sqrt{15}$
5/2	5/2	$\sqrt{7}/\sqrt{5}$	$3\sqrt{7}/2\sqrt{5}$	$-3\sqrt{7}/20\sqrt{5}$	0	$9\sqrt{7}/10\sqrt{5}$
3/2	1/2	$\sqrt{5}/\sqrt{6}$	$-\sqrt{5}/\sqrt{6}$	$13\sqrt{5}/40\sqrt{6}$	$-\sqrt{6}/16$	0
1/2	3/2	$-\sqrt{5}/\sqrt{3}$	$\sqrt{5}/\sqrt{3}$	$-13\sqrt{5}/40\sqrt{3}$	$-\sqrt{3}/8$	0
3/2	5/2	$\sqrt{3}/\sqrt{5}$	$-\sqrt{3}/\sqrt{5}$	$-11\sqrt{3}/40\sqrt{5}$	$\sqrt{35}/8$	$4\sqrt{7}/5\sqrt{5}$
5/2	3/2	$-3/\sqrt{10}$	$3/\sqrt{10}$	$33/40\sqrt{10}$	$\sqrt{105}/8\sqrt{2}$	$-2\sqrt{42}/5\sqrt{5}$

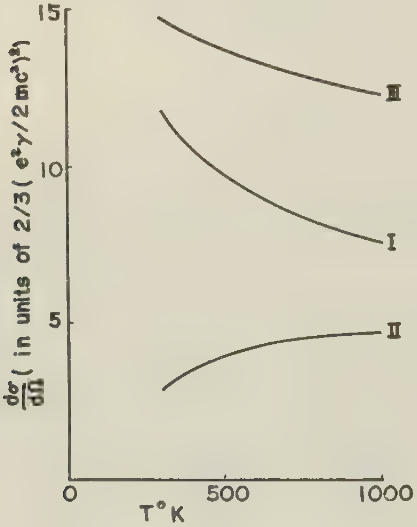

Fig. 4. Temperature pependence of the foreward scattering cross section. Curves I, II and III respectively elastic part, inelastsc part and the sum of them. The wave length of the incident neutron is taken to be 1.212A.

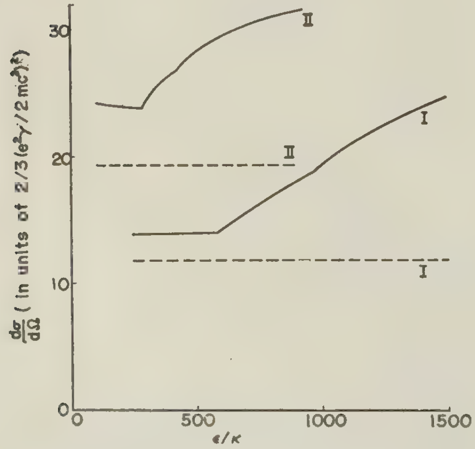

Fig. 5. Variation with ε of the foreward scattering cross sections for Co²⁺ (I) and for Fe²⁺ (II) at T=300°K. The dotted curves represent the elastic parts.

Fig. 5, ε-dependence of $d\sigma/d\Omega$ is shown, and the qualitative behaviour is similar to that of Eu^{3+}.

When the wave length of the neutron is taken to be 1.212A and T=300°K, the elastic and the inelastic parts are estimated respectively 0.56 and 0.14 barns per steradian for the foreward scattering cross section and 0.48 and 0.16 barns for the total cross section.

(d) Fe^{2+} ($L'=1$, $S=2$)

The functions $F_{\nu}^{\pm}(J', J)$ for Fe^{2+} are

$$F_1^{\pm}=-\left(F_0-\frac{19}{14}F_2+\frac{9}{14}F_4\right)(J' \| T_1(L') \| J)$$

$$+\left(2G_0-\frac{9}{14}G_4\right)K^{0}_{1,\pm}(J', J)$$

$$=\left(\frac{5}{7}G_2+\frac{2}{7}G_4\right)K^{2}_{1,\pm}(J'\ J)\ ,$$

$$F_2^{\pm}=\left(\frac{5}{7}G_2+\frac{2}{7}G_4\right)K^{2}_{2,\pm}(J'\ J)$$

and

$$F_3^{\pm}+\left(\frac{5}{7}G_2+\frac{2}{7}G_4\right)K^{2}_{3,\pm}(J'\ J)$$

$(J' \| T_1(L') \| J)$ and $K^{\nu}_{\mu,\pm}(J'\ J)$ are tabulated Table III.

In the same situation as Co^{2+}, the elastic and the inelastic parts are estimated respectively to be 0.92 and 0.50 barns per steradian for the foreward cross section and 0.70 and 0.39 barns for the total cross section. ε-dependence of cross section is similar to the former cases as is shown in Fig. 5.

3) CoF_2

The lowest orbital state of Co^{2+} in the crystalline field with lower symmetry than cubic is nondegenerate. But the orbital angular momentum contributes to the magnetic moment to some extent via spin-orbit coupling, and $\boldsymbol{L}$ is replaced in the perturbation treatment, by

$$\boldsymbol{L}=\boldsymbol{a}\cdot\boldsymbol{S}$$

Table III. $(J' \| T_1(L) \| J)$ and $K_{\mu,\pm}^{\nu}(J', J)$

J'	J	$(J' \| T_1 \| J)$	$K_{1,\pm}^{0}(J', J)$	$K_{1,\pm}^{2}(J', J)$	$K_{2,-}^{2}(J', J)$	$K_{3,\pm}^{2}(J', J)$
1	1	$-1/\sqrt{2}$	$3/\sqrt{2}$	$-3/10\sqrt{2}$	0	0
2	2	$1/\sqrt{6}$	$5/\sqrt{6}$	$13/10\sqrt{6}$	0	$-\sqrt{21}/5$
3	3	$2/\sqrt{3}$	$4/\sqrt{3}$	$-2/5\sqrt{3}$	0	$6/5$
2	1	$3/\sqrt{10}$	$-3/\sqrt{10}$	$6/5\sqrt{10}$	$-\sqrt{3}/2\sqrt{10}$	$-\sqrt{21}/5\sqrt{10}$
1	2	$-3/\sqrt{2}$	$3/\sqrt{2}$	$-2\sqrt{3}/5\sqrt{2}$	$-1/2\sqrt{2}$	$\sqrt{7}/5\sqrt{2}$
3	2	$\sqrt{2}/\sqrt{3}$	$-\sqrt{2}/\sqrt{3}$	$-7\sqrt{2}/20\sqrt{3}$	$\sqrt{3}/2$	$6/5$
2	3	$-\sqrt{14}/\sqrt{15}$	$\sqrt{14}/\sqrt{15}$	$7\sqrt{14}/20\sqrt{15}$	$3\sqrt{7}/2\sqrt{15}$	$-6\sqrt{7}/5\sqrt{5}$

where $\boldsymbol{\alpha}$ is a tensor. CoF_2 belongs to this case. In order to explain the magnetic susceptibility Nakamura and Taketa (hereafter refered to as $N-T$)[10] estimated the components of $\boldsymbol{\alpha}$ to be

$$\alpha_{xx}=0.48$$

$$\alpha_{yy}=0.62$$

$$\alpha_{zz}=0.06$$

choosing the principal axes properly.

The energy levels split into low lying two Kramers doublets and higher ones. The separation between the lowest two doublets has been estimated to be 130 k by $N-T$ or 240 k by Stout and Catalano[11]. We assume that the separation is 240 k though the results are not very dependent on the choice of the value. Using the matrix elements of the spin angular momentum estimated by $N-T$, we can estimate the cross section, we may neglect F_2, G_2, F_4 and G_4 because the contributions of these terms to the cross section are much smaller than that of F_0 and G_0 unless the wave length of the incident neutron is very short.

When the wave length of the neutron is taken to be 1.212A and $T=300°$K. The foreward scattering cross section is estimated to be 0.98 barns per steradian, which is about 25 percent larger than the observed one[9]. Unlike the background due to the nuclear scattering the magnetic scattering is larger for smaller scattering angle. The observed value is obtained from the the extrapolation of the measurements at large angles to $\theta=0$, since the short range order effect is appreciable. Therefore, the observed value may not be accurate. On the other hand, the coherent scattering is in satisfactory agreement with the one calculated from $N-T$'s theory. The elastic and the inelastic parts are respectively 0.65 and 0.33 barns per steradian. The elastic part decreases slightly with increasing temperature, while the inelastic part increases. Then, the sum of them is nearly constant except at low temperatures. But they depend on ε as in the former cases though the increase when ε exceeds 240 k is not so remarkable as in the case of Eu^{3+}.

§ 4. Conclusion

In the case when the level separations of the magnetic ions are comparable with kT at room temperature, we have extended Trammell's theory to include the inelastic scattering, and estimated the scattering cross sections by the ions, Eu^{3+}, Sm^{3+}, Co^{2+} in oxide and fluoride and Fe^{2+} in oxide as the function of the temperature and the energy of the incident neutron. For these ions the inelastic parts of the cross sections are appreciable, and the cross sections depend on the energy of the incident neutron as were expected previously. If the increase of the cross section when ε exceeds the level separations is observed, we may detected the level separations, though they may be more or less affected by the crystalline field for the rare earth ions or the exchange interaction and the effect of the crystal distortion for CoO and FeO. The cross section, more or less, depends on the temperature, but the aspect of this dependence is different for different ions. Unfortunately, we have no experimental data to compare with our results for Eu^{3+}, Co^{2+} in CoO and Fe^{2+} in FeO.

In magnetically ordered state, the spin can change its orientation during the collision if the Curie point is not so high, since the work required to change the spin state is approximately equal to zJ where J is the exchange integral and z the number of the nearest neighbours,and is comparable with energy of the neutron. Therefore, we may expect the inelastic scattering which comes from such a transition. The contribution of the transition to the inelastic scattering is given by $(e^2\gamma F/mc^2)^2\times 2S(1+(\boldsymbol{e}\cdot\boldsymbol{\kappa})^2)$, where F is the form factor and $\boldsymbol{e}$ and $\boldsymbol{\kappa}$ are the unit vectors parallel to the scattering and magnetic vectors, respectively. Magnetic scattering by MnO, FeO, CoO and NiO at low temperature has been observed by Roth[12], and an appreciable diffuse scattering has been observed. Above mentioned transition may contribute to the diffuse scattering, because kT_N of these crystals are smaller than the energy of neutron used in his experiment.

The author wishes to express his sincere thanks to Dr. T. Nakumura for suggesting this problem and for his valuable discussions.

Time Decrease of Magnetic Permeability in Some Mixed Ferrites

By Keizo OHTA

Kobayashi Institute of Physical Research, Kokubunji, Tokyo

(Received July 30, 1960)

The time decrease of the magnetic permeability after demagnetization, or disaccomodation, was measured for Mn-Zn, Ni-Zn, Cu-Zn and Mg-Zn ceramic ferrites. Considerable disaccomodation was observed with samples containing Fe_2O_3 over the stoichiometric composition. In the case of Mg-Zn ferrites, the disaccomodation is remarkable on both sides of the stoichiometric composition, where it is fairly small. For the specimens sintered in air, the disaccomodation is larger for higher electrical-conductive specimens, while such a correlation to the conductivity disappeared after the specimens were annealed in the nitrogen atmosphere. A single crystal of Ni-Zn ferrite, which is supposed to contain a very small amount of vacancies, also shows a very small disaccomodation. The activation energy determined from the disaccomodation measurements is about 0.5–0.8 eV for Mg-Zn ferrites. It is suggested that the displacement of either vacancies or interstitial ions may possibly be a main origin of the phenomenon.

§1. Introduction

It is normally observed that the magnetic permeability of ferromagnetic materials decreases with time after demagnetization. This phenomenon is termed the *disaccomodation*. The disaccomodation in ferrite was first observed with a Mn-Zn ferrite by Snoek[1] in 1947. He suggested that the electron displacement between divalent and trivalent iron ions in ferrite would be the cause of this phenomenon, just as the diffusion of interstitial carbon or nitrogen atoms was as the cause for the disaccomodation in alpha-iron. Further investigations were made by Enz[2] for a single crystal of Mn-Fe ferrite and by Miyahara and Yamadaya[3] and by Shichijo *et al.*[4] for Mn-Zn ceramic ferrites.

Theory of the *magnetic after-effect*, which is closely related to the disaccomadation, was first proposed by Snoek[5] and then revised by Néel[6],[7],[8], who assumed that the time change in anisotropy energy due to the rearrangement of atom pairs through the diffusion of atoms is the main origin of the magnetic after-effect. The change in anisotropy energy could also be the origin of the disaccomodation. In the case of alpha-iron, the main origin is considered to be the movement of either carbon or nitrogen atoms between different interstitial lattice sites. A similar effect was also proposed for magnetic alloy, where the different sorts of atoms changes their positions substitutionally among the lattice sites. In the case of ferrites, two possibilities can be considered as the origin of the disaccomodation, i.e. the diffusion of electrons between divalent and trivalent iron ions as proposed by Snoek[1], and the diffusion of ions themselves in or among various sites of spinel lattice.

The present author[9] has studied on the disaccomodation of Ni-Zn ferrites, and clarified that the disaccomodation is observed only in the specimens containing excessive iron ions than the content of stoichiometric ferrite, and it becomes remarkable as the content of iron increases. The same result was observed for the time decrease of the permeability after an application of the mechanical compression on the same specimens.

In this paper, the results of the disaccomodation measurements are reported for various mixed ferrite series, such as ceramic Mn-Zn, Ni-Zn, Mg-Zn and Cu-Zn ferrites. The experiment has also been made by using a single crystal of Ni-Zn ferrite.

§ 2. Preparation of Specimens and the Procedure of Measurement

Ceramic ferrites tested were prepared by an ordinary ceramic technique; The mixtures of metal oxides such as Fe_2O_3, CuO, MgO, ZnO, NiO, and or carbonate $MnCO_3$ were baked at 1000°C for two hours, crushed down to fine powders, and then compressed into toroidal forms. They were sintered in the air for two hours at 1250°C for Cu-Zn ferrites, at 1350°C for Ni-Zn and Mn-Zn ferrites, and at 1400°C for Mg-Zn ferrites, and after cooled down to 1000°C, they were rapidly cooled in the air. The specimens prepared were of a ring form, about 25 mm in outer diameter, 20 mm in inner diameter, and 5 mm in thickness. The compositions of the specimens are in the range of $58Ni_{0.4}Zn_{0.6}O$-$42Fe_2O_3$ to $40Ni_{0.4}Zn_{0.6}O$-$60Fe_2O_3$ for Ni-Zn ferrites, and in the range of $58M_{0.6}Zn_{0.4}O$-$42Fe_2O_3$ to $35M_{0.6}Zn_{0.4}O$-$65Fe_2O_3$ for other ferrites, where M represents divalent metal ions such as Mn, Mg or Cu.

A single crystal of Ni-Zn ferrite was grown from the melt by the Bridgeman method. The furnace used for this purpose was similar of Smilten's[10] one. A plutinum crucible containing the raw material was suspended in the furnace, which was held at 1700°C with the temperature gradient of 30°C per cm along its vertical axis, and then lowered down at the rate of 10 mm per hour. A picture frame toroid was cut out from the (110) single crystal plate, by the aid of an ultrasonic vibrating cutter. Each of the four legs of the frame is parallel to one of the ⟨111⟩ directions. The length of each legs is 4.3 mm and its thickness is 2 mm. The composition of this frame specimen was $40Ni_{0.4}Zn_{0.6}O$-$60Fe_2O_3$. All specimens are ascertained to be single phase of spinel structure, except some of the specimens with highest iron content.

Measurements of the permeability were carried out by A.C. bridge method. The specimens were first demagnetized by decreasing

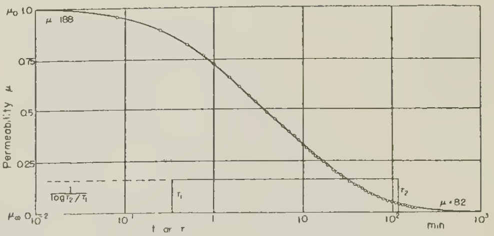

Fig. 1. Typical example of the disaccomodation curves. The specimen is $40Mg_{0.6}Zn_{0.4}O$-$60Fe_2O_3$. The measuring temperature is −10°C. The amplitude of measuring A.C. field, H_m is 10 m Oe.

the amplitude of 50 c.p.s. field from 10 Oe, and then exposed to 1 kc field with the amplitude smaller than 0.05 Oe for the permeability measurements.

A typical example of the time-decrease of permeability is shown as a function of the logarithm of the time *t*, in Fig. 1. The solid curve represents the function proposed by Richter[11]:

$$\psi(t)=\frac{1}{\log \tau_2/\tau_1}\int_{\tau_1}^{\tau_2}\frac{1}{\tau}\exp\left(-\frac{t}{\tau}\right)d\tau\ ,$$

where τ is the relaxation time in a unit process of changing permeability, and τ_1 and τ_2 are, respectively, the lower and upper limits of the assumed flat distribution of τ. The value of τ_1 and τ_2 in Fig. 1 are chosen to get the best fit between theory and experiment. In some cases only a linear portion of the curve of this type was observed, depending upon the measuring temperature. In order to measure the magnitude of the disaccomodation, we adopted the quantity $D=(\mu_{0.1}-\mu_{10})/\mu_{0.1}$, where $\mu_{0.1}$ and μ_{10} are the permeabilities at 0.1 and 10 minutes after demagnetization, respectively.

The electrical conductivity was also measured for the specimens at room temperature by means of the two-point-contact method with D.C. bridge using indium amalgum as a electrode as used by Uitert[12]. The measurements were extended to low temperatures for some specimens in order to determine the activation energies.

§ 3. Experimental Results and Discussions

3.1. *Effect of the Fe_2O_3 content on the disaccomodation*

It has been found that the disaccomodation is very sensitive to the content of Fe_2O_3 for all kinds of ferrites tested. In Fig. 2a) to d), the disaccomodation, *D*, at room temperature are shown as a function of the Fe_2O_3 content. It is seen in these graphs that the disaccomodation is remarkable for specimens containing an excessive Fe_2O_3 (more than 50 mol %), while it is very small for specimens containing a deficient Fe_2O_3 (less than 50 mol %), except for Mg-Zn ferrites which show a fairly large disaccomodation for iron-deficient region.

Electrical resistivities, ρ, of Ni-Zn and Mg-Zn ferrites at room temperature are given as a function of the Fe_2O_3 content in Fig. 3a) and b). The resistivity decreases with an increase of the Fe_2O_3 content, which is in agreement with the measurements by Uitert[12]. This fact looks like to support an idea that

(d)

Fig. 2. Disaccomodation as dependent of the Fe_2O_3 content in several ferrite series;

(a) $Ni_{0.4}Zn_{0.6}O$-Fe_2O_3 sintered at 1350°C; and annealed in nitrogen atmosphere at 1250°C,
(b) $Mn_{0.6}Zn_{0.4}O$-Fe_2O_3 sintered at 1350°C,
(c) $Cu_{0.6}Zn_{0.4}O$-Fe_2O_3 sintered at 1250°C,
(d) $Mg_{0.6}Zn_{0.4}O$-Fe_2O_3 sintered at 1400°C.

the disaccomodation has the same origin as that of the electrical conductivity which is believed to be due to the diffusion of electrons between ferrous and ferric ions in octahedral sites. In the case of Mg-Zn ferrites (Fig. 3b), the resistivity decreases also in the iron-poor region as well as in the iron-rich region. It is interesting to note that the disaccomodation of this ferrite series behaves in the same way as shown in Fig. 2d, which seems to support the idea mentioned above.

Fig. 3. Electrical resistivity as dependent on the Fe_2O_3 content in (a) $Ni_{0.4}Zn_{0.6}O$-Fe_2O_3 and (b) $Mg_{0.6}Zn_{0.4}O$-Fe_2O_3 series.

3.2. *Disaccomodation as a function of the temperature*

Generally speaking, the disaccomodation is strongly dependent upon the measuring temperature. Practically no disaccomodation was detected below the dry ice temperature for all specimens. The μ vs. $\log t$ curves measured at various temperatures are shown in Fig. 4 for Mg-Zn ferrite containing 42 Fe_2O_3, where the permeabilities at $t=0$ and ∞ are taken as 100 and 0, respectively.

The minimum and the maximum relaxation times τ_1 and τ_2 were calculated from the curves in Fig. 4, and plotted as a function of $1/T$ in Fig. 5. The values of the activation energy, E_a, calculated from τ vs $1/T$ lines thus obtained were about 0.7 eV for 42 Fe_2O_3, 0.5–0.8 eV for 54 Fe_2O_3 and 0.5–0.7 eV for 60 Fe_2O_3.

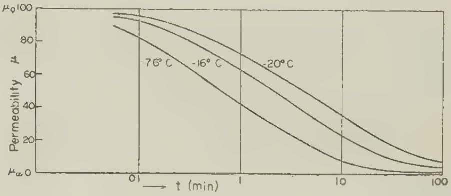

Fig. 4. Thermal change of the disaccomodation in $58Mg_{0.6}Zn_{0.4}O$-42 Fe_2O_3.

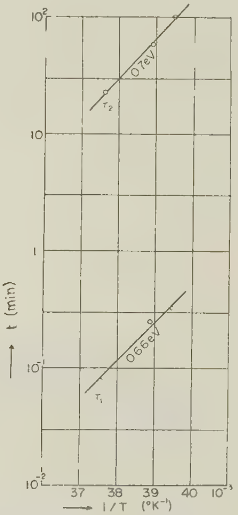

Fig. 5. Maximum and minimum relaxation time τ_1, τ_2 as a function of $1/T$ for $58Mg_{0.6}Zn_{0.4}O$-42 Fe_2O_3.

The temperature dependency of the electrical conductivity in Mg-Zn ferrite with 42 Fe_2O_3 is shown in Fig. 6, from which the activation energy was determined to be 0.18 eV in the vicinity of room temperature. The value for the specimen with 60 Fe_2O_3 is 0.16.

It has been known that many ferrites show large magnetic relaxation losses in the high frequency range, and its activation energy agrees fairly well with that of the electrical conductivity. From this agreement, it has been concluded by Wijn[13] that the origin of the relaxation loss may be the diffusion of electrons between divalent and trivalent iron ions, as is the case for the electrical conductivity.

In the case of the disaccomodartion, however, the activation energies are very large as compared with that of the electrical conductivity, as stated above. Enz[2] also showed that the activation energies of the disaccomodation and of the conductivity were about 0.7 and 1.8 eV, respectively for a single crystal of Mn-Fe ferrite, whose composition is $Mn_{0.84}Fe_{2.14}O_4$. This result was also supported by recent measurement made by Shichijo *et al.*[4] who obtained the values of 0.55 and 0.18 eV, respectively, for the Mn-Zn ferrite ceramics with the composition of $(MnO)_{28}(ZnO)_{19}(Fe_2O_3)_{53}$.

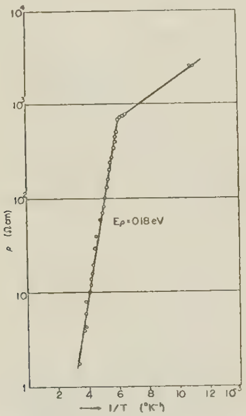

Fig. 6. Thermal change of the electrical resistivity, ρ, in $58Mg_{0.6}Zn_{0.4}O$-$42\ Fe_2O_3$.

Enz[2] explained this discrepancy by assuming that a small amount of Mn^{3+} would be present in both octahedral and tetrahedral sites of spinel lattice, thus giving rise to various types of electron transitions between Mn^{3+}, Mn^{2+}, Fe^{3+} and Fe^{2+} ions which would distribute over octahedral and tetrahedral sites. He assumed that the electron transition with the lowest activation energy will be responsible for the electrical conductivity, while that with a fairly high activation energy will play an important role in giving rise to the disaccomodation.

According to his theory, it must be expected that the relaxation time of the disaccomodation must spread over a fairly wide range which covers the relaxation time of high frequency losses. Actually, however, the relation between τ and $1/T$ for the disaccomodation is confined between the two lines denoted by τ_1 and τ_2 in Fig. 7, and is completely separated from that of high frequency losses. The origin of the disaccomodation, therefore, must be explained by an entirely different mechanism. The fact that Mg-Zn and Cu-Zn ferrites would have very few trivalent metal ions except Fe^{3+} but still show a fairly large disaccomodation conflicts with the idea proposed by Enz.

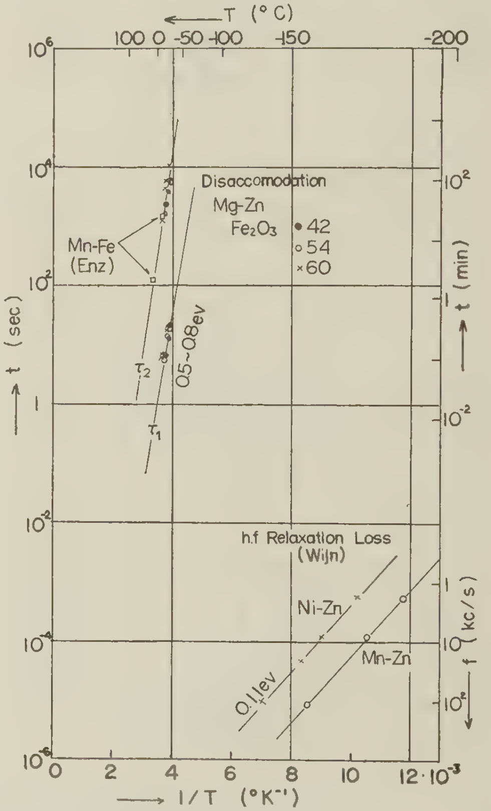

Fig. 7. Relation between τ and $1/T$, for Mg-Zn ferrites as compared to that of high-frequency relaxation losses.

3.3. *Influence of the sintering atmosphere*

The disaccomodation is greatly affected by the sintering atmosphere, which changes the degree of oxidation of the specimens. $40Ni_{0.4}$-$Zn_{0.6}O$-$60Fe_2O_3$ ferrite was used to study these effect, and the results are summerized in Table I.

After sintered at 1350°C for two hours, some specimens were quenched and the remaining specimens were cooled slowly in the furnace. These heat treatments were made in the air. There is a small difference in the

Table I. Effect of the sintering atmosphere on the disaccomodation, D, in $40Ni_{0.4}Zn_{0.6}O$-60 Fe_2O_3.

No.	Heat treatment	D (%)
1	sintered at 1350°C in air and cooled slowly in air	25.3
2	rapidly in air	25.0
3	annealed at 1250°C in air and cooled slowly in N_2	11.5
4	in N_2 and in air	6.8
5	in N_2 and in N_2	1.1

disaccomodation, D, between slowly cooled specimens and rapidly cooled ones. Next, these specimens were annealed again at 1250°C for a half an hour, and then cooled in the furnace. This heat treatment was carried out in nitrogen atmosphere during the whole process, or only during the cooling cycle, or only during the annealing cycle. It may be seen from Table 1 that the disaccomodation decreases with decreasing degree of oxidation. The lowest disaccomodation is observed in the specimen heat-treated in nitrogen atmosphere during the whole process.

The disaccomodation of the Ni-Zn-Fe series which has been annealed at 1250°C in nitrogen atmosphere compared with that of the specimens sintered in air atmosphere in Fig. 2a. It can be seen that D decreases to a considerable extent by nitrogen treatment.

It may be expected that nitrogen treatment deoxidizes the specimens, thus changing some excess ferric ions to ferrous ions. Such an increase in the number of ferrous ion or ferrous-ferric ion pairs, will result in increase in electrical conductivity. This is actually the case, as seen from Fig. 3a. Thus, we might expect that the disaccomodation would be increased by nitrogen treatment, if electron diffusion is really the origin of disaccomodation. The experimental facts, however, are entirely opposite, as mentioned above.

The actual effect of nitrogen treatment can be interpreted as follows: It is commonly recognized that ferrites containing excessive Fe_2O_3 are normally oxidized to some extent, when they are sintered and cooled in the air. It is assumed here that vacancies caused by oxidation is responsible for the disaccomodation. When the specimens are treated in nitrogen atmosphere, however, the number of vacancies will be decreased, thus decreasing the disaccomodation. This model can also explain the effect of iron content on the disaccomodation: That is, when the iron content is increased from the stoichiometric composition, the number of vacancies is expected to increase, because trivalent iron ions are hard to be reduced to divalent ions.

In the case of Mg-Zn ferrites the disaccomodation increases with the deficiency of Fe_2O_3, contrary to the other ferrite series. This can be explained in terms of the effect of excess Mg ions. Since divalent Mg ions can not be oxidized to trivalent, the excess Mg ions added to the stoichiometric composition should enter into the interstitial lattice

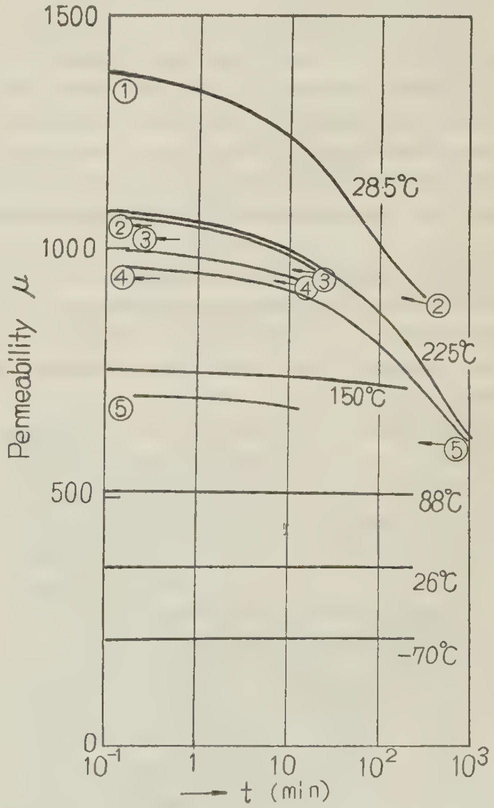

Fig. 8. Time decrease of the permeability in nitrogen-annealed $40Ni_{0.4}Zn_{0.6}O$-60 Fe_2O_3 at various temperatures.

sites. Paladino[14] who recently investigated the phase diagram of Mg-Fe ferrites reached the same conclusion. We can, therefore, explain the experiment by assuming that the interstitial Mg ion is also responsible for the disaccomodation. This effect cannot be expected for Mn-Zn and Ni-Zn ferrites, because in these cases Mn or Ni ions can be changed to trivalent ions, thus maintaing the regular spinel structure.

Furthermore, the time decrease of permeability was measured at higher temperatures for the nitrogen-treated Ni-Zn 60 Fe_2O_3 ferrite, which showed no disaccomodation at room temperature. As shown in Fig. 8, very remarkable changes in permeability were observed above 200°C. The main part of this change, however, was found to be irreversible. In other words, this change is supposed to be acompanied with the change in the structure of the material (*aging effect*). Thus this phenomenon is regarded as independent for the present interest.

In the case of Ni-Zn ferrite single crystal, a negligibly small disaccomodation was observed at and below room temperature ($D\approx 1\%$), although ceramics with the same composition shows a fairly large disaccomodation. It can be considered that this is due to the fact that the single crystal is more perfect and free from vacancies than the air-sintered ceramics. (On the way of the experiment, a large disaccomodation was once observed even at the liquid oxigen temperature. But, it turned out that this was effectuated by heat generation due to the demagnetizing process.)

The value of activation energy obtained from the experiment of disaccomodation, i.e. 0.5–0.8 eV, is also consistent with the model proposed above. Namely, these values are fairly close to 0.9 eV which has been obtained by Bozorth[15] as the activation energy of atomic diffusion from the experiment of magnetic annealing effect of Co ferrites. Lindner[16] has reported about 3 eV as the activation energy of Fe, Ca and Zn ions in Zn and Ca ferrite, basing on the measurements of diffusion by means of the radioactive tracer, but this is expected to include the energy of formation of vacancies or interstitial atoms.

Thus it may be concluded that the main origin of the disaccomdation in various ferrites is the diffusion of either vacancies or interstitial ions generated by oxidation or reduction of the materials.

3.4. *Magnetization process and the field of after-effect*

Here we discuss what kinds of magnetizing processes are responsible for the disaccomodation. The magnetocrystalline anisotropy constant, measured by using the torque magnetometer with the (110) disc of the NiZn ferrite single crystal, is $K_1=-1.7\times10^4$ erg/cc at room temperature. The initial permeability, μ_i, due to the rotational process, as calculated by the formula:

$$\mu_i=\frac{4\pi J_s^2}{3|K_1|}$$

is 60, using the observed value $J_s=490$ gauss. While, the value of measured for the ceramics and the single crystal of Ni-Zn 60 Fe_2O_3 ferrite, are 270 and 750, respectively. This indicates that the displacemet of magnetic domain walls is predominate over the rotational process in these specimens. It can be assumed that this is generally the case for the other kinds of ferrites.

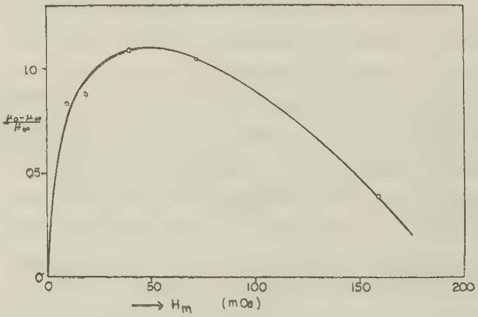

Fig. 9. Relation between the disaccomodation and measuring A.C. field, H_m, for $40Mg_{0.6}Zn_{0.4}O$-60 Fe_2O_3 at 1°C.

Using Mg-Zn 60 Fe_2O_3 ferrite, the disaccomodation at 1°C was measured as a function of the amplitude of the measuring A.C. field, H_m. The ratio $D_\infty=(\mu_0-\mu_\infty)/\mu_\infty$ has the maximum value for $H_m\approx50$ mOe (Fig. 9), where μ_0 and μ_∞ are the values of the permeability at $t=0$ and ∞, respectively. The shape of this curve is similar to the theoretical one proposed by Néel[6] for the after effect due to 180° wall displacements. According to the process adopted by Brissoneau[7] and by others[8],[17], the magnetic induction, B vs H_m curves are constructed for various durations of time from the instant of demagnetization (Fig. 10). From Fig. 10, the *field of magnetic after effect* or *stabilization field*, H_0, which corresponds to the difference of field between two curves of $t=0$ and ∞, was determined as 35 mOe.

According to Néel's[9] theory, the field of after effect for 180° wall displacements is expressed as:

$$2H_0J_s=\frac{cw^2}{3kT}f(U)G(t)\ ,$$

where $f(U)$ the variation of the energy as the function of the position of domain wall U, $G(t)$ a function of time which varies from 0 for $t=0$ to 1 for $t=\infty$, w the change in the atom pair energy due to the displacement of interstitial atom, c the concentration of interstitial atoms, k the Boltzman constant, and T the absolute temperature.

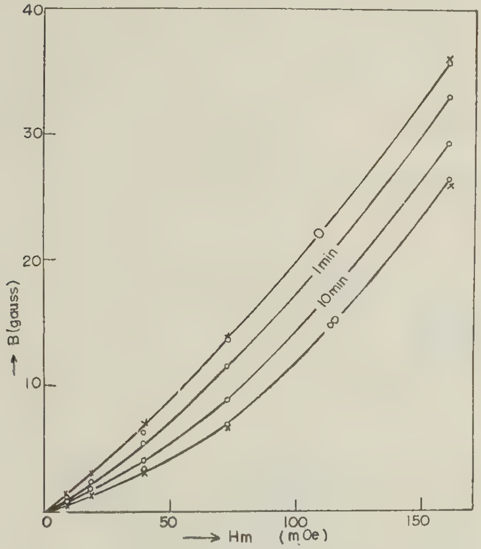

Fig. 10. Relation between magnetic induction, B, and measuring field, H_m, at various times measured from the demagnetization.

Néel has calculated the function $f(U)$ and showed that the maximum value is 2 for 180° wall motion. Here, we consider the case in which $G(t)=1$, $f(U)=2$, $H_0=35\times10^{-3}$ Oe, $J_s=$ $=4.5\times10^2$ gauss, then approximately $w=1.3\times10^{-6}/\sqrt{c}$ is obtained. If we consider the case in which the atomic pairs change their direction, the value of w is changed by the factor 2.9, and thus we have $w=3.8\times10^{-6}/\sqrt{c}$.

There are two possible mechanisms by which vacancy or interstitial ion contributes to the disaccomodation: One is the case that the vacancies accerelate the diffusion of metal ions in the spinel lattice without any direct contribution to the anisotropy. Tne other case is that the vacancies have a direct contribution to the anisotropy through the rearrangement of ion-vacancy pairs. If we assume the second case, and put the vacancy concentration, as $c=2.3\times10^{20}$, which was determined from chemical analysis of ferric and ferrous ions, into the formula of w, we have $w=2.6\times10^{-16}$ erg or 1.5×10^8 erg/mol. This value seems fairly reasonable as compared to the value of the dipole-dipole interaction determined by Néel[18] by using the magnetostriction data of iron-nickel alloys. The same estimation has not been made for the mixed ferrites, but the order of magnitude will be the same, because the magnetostriction constants of ferrites are the same order of magnitude as those of alloys.

§ 4. Summary

1) It was observed for Mn-Zn, Ni-Zn, Cu-Zn and Mg-Zn ceramic ferrites that the disaccomodation increases with an increase of Fe_2O_3 from stoichiometric composition MFe_2O_4.

2) Only in the case of Mg-Zn ferrites, a remarkable disaccomodation was observed also in the region of defficient Fe_2O_3. It takes a minimum value at the stoichometric composition.

3) The tendencies 1) and 2) are also seen for electrical conductivity. But this correlation is found to be superficial, because, when the specimens of Ni-Zn ferrite were annealed in nitrogen atmosphere, the disaccomodation was remarkably decreased, while the electrical conductivity was increased.

4) A negligibly small disaccomodation was observed with the Ni-Zn ferrite single crystal, which is supposed to contain a very small amount of vacancy.

5) The activation energies determined from the disaccomodation measurements with Mg-Zn ferrites are 0.5–0.8 eV, which are fairly large as compaired to that of the electrical conductivity (0.16–0.18 eV).

6) It may be concluded that the disaccomodation is closely related to the vacancy or interstitial ions, the displacement of which may change the local anisotropy, thus changing the permeability.

Acknowledgement

The author should like to express his sincere thanks to Prof. S. Chikazumi for his guidance and kind inspection of the manuscript, and to Prof. S. Miyahara, Dr. T. Yamadaya and Mr. T. Wakiyama for their helpful advices. Thanks are also due to Dr. N. Sakamoto and Dr. N. Miyata for their kind advices for the preparation of single crystal, and to Mr. T. Ikeda for his assistance in this experiment.

Oxygen Positional Parameters of Tetragonal Mn_3O_4*

By Ken'iti SATOMI**

Tokyo Institute of Technology, Oh-okayama,
Tokyo, Japan

(Received August 6, 1960)

The positions of the oxygen ions of tetragonal Mn_3O_4 are determined through the Debey-Scherrer X-ray analysis, by the extension of the Bertaut's method and with least square method. The assigned correction for the anomalous scattering on Mn to Fe-Kα radiation is somewhat larger than the calculated value. The two oxygen parameters ε and δ for the space-group D_{4h}^{19} are 0.032~0.036 and 0.008~0.010. These values correspond to the case that the tetragonal deformation comes from the octahedral sites but the tetrahedral sites resist to the deformation.

§1. Introduction

Since the investigation by Barth and Posnjak[1] about the existence of the inverse spinels, the cation distribution and the oxygen parameters of the spinels have been investigated by many authors and the main factors which determine the cation distribution are given for the usual ferrites by Verwey et al,[2] being regarded as purely ionic crystals. On the other hand, as they pointed out already, the deviation from the ionic crystal in same spinels, especially in those which do not contain much Fe^{3+} ions, becomes more and more clear. In this respect, Goodenough et al[3] proposed according to the Pauling's theory of the hybridized covalent bond that the Mn^{3+} or Cu^{2+} ions in the spinels prefer the octahedral site and make dsp^2 square covalent bond while the Mn^{2+} and Fe^{3+} ions in the spinels prefer the tetrahedral site and make sp^3 tetrahedral covalent bond. If there are sufficient amount of these ions in the octahedral site to establish the order of the direction of the deformed octahedron, the tetragonal deformation of a crystal as a whole will result[4]. Other authors[5] discussed these problems using the crystalline field splittings of the ionic energy levels.

** Present adress: Nippon Telegraph and Telephone Public Corporation Electrical Communication Laboratory Tokyo, Japan.

Being interested in this deformation, the present author has investigated the oxygen position around the Mn^{3+} ions in the octahedral site of tetragonal Mn_3O_4 by the measurement fo the Debey-Scherrer X-ray diffraction intensities.

§ 2. Experimentals

The powder specimens of Mn_3O_4 were prepared by the decomposition of manganous oxalate precipitated from the mixture of the boiling ammonium oxalate solution and conc. manganous sulphate solution. To prevent the formation of the vacancies of the γ-Mn_2O_3 type, this powder was heated for two hours at 1100°C and then is quenched by putting it between two aluminum plates. The annealing temperature was chosen because it is higher than the decomposition temperature of Mn_2O_3[6] but lower than the transition temperature from the tetragonal to cubic phase[7]. Although the powder was not coase, it was rubbed in an agate-mortar. Then the powder was packed in a frame and the flat surface was used for the measurement of the X-ray diffraction. The diffraction intensities were recorded by the Norelco diffractometer using Fe–Kα radiation with slow scanning speed. All the measured lines of this sample can be indexed according to the space group D_{4h}^{19} with $a=5.76$ Å and $c=9.46$ Å Fig. 1 shows the diffraction lines of Mn_3O_4 and the relations between them and those of a cubic spinel. The observed breadths of the diffraction lines are found to be about 1/5°. This is mainly the instrumental broadening, because the dimension of the powder observed under the microscope were about 10 microns.

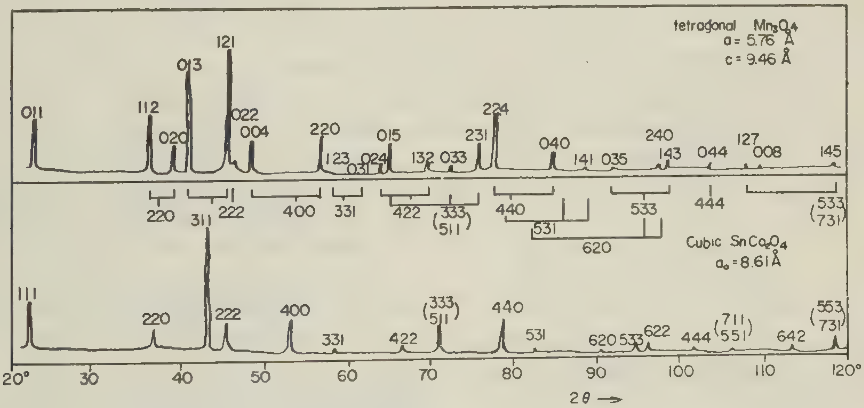

Fig. 1. X-ray diffraction patterns of tetragonal Mn_3O_4 and cubic $SnCo_2O_4$.

§ 3. Method of Analysis

The analysis of the measured integral intensities of the lines (hkl) was performed by a method similar to that used by Bertaut[8] in his investigation of the cation distribution of Cu ferrite. Then the result was refined by the least square method. The author extended the Bertaut's method so as they could be applied to the case of the tetragonally deformed spinel Mn_3O_4. Based upon the description of the International Tables of the D_{4h}^{19}, the positions of the oxygen ion are expressed as 16(h) site and the positions of Mn ions are expressed as 4(a) and 8(d). Their coordinates are respectively $(0, 1/4-\varepsilon, 3/8+\delta)$, $(0, 0, 0)$ and $(0, 1/4, 5/8)$ etc. For $\varepsilon=\delta=0$ the oxygen lattice is only uniformly deformed from the face-centred cubic closepacked to the face-centred tetragonal with the Z-axis streched by $c/\sqrt{2}a$ times. For $\varepsilon=2\delta$ the oxygen position is the same as in the spinel unless the tetragonal deformation is considered. If $\varepsilon>2\delta$ the ratio of the displacements is larger in the XY-plane than parallel to the Z-axis in the sence to compensate the deformation of the tetrahedral site from the regular tetrahedron. To determine the position of the oxygen, first of all we calculate the crystal structure factors for the small values of ε and δ retaining only the contribution of the linear terms of parameters. The result is shown for the relatively low angle lines in the Table I. It is seen that the first order contribution of the oxygen parameters exists for the lines: (011)(013)(121)(123)(031)(015)(033)(231)(035) and (143) etc. Although for the cubic spinels only the intensity of the (111) lines is strongly dependent on the oxygen parameter $u-3/8$, for the tetragonal Mn_3O_4 the intensities of so many diffraction lines are influenced by the oxygen positional parameters that the two parameters ε and δ can be determined fairly well. If we put $\varepsilon/2=\delta=u-3/8$, these structure factors is of course the same as those in the spinels.

Table I. The crystal structure factors $F(hkl)$ and the numbers of the planes $p(hkl)$ of Mn_3O_4.

$h\ k\ l$	p	$\lvert F(h\,k\,l)\rvert$ per formula unit $A(B_2)O_4$

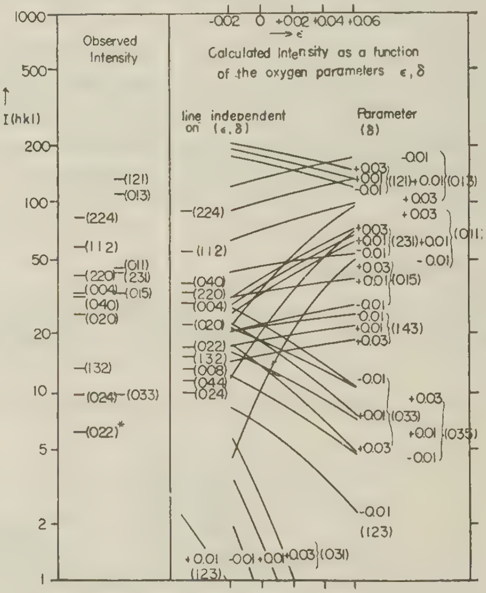
2 2 0	4	$2B \quad -A \quad + \quad 4O$
1 2 3	16	$B-\frac{1}{\sqrt{2}}A-(3\delta+\varepsilon)\cdot 4\pi O$
0 3 1	8	$B-\frac{1}{\sqrt{2}}A+(\delta-3\varepsilon)\cdot 4\pi O$
0 2 4	8	A
0 1 5	8	$B+\frac{1}{\sqrt{2}}A+(5\delta+\varepsilon)\cdot 4\pi O$
1 3 2	16	A
0 3 3	8	$B+\frac{1}{\sqrt{2}}A-(3\delta+3\varepsilon)\cdot 4\pi O$
2 3 1	16	$B+\frac{1}{\sqrt{2}}A+(\delta+3\varepsilon)\cdot 4\pi O$
2 2 4	8	$2B \quad +A \quad + \quad 4O$
0 4 0	4	$2B \quad +A \quad + \quad 4O$
0 3 5	8	$B+\frac{1}{\sqrt{2}}A+(5\delta-3\varepsilon)\cdot 4\pi O$
1 4 3	16	$B+\frac{1}{\sqrt{2}}A-(3\delta-\varepsilon)\cdot 4\pi O$
0 4 4	8	$2B \quad -A \quad + \quad 4O$
0 0 8	2	$2B \quad +A \quad + \quad 4O$



* The correction of f in § 4 can explane the weak observed value but $I(022)$ is not exact for the overlap with (121).

Fig. 2. The observed and the calculated intensities of the diffraction lines of Mn_3O_4.

Upon using the Thomas-Fermi scattering factors for Mn, the Hartree scattering factors for O^{2-} and the Lorentz' and polarization factors of the diffraction intensity for a polycrystalline block i.e. $1+\cos^2 2\theta/\sin^2\theta\cos\theta$, the intensity values were calculated. The results are shown in the Fig. 2, where the ordinate represents the logscale intensity, the abscissa denotes ε and the curves are drawn for various δ's. The lines (123) and (031), which correspond to the spinel line (331), are too weak to be used for the determination of the oxygen parameters.

Looking at the Table I and the Fig. 2 we can see immediately that the intensity ratio of the following lines can be used most effectively, to determine ε and δ separately, and to estimate the deviation from $\varepsilon=2\delta$,

$$\delta: \frac{I(013)}{I(015)}, \quad \varepsilon: \frac{I(013)}{I(033)}, \ \frac{I(121)}{I(231)}; \ \frac{I(011)}{I(015)}, \quad \varepsilon-2\delta: \frac{I(121)}{I(013)}, \ \frac{I(143)}{I(035)}.$$

There are many lines to use for the determination of the average displacement of the oxygen from the tetrahedral site toward the octahedral sites,

$$\varepsilon+2\delta: \frac{I(015)}{I(033)}, \ \frac{I(231)}{I(033)}; \ \frac{I(013)}{I(011)}, \ \frac{I(011)}{I(033)} \qquad \text{etc.}$$

For the ratios coming after the semicolon, the result should deviate if it happens that the structure factors of the Mn ions on the octahedral and the tetrahedral sites are different. What site is more dense in the electronic distribution can be estimated by selecting the lines sensitive for it and by calculating their intensity ratios ξ

$$\xi=\frac{\{I(112),\, I(020)\}}{\{I(004),\, I(220)\}} \cong \frac{\{f_{\text{tet}}\}^2}{\{2f_{\text{oct}}-f_{\text{tet}}+4f_{\text{oxy}}\}^2} \times \frac{\phi(\theta)}{\phi'(\theta')} \times \frac{p}{pp'} \qquad \text{etc.}$$

Where $\phi(\theta)$ is the part of the atomic structure factors and the other geometrical factors which depends upon the scattering angles. The corrections from the ratio $\xi_{\text{calc.}}$ calculated for the distribution $\mathrm{Mn(Mn)_2O_4{}^{2\cdot}}$ are estimated and compared with the experimental data for the most probable distributions

$$\mathrm{Mn^{3+}_{2/3}}V_{1/3}\mathrm{(Mn^{3+})_2O_4{}^{2-}}, \quad \mathrm{Mn^{3+}(Mn^{3+}_{5/3}}V_{1/3})\mathrm{O_4{}^{2-}}, \quad \mathrm{Mn^{2+}(Mn^{3+})_2O_4{}^{2-}}, \quad \text{and} \quad \mathrm{Mn^{3+}(Mn^{2+}Mn^{3+})O_4{}^{2-}},$$

assuming that

$$f_{\mathrm{O^{2-}}}=10\,, \ f_{\mathrm{Mn}}=25\,, \ f_{\mathrm{Mn^{2+}}}=23\,, \ f_{\mathrm{Mn^{3+}}}=22 \text{ and } \phi(\theta)/\phi'(\theta')\cong\text{const. for various distributions,}$$

where the metal ions in the parentheses occupy the octahedral site and the metal ions outside of it occupy the tetrahedral site and v indicates vacancy. The existence of the metal ion vacancies v is considered, because it is believed that the disappearence of the tetragonal deformation by the substitutions of the Mn ions in spinels is dependent on the degree of the oxydation9). In the end, there are no contradiction in assigning the normal 2(33) spinel arrangement for Mn_3O_4,

$$\frac{\xi_{3v(3)}}{\xi_{\text{calc.}}}=0.3^*, \quad \frac{\xi_{3(3v)}}{\xi_{\text{calc.}}}=1.10\,, \quad \frac{\xi_{2(33)}}{\xi_{\text{calc.}}}=0.96\,, \quad \frac{\xi_{3(23)}}{\xi_{\text{calc.}}}=0.82 \quad \text{and} \quad \frac{\xi_{\text{obs.}}}{\xi_{\text{calc.}}}=0.92$$

where the same constant factors for each distribution are eliminated by taking the ratio $\xi/\xi_{\text{calc.}}$.

For the correction of the temperature factor $\exp\{-B(\sin\theta/\lambda)^2\}$ it must be given $B=\dfrac{6h^2}{mk\theta}\left\{\dfrac{\Phi(X)}{X}+\dfrac{1}{4}\right\}$, $X=\dfrac{\theta}{T}$, where θ is the Debey temperature. For NaCl $\theta=281$°K, $m=m_{\mathrm{Cl}}+m_{\mathrm{Na}}/2\cong 30$ and $B=1.43\times 10^{-16}$. Here θ of Mn_3O_4 is estimated using the frequency of the optical mode of the lattice vibrations, as it has been observed by the author10) in the far infrared region. The observed values are 200 $\mathrm{cm^{-1}}$ for NaCl, 600 $\mathrm{cm^{-1}}$ for Mn_3O_4 and then $\theta_{\mathrm{Mn_3O_4}}/\theta_{\mathrm{NaCl}}\cong\nu_{\mathrm{Mn_3O_4}}/\nu_{\mathrm{NaCl}}\cong 3.0$. From this and $m=3m_{\mathrm{Mn}}+4m_{\mathrm{O}}/7\cong 33$, the correction for Mn_3O_4 is given as $B_{\mathrm{Mn_3O_4}}=0.18\times 10^{-16}$. The Mn_3O_4 belongs to relatively hard crystals and the correction for the thermal vibrations is not great for the relatively low angle lines for which $10^{-8}\sin\theta/\lambda$ is smaller than 0.3.

The corrections of the absorption and the extinction can be neglected if the sample is the ideal polycrystalline block. The diffracted intensity is reduced only by a constant factor for the whole lines.

---

* γ-Mn_2O_3 shows this vacancy distribution and a slight existence of the vacancy in the sample have a large effect on the result but the more exact calculation does not show the posibility of the existence of vacancies on this investigation.

Each intensity ratio for the lines dependent upon the oxygen parameters is calculated and the loci which satisfy both the observed and calculated intensity ratios are given on the $\mathcal{E}$-δ plane, as shown in the Fig. 3. If these loci cross at one point, this point gives the result consistent for all the line intensities. This method of determining two parameters has been used by Hastings and Corliss[11] to give the cation distribution x and the oxygen parameter u of the Mn ferrite by the Neutron diffraction method. On the determination of the cross point, one must be careful of the fact that the error in the observed intensity of each line gives rise to a different amount of shifts of the loci on the $\mathcal{E}$-δ plane. Due to the uncertainty of drawing the base lines on the diffraction pattern and the approximations used in the calculations, the result will be given as $\delta=0.008\sim0.012$ and $\mathcal{E}=0.032\sim0.040$.

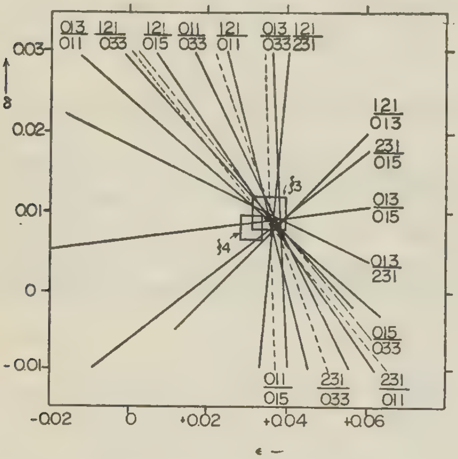


Fig. 3. The graphical determination of the oxygen parameters ε and δ of Mn_3O_4.

§4. Refinements of the Results

In the above calculation, the contribution from the higher order terms of $\mathcal{E}$ and δ, the anomalous scattering of the Mn ion core and the charge difference of Mn ions on the octahedral and tetrahedral sites are neglected. In this section the result obtained graphically is refined by the application of the least square method to the deviations of the calculated line intensities from the observed ones, $\Delta_{hkl}=I_{hkl}(\text{obs.})-I_{hkl}(\text{calc.})$. The exact formula for the dependence on $\mathcal{E}$ and δ and the new $f_{Mn^{2+}}$ and $f_{Mn^{3+}}$ obtained by Thomas and Umeda (TFD) and $f_{O^{2-}}$ in the 2+ wells obtained by Suzuki (HF)[13] are used in the refinement. When many lines can be used for the determination of parameters the least square method is suitable in weighing each line[14),15)].

The calculations are put forward to derive the most probable values of the scaling factor K, oxygen parameters $\mathcal{E}$ and δ, temperature factor B and the real part of the anomalous scattering factor f. The last parameter f is efficient for the correction of f_{Mn} to the Fe-$K\alpha$ radiation, the wave length of which is just in front of the absorption edge of Mn

ion[16]. The calculation started with $\varepsilon=0.04$, $\delta=0.01$, $f=-3.5$, $B=0$ and $K=1.9$ and the refined K, ε, δ and f are determined from solving the normal equations:

$$-\sum_{hkl}\Delta\frac{\partial\Delta}{\partial K}=\Delta K\sum_{hkl}\left(\frac{\partial\Delta}{\partial K}\right)\left(\frac{\partial\Delta}{\partial K}\right)+\Delta\delta\sum_{hkl}\left(\frac{\partial\Delta}{\partial K}\right)\left(\frac{\partial\Delta}{\partial\delta}\right)+\Delta\varepsilon\sum_{hkl}\left(\frac{\partial\Delta}{\partial K}\right)\left(\frac{\partial\Delta}{\partial\varepsilon}\right)+\Delta f\sum_{hkl}\left(\frac{\partial\Delta}{\partial K}\right)\left(\frac{\partial\Delta}{\partial f}\right)$$

$$-\sum_{hkl}\Delta\frac{\partial\Delta}{\partial\delta}=\Delta K\sum_{hkl}\left(\frac{\partial\Delta}{\partial\delta}\right)\left(\frac{\partial\Delta}{\partial K}\right)+\Delta\delta\sum_{hkl}\left(\frac{\partial\Delta}{\partial\delta}\right)\left(\frac{\partial\Delta}{\partial\delta}\right)+\Delta\varepsilon\sum_{hkl}\left(\frac{\partial\Delta}{\partial\delta}\right)\left(\frac{\partial\Delta}{\partial\varepsilon}\right)+\Delta f\sum_{hkl}\left(\frac{\partial\Delta}{\partial\delta}\right)\left(\frac{\partial\Delta}{\partial f}\right)$$

$$-\sum_{hkl}\Delta\frac{\partial\Delta}{\partial\varepsilon}=\Delta K\sum_{hkl}\left(\frac{\partial\Delta}{\partial\varepsilon}\right)\left(\frac{\partial\Delta}{\partial K}\right)+\Delta\delta\sum_{hkl}\left(\frac{\partial\Delta}{\partial\varepsilon}\right)\left(\frac{\partial\Delta}{\partial\delta}\right)+\Delta\varepsilon\sum_{hkl}\left(\frac{\partial\Delta}{\partial\varepsilon}\right)\left(\frac{\partial\Delta}{\partial\varepsilon}\right)+\Delta f\sum_{hkl}\left(\frac{\partial\Delta}{\partial\varepsilon}\right)\left(\frac{\partial\Delta}{\partial f}\right)$$

$$-\sum_{hkl}\Delta\frac{\partial\Delta}{\partial f}=\Delta K\sum_{hkl}\left(\frac{\partial\Delta}{\partial f}\right)\left(\frac{\partial\Delta}{\partial K}\right)+\Delta\delta\sum_{hkl}\left(\frac{\partial\Delta}{\partial f}\right)\left(\frac{\partial\Delta}{\partial\delta}\right)+\Delta\varepsilon\sum_{hkl}\left(\frac{\partial\Delta}{\partial f}\right)\left(\frac{\partial\Delta}{\partial\varepsilon}\right)+\Delta f\sum_{hkl}\left(\frac{\partial\Delta}{\partial f}\right)\left(\frac{\partial\Delta}{\partial f}\right).$$

The standard deviations are given by $\sigma_i=\sqrt{\sum_{hkl}\Delta^2_{hkl}/m-s\cdot\Delta_{ii}/D}$, where m is the number of the used lines, s is the number of all the parameters to determine. The result is

$$K=2.28\pm0.21\,,\quad \delta=0.0083\pm0.0015\,,\quad \varepsilon=0.0320\pm0.0027\,,\quad f=-4.4\pm0.7\,.$$

The correction for the anomalous scattering of f_{Mn} turns out to be a little larger than the calculated value -3.5. To take account of B, we selected the lines which depend not so strong on ε and δ and determined K, f and B from these lines. Then based upon these values, ε and δ are obtained from the lines which depend strongly on these parameters. The result is $B=0.4\pm0.3\times10^{-16}$ and the other values are not much altered.

§ 5. Discussion

The coordinate of ions and the angles α, β, ϕ etc. as well as the schematic result are shown in the Fig. 4. Cell dimensions are expressed as $c\cong(1+2\gamma/3)a_0$ and $a\cong(1-\gamma/3)a_0/\sqrt{2}$ using a_0 the edge of the cube and γ the degree of the tetragonal deformation $c/\sqrt{2}a-1$. The volume of the cube is twice as large as the tetragonal unit cell of Mn_3O_4. The observed values $\varepsilon=0.036$, $\delta=0.009$, $\gamma=0.16$ and $a_0=8.54$ Å are used in the calculation.
The oxygen—metal distances are

$$\begin{aligned}
r_{\text{octahedralsite-oxygen in } c\text{-plane}} &\cong(1-2\varepsilon-\gamma/3)a_0/4\cong1.8_8\ \text{Å}\\
r_{\text{octahedralsite-oxygen // } c\text{-axis}} &\cong(1-4\delta+2\gamma/3)a_0/4\cong2.2_8\ \text{Å}\\
r_{\text{tetrahedralsite-oxygen}} &\cong(1+8\varepsilon/3+8\delta/3)\sqrt{3}a_0/8\cong2.0_7\ \text{Å}\,.
\end{aligned}$$

The oxygen—oxygen distances are

$$\begin{array}{lll}
(1\text{–}0) & \cong(1-4\varepsilon-\gamma/3)a_0/2\sqrt{2} & \cong2.4_3\ \text{Å}\\
(2\text{–}0)(3\text{–}0) & \cong(1-4\delta-2\varepsilon+\gamma/6)a_0/2\sqrt{2} & \cong2.7_7\ \text{Å}\\
(4\text{–}0) & \cong(1+4\varepsilon-\gamma/3)a_0/2\sqrt{2} & \cong3.2_9\ \text{Å}\\
(5\text{–}0)(6\text{–}0) & \cong(1+4\delta+2\varepsilon+\gamma/6)a_0/2\sqrt{2} & \cong3.4_2\ \text{Å}\\
(7\text{–}0)(9\text{–}0)(10\text{–}0)(12\text{–}0) & \cong(1+\gamma/6)a_0/2\sqrt{2} & \cong3.1_0\ \text{Å}\\
(8\text{–}0)(11\text{–}0) & \cong(1-\gamma/3)a_0/2\sqrt{2} & \cong2.8_6\ \text{Å}\,,
\end{array}$$

the ion numbers correspond to those in the Fig. 4.
The interbond angles are

$$\begin{array}{llll}
\alpha & \cong2\cos^{-1}\dfrac{1}{\sqrt{3}}+2\dfrac{\sqrt{2}}{3}(4\varepsilon-8\delta-\gamma) & \Delta\alpha & \cong-2\Delta\alpha'\cong-4._8{}^\circ\\
\beta & \cong\pi/2-4\varepsilon & \Delta\beta & \cong-8._2{}^\circ
\end{array}$$

$$\beta' \cong \pi/2-4\delta-2\varepsilon \qquad \Delta\beta' \cong \Delta\beta''/\sqrt{2} \cong -6._2{}^\circ$$

$$\phi \simeq \pi-\cos^{-1}\frac{1}{\sqrt{3}}+2\frac{\sqrt{2}}{3}(4\delta-5\varepsilon+\gamma/2) \qquad \Delta\phi \simeq -3._7{}^\circ$$

$$\phi' \cong \pi-\cos^{-1}\frac{1}{3}-\varepsilon/4-3\delta-\gamma/3\sqrt{2} \qquad \Delta\phi' \cong -4._2{}^\circ$$

$$\phi'' \cong \pi/2+4\delta+2\varepsilon \cong \pi-\beta' \qquad \Delta\phi'' \cong 6._2{}^\circ \,.$$

If the positions of oxygen ions are deformed uniformly by $\gamma=0.16$ from the cubic close-packed arrangement to the tetragonal one, we should have $\Delta\alpha \cong -8._6{}^\circ$. The observed value $\Delta\alpha \cong -4._8{}^\circ$ is nearly half as large. For the regular octahedron, the interbond angles are $\beta=\beta'=\beta''=90^\circ$ but for the observed one they are 82°, 84° and 86° and the longer edge of the rectangle is parallel to the Mn^{3+} line on *c*-plane (c.f. Fig. 4). The similar deformations are known in the octahedron around the ions Cu^{2+}, Pd^{2+}, Pt^{2+} etc. which make the square covalent bond and linear complex in oxides or chlorides[17),18)].

For the sake of comparison let us review the results of spinels $MnFe_2O_4$ and $CuFe_2O_4$. The inter ionic distances in $MnFe_2O_4$, obtained by Hastings' data, are[11)]

$r_{\text{octahedralsite-oxygen}} = 2.0_5$ Å

$r_{\text{tetrahedralsite-oxygen}} = 2.0_0$ Å

(1, 2, 3–0) $\cong 2.7_8$ Å

(4, 5, 6–0) $\cong 3.2_6$ Å

(7, 8, 9, 10, 11, 12–0) $\cong 3.0_1$ Å

and those of $CuFe_2O_4$, calculated by Prince's data, are[19)]

$r_{\text{octahedralsite-oxygen in } c\text{-plane}} \cong 1.9_9$ Å

$r_{\text{octahedralsite-oxygen} \,//\, c\text{-axis}} \cong 2.1_8$ Å

$r_{\text{tetrahedralsite-oxygen}} \cong 1.8_9$ Å

(1–0) $\cong 2.7_2$ Å

(2, 3–0) $\cong 2.9_0$ Å

(4–0) $\cong 3.0_9$ Å

(5, 6–0) $\cong 3.0_9$ Å

(7, 9, 10, 12–0) $\cong 2.9_9$ Å

(8, 11–0) $\cong 2.9_0$ Å .

The summations of the ionic radii give the following lengths:

$Mn^{3+}O_6$ octahedron (Mn-oxygen) $\cong 2.0_2$ Å
(oxygen-oxygen) $\cong 2.8_6$ Å

$Mn^{2+}O_4$ tetrahedron (Mn-oxygen) $\cong 2.2_0$ Å
(oxygen-oxygen) $\cong 3.6_0$ Å

$Fe^{3+}O_6$ octahedron (Fe-oxygen) $\cong 2.0_0$ Å
(oxygen-oxygen) $\cong 2.8_3$ Å

$Fe^{3+}O_4$ tetrahedron (Fe-oxygen) $\cong 2.0_0$ Å
(oxygen-oxygen) $\cong 3.2_9$ Å

In the above results, $r_{\text{oxygen-octahedralsite in } c\text{-plane}}$ are shorter than the sum of the ionic radii, and $r_{\text{tetrahedralsite-oxygen}}$ are also shorter than that but longer than the $r_{\text{tetrahedralsite-oxygen}}$ of the $MnFe_2O_4$ in which it is believed that the tetrahedralsite Mn ion forms covalent bond. The differences in the bond lengths and the interbond angles for the same $Mn^{2+}O_4$ tetrahedron between Mn_3O_4 and $MnFe_2O_4$ might come from the fact that in the $MnFe_2O_4$ the octahedralsite Fe^{3+} is purely ionic while in Mn_3O_4 the octahedralsite Mn^{3+} is covalent and the oxygen *p* orbit cannot be directed to both the tetrahedralsite and the octahedralsite at the same time[3)]. The similar contraction of the bonds of the tetrahedral site by 0.1 Å compared with the sum of the ionic radii exists in $Fe^{3+}O_4$ tetrahedron in the $CuFe_2O_4$ spinel. Although the tetragonal deformation is not so great as Mn_3O_4, Prince et al state that the tetrahedron $Fe^{3+}O_4$ is almost regular in $CuFe_2O_4$.

As is shown in Fig. 5 the above geometrical relations are visualized on the $(\varepsilon-\delta)$ plane by drawing the loci which satisfy the specific conditions for the angle and the length of the tetrahedral bonds. If the tetrahedron does not change its angles for the overall deformation of the unit cell, there must be approximate relations

$$4\varepsilon-8\delta-\gamma \cong 0 \,.$$

Since γ amounts to 0.16 for Mn_3O_4, then ε and δ must be on the line (b). If the deformation is uniform, they must be on the line (a). If the length of the tetrahedral bond does not vary and is put to be equal to the value found on $MnFe_2O_4$ by Hastings the ε and δ must be on the line (c) which satisfies

$$(1+8\varepsilon/3+8\delta/3)\sqrt{3}\,a_0/8 \cong 2.00 \text{ Å} \,.$$

On the other hand, if the sum of the ionic radii is used for this, the line (d) is obtained. By the cross point of the two lines (b) and (c) is represented an extreme case in which the tetrahedron does not deform at all. Another extreme case is given by the cross point of the lines (a) and (d), which means the model of rigid spheres freely slideable. If the octahedron has the six bonds of the same lengths, ε and δ must be on the line (e). If the average length of these bonds is kept constant, the line (f) is obtained for the case in which the average is equal to the summation of the ionic radii and the line (g) is obtained for the case in which the lengths of bonds contract by 0.1 Å from the value of (f).

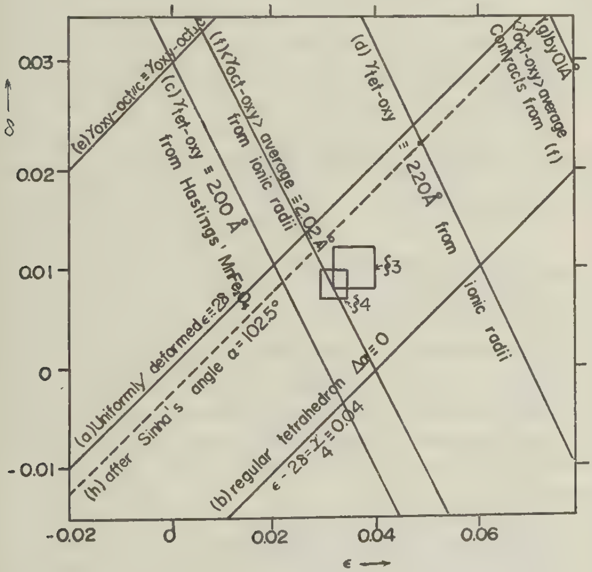

Fig. 5. The specific conditions on the oxygen positions given from the formation of the ideal bond in the each site of the tetragonal Mn_3O_4 and the experimental results given as the squares, the larger from § 3 and the smaller from the § 4. The both are shown on the same ε–δ plane as in Fig. 3.

In the Fig. 5 the probable values of $\mathcal{E}$ and δ measured for Mn_3O_4 are shown by small squares. This square is in the middle of the quadrilateral formed by the lines (a), (b), (c) and (d). This shows that the oxygen position is determined by the balance between the deformation due to the octahedral site becoming tetragonal and the deformations due to the tetrahedron preserving its regular form against the tetragonal deformation of the crystal as a whole. Contrary to the case, if the cause of the tetragonal deformation is not on the octahedral site but on the tetrahedral site, the measured point of the oxygen parameters will be on the other side of the line (a). In the Fig. 5 Sinha's result is also shown by the line (h)[20].

On the contrary to Mn_3O_4, the tetragonal contraction along the *c*-axis exists for the $CuCr_2O_4$ spinel[21] and the tetragonal deformation exists also for the iron-chromite spinels of which the average oxygen parameter u has been given by Derbyshire.[22] When the two oxygen parameters are separated for these spinels, from the reasoning similar to the case of the elongation, it will become clear that whether the tetragonal deformation of these compound comes from the tetrahedral site or the octahedral site. If the contraction of $CuCr_2O_4$ comes from the Cu ions as is stated by Dunitz et al, the displacement of the oxygen should be also $\mathcal{E}>2\delta$ not withstanding the fact that γ is negative. The author hopes that for these oxides a detailed investigation of the electron density around the each site should be performed.

Acknowledgement

The author thanks Mr. K. Kato of Kubo Laboratory of Tokyo Institute of Technology for the measurement of the powder X-ray patterns and he also thanks Professor I. Aoki of Chiba University for helpful suggestions in the analysis. The author is most thankful to Professors Y. Takagi and S. Sawada of Tokyo Institute of Technology for their guidance and encouragement through the investigation.

Nuclear Quadrupole Resonance Under High Pressure, I.

By Tokujiro FUKE

Faculty of Engineering, Tokushima University, Tokushima

(Received September 16, 1960)

The nuclear quadrupole resonance frequencies of I^{127} in stannic tetraiodide (SnI_4), As^{75} in arsenolite (As_4O_6), Br^{81} in paradibromobenzene (p-$C_6H_4Br_2$) and in potassium bromate ($KBrO_3$) were measured as a function of hydrostatic pressure at various temperatures. The pressure range was 1–9000 kg/cm^2 in the temperature range from $-77°$ to 100°C, and 1–1000 kg/cm^2 at liquid oxygen temperature, respectively.

In general, the pressure and the temperature dependence of the resonance frequency is found to agree with Bayer's theory incorporated with Kushida-Benedek-Bloembergen's theory. It is noticed, however, that an anisotropic change of the internal parameters for the positions of atoms in a unit cell would contribute appreciably to the analysis of the data even in the cases of cubic crystals, SnI_4 and As_4O_6 and that a deviation from the Bayer curve is observed in As_4O_6. Doublet lines for SnI_4 are found to behave differently as a function of volume, and it is concluded for the molecular crystal, As_4O_6 that the effective modes of lattice vibration which are responsible for the temperature dependence of the resonance frequency, are intra-molecular modes rather than a tipping mode of the molecule as a whole.

§ 1. Introduction

A theory for the temperature dependence of the nuclear quadrupole resonance frequency was first proposed by Bayer[1], and it was modified by a few investigators[2),3),4)], and the discrepancy between the theories and observed data which exists more or less in almost all cases, was explained by Kushida, Benedek, and Bloembergen[5]*. They observed pressure dependence of the resonance frequency at various temperatures and pointed out that the temperature dependence at constant pressure includes not only an explicit temperature dependenec in the amplitude of particular mode of lattice vibration $\langle\theta^2\rangle$ but also an implicit temperature dependence via the volume dependence of the static field gradient $q(V)$ as well as $\langle\theta^2\rangle$. And KBB obtained the value of q and $\langle\theta^2\rangle$ as a function of volume and concluded that the observed temperature dependence of the resonance frequency is accounted for by Bayer type theory, if the effects of the thermal expansion on q and $\langle\theta^2\rangle$ are properly taken into account. They also obtained many other important informations from the values of $q(V)$ thus derived.

---

* Hereafter their article will be referred as KBB.

Recently Barnes and Engardt[6] explained the anomalous positive temperature dependence of bromine quadrupole resonance frequencies in titanium tetrabromide $TiBr_4$ in terms of the large and negative pressure dependence of these lines on the base of KBB's analysis.

It is the purpose of this article to see how precisely and to what extent the KBB theory is applicable. The resonance frequencies studied under hydrostatic pressure in the present investigation are in the range of 100–250 Mc/sec at various temperatures which include liquid oxygen temperature.

The possibility of deviation from KBB theory was first suggested by Walsh[7] in his pressure experiment of electron spin resonance for ammonium alum $(NH_4)_2SO_4\cdot Al_2(SO_4)_3\cdot 24H_2O$. He pointed out the importance of " out-of scale " displacements of individual atoms in a unit cell under hydrostatic pressure even for a cubic crystal.

The similar idea was also proposed by Bernheim and Gutowsky[8] when they explained the observed deviation from V^{-1} law[5] for the volume dependence of the quadrupole splitting of Na^+ in ionic crystals with the form $NaXO_3$, in which X is either Cl, Br, or N.

Because cubic crystals are appropriate in order to check this kind of mechanism, SnI_4 and As_4O_6 were chosen in the present investigation. And p-$C_6H_4Br_2$ and $KBrO_3$ were also used in order to make comparison with the KBB's results for similar samples p-$C_6H_4Cl_2$ and $KClO_3$ respectivaly.

It was intended also that the volume dependence of the doublet lines in SnI_4 was compared with each other and that their different behavior would be accounted for by the chemical inequivalence of the positions for iodine nuclei. It is suggested that the similar study of the pressure dependence of multiplet lines in many other samples would reveal the detailed origin of such multiplicity.

§ 2. Experimental Method

The apparatus used in the present experiment consists of *a*) a high-pressure pump and a pressure gauge, *b*) a pressure bomb in which an rf coil and the sample are enclosed, and *c*) a spectrometer and a frequency meter.

In Fig. 1 is shown the main part of the apparatus. At the right part of the figure is seen the high-pressure pump* which generates hydrostatic pressure up to 10000 kg/cm². The pressure-generating cylinder is made of Cr-Mo-steel (SCM3) with 120 mm o.d., 16 mm i.d., and 200 mm height. The plunger which is made of high carbon steel (S55C) and has a Bridgman packing[9], is driven by the 30-ton hydraulic rum.

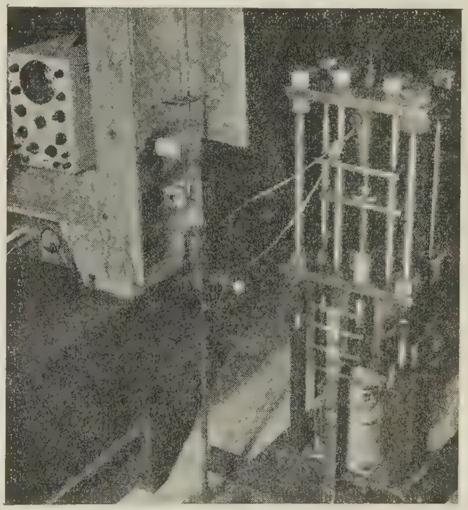

Fig. 1. Photograph of the main part of the experimental apparatus.

It is noted that the active volume of the cylinder is made large enough compared with the sample space of the bomb so that a by-pass pump system[9] can be eliminated.

A pressure gauge which consists of manganin wire[9] is installed in a gauge coil plug at the upper part of the wall of the cylinder. An Amagat cone-seal[9] is used as a high pressure electrode for the gauge coil, and the details of its insulator part will be shown later. The change in the resistance of the coil caused by the pressure is measured with a conventional bridge, and overall accuracy of the pressure measurement with this method is about 5 kg/cm^2. The gauge coil is calibrated against the freezing point of mercury at 0°C[9], using the discontinuity in the resistance of mercury at the freezing point.

---

* The high-pressure pump was designed by Professor Y. Kôi and constructed under his guidance.

In Fig. 2 is shown the high-pressure bomb assembly. It is similar in structure to the one used by Benedek and Kushida[10] when they observed the pressure dependence of NMR line in antiferromagnetic MnF_2. The material of the bomb is, however, the same kind of steel as the pressure-generating cylinder, since it is less expensive than Be-Cu which was used by them, and satisfactory for the present zero-field measurement, if frequency modulation is used. The o.d. and the i.d. of the bomb are 60 mm and 12 mm respectively, and the bomb was tested several times up to 10 000 kg/cm^2 and is used regularly up to 9000 kg/cm^2. The bomb and the pressure-generating cylinder are connected with a piece of flexible stainless-steel tubing (1/8″ o.d. and 0.025″ i.d.)*.

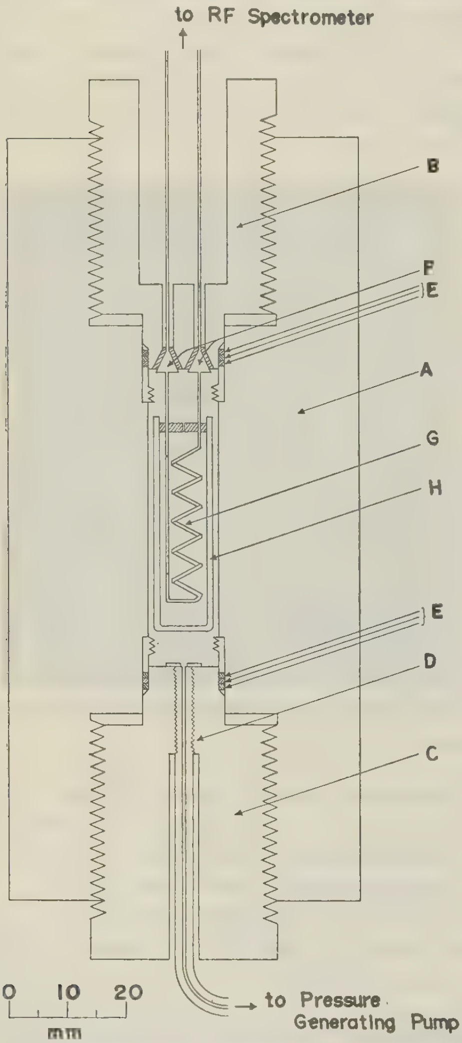

Fig. 2. High-pressure bomb and plug assembly. (*A*) Cr-Mo-steel bomb. (*B*) (*C*) Cr-Mo-steel plug. (*D*) Stainless steel connecting tubing. (*E*) Sealing washers. (*F*) Conical seals for electrical terminals. (*G*) Radio frequency coil. (*H*) Sample holder

A pair of Amagat cones were used as high-pressure electrical leads of the bomb. Since these leads are connected to an rf sample coil in the bomb, the insulator of the high-pressure leads ought to be chosen with a special care. Although the traditional material, pipe stone, was used by KBB[5], this is not appropriate for the present purpose, because of its relatively high dielectric loss in the frequency range of the present experiment. Walsh[7] and Benedek-Kushida[10] reported that artificial mica is satisfactory for this purpose in sub-micro to microwave region.

Therefore, artificial mica, Micalex M-21**, was tried first as the insulating material. Its electrical character was found to be satisfactory, and the initial sealing of the conical shell was achieved with the doping by epoxy resin. Chances of cracking were increased, however, with the increase in thickness of the conical shell, which was necessary at the frequency of 200 Mc/sec or more in order to reduce the capacity between the bomb and the electrodes. More precise machining might improve the situation.

As an easy method epoxy resin shell was tried, which can be made simply by curing the resin between the cone and the bomb without any skillful machining, and was found to give fair result below 150 Mc/sec. This type of electrical lead has been used at the gauge coil plug for a long time without any trouble. Although this method of sealing has a disadvantage of relatively high dielectric loss above 200 Mc/sec, the mixing of either Micalex or MgO_2 powder with this material improved the high frequency character, and the frequency range in the present experiment was safely covered with this method.

---

* This tubing was purchased from Harwood Engineering Co., Inc., U.S.A.

** Product of Toshiba Electric Co.

Petroleum benzine was used as pressure-transmitting medium at and above −77°C. Even at −77°C the pressure in the bomb was believed to be hydrostatic up to 9000 kg/cm², because any abrupt broadening of the line width was unobserved. At liquid oxygen temperature, petroleum ether was used, and the measurement was carried out up to about 1000 kg/cm², using another bomb. Its steel connecting tubing (6 mm o.d. and 2 mm i.d.), comes out through the same plug as the electrical leads in order to minimize the dipping of the tubing in the liquid oxygen. The maximum pressure available at this temperature is limited by the freezing of the transmitting liquid in the tubing instead of by its freezing in the bomb, as is evidenced by the fact that the pressure shift of the resonance frequency stops increasing before the line width increases suddenly when the pressure is increased above this limit. Therefore, it is suggested that the measurement under the higher pressure at this temperature would be possible, if the sample and the gauge coil are installed in the same bomb, the pressure is applied to the bomb first without cooling, and then the whole assembly is cooled down in the liquid oxygen bath.

Kôi's spectrometer[11] is satisfactory for the detection of the resonance line. This spectrometer has Lecher-line tuning circuits and can be used either as a regenerative or a superregenerative spectrometer. Usually superregenerative scheme was used in order to get a better signal to noise ratio. The resonance lines were displayed on a CRO screen, and their frequencies were measured by superposing a signal from a heterodyne wavemeter on the resonance signal, the accuracy of the measurement being better than 5 kc/sec.

§ 3. Experimental Results

A) *Stannic Iodide* SnI_4

The sample is an assembly of fine crystal grains which were prepared by heating the stoichiometric amount of Sn and I in an evacuated ampule.

Doublet quadrupole lines for this sample was first observed by Dehmelt[12] at room temperature, and they were explained in terms of a chemical inequivalence of the positions for iodine nuclei. The temperature dependence of the resonance frequencies for these doublets was measured as well[13),14)].

In the present experiment the resonance frequency was measured as a function of hydrostatic pressure up to 9000 kg/cm² at

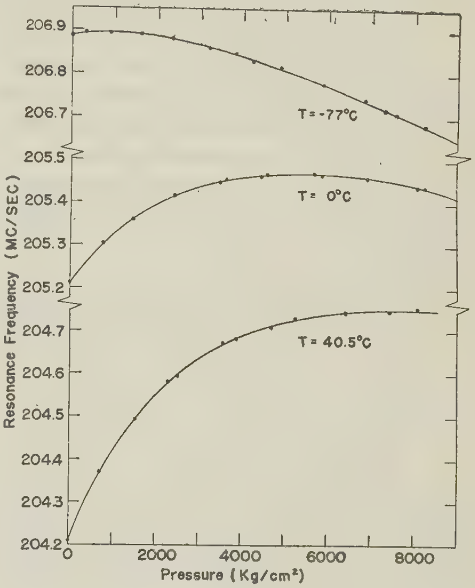

Fig. 3(a). The resonance frequency of the higher frequency line of the I^{127} doublet lines in SnI_4 plotted as a function of pressure at three temperatures.

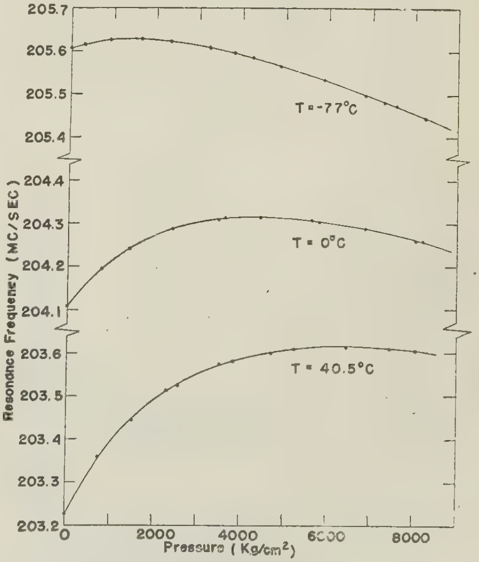

Fig. 3(b). The resonance frequency of the lower frequency line of the I^{127} doublet lines in SnI_4 plotted as a function of pressure at three temperatures.

$-77°$, $0°$, and 40.5°C. At each temperature the measurements were repeated while the pressure was increased and decreased. Right after the pressure was varied, the resonance frequency was not stationary, and it drifted to the direction which can be explained in terms of the recovery from an adiabatic heating or cooling during the change in the pressure. After several minutes the frequency reached the stationary value, which has no hysteresis within the experimental error. Each component of the doublet lines was measured alternatively at each pressure in order to measure the separation between these lines precisely.

The pressure dependence of the resonance frequencies for the higher and the lower frequency lines are shown in Figs. 3(a) and 3(b), respectively. At liquid oxygen temperature the resonance frequency decreased linearly with the increasing pressure up to 1000 kg/cm^2, and the values of $(\partial\nu/\partial P)_{P=0}$ for the higher and the lower frequency lines are 75 and 47 cps/(kg/cm^2), respectively. Their resonance frequencies at atmospheric pressure at this temperature were 208.912 and 207.481 Mc/sec.

B) *Arsenolite* As_4O_6

The sample was of commercial reagent grade with purity of 99.8%. In Fig. 4 the resonance frequency of As^{75} in this sample is plotted as a function of pressure at $-77°$, $0°$, and 97°C, respectively*. The resonance frequency at liquid oxygen temperature is found to be 116.837 Mc/sec*, and the pressure shift at 1000 kg/cm^2 is smaller than the line width, 10 kc/sec, which has been broadened by pressure.

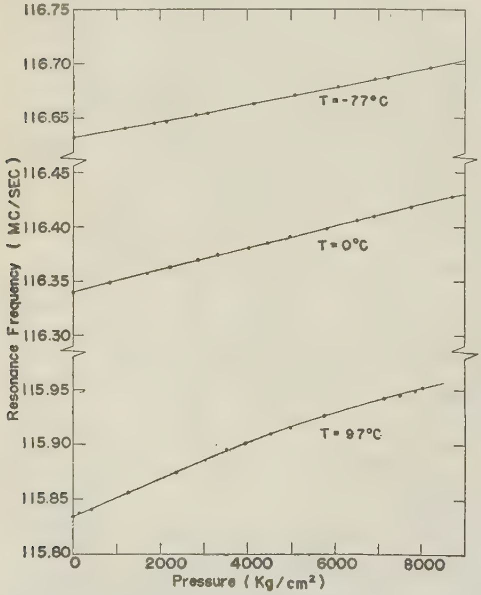

Fig. 4. The resonance frequency of the As^{75} nucleus in As_4O_6 as a function of pressure at three temperatures.

C) *Paradibromobenzene* p-$C_6H_4Br_2$

The sample was recrystallized from an alcoholic solution. In Fig. 5 the pressure dependence of Br^{81} in this sample is shown as a function of pressure at $-77°$, $0°$, and 44.5°C, respectively. It is noted that the resonance frequency decreases almost linearly with increasing pressure at -77°C. This behavior ought to be compared with the similar experiment of KBB[5] for p-$C_6H_4Cl_2$, where *ν-versus-P* curve shows the similar linear decrease only above 4000 kg/cm^2.

The resonance frequency at the liquid oxygen temperature decreased linearly with pressure up to 1000 kg/cm^2, and it was found

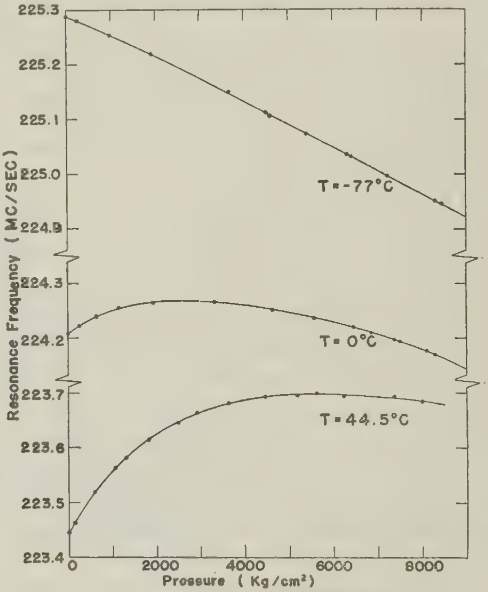

Fig. 5. The resonance frequency of the Br^{81} nucleus in p-$C_6H_4Br_2$ as a function of pressure at three temperatures.

---

* Since the observed temperature dependence of the resonance frequency at atmospheric pressure is slightly different from the value reported by Bray, O'Keefe, and Barnes[15], the measurement of the resonance frequency at -77°C and liquid oxygen temperature was repeated with the regenerative spectrometer.

that $(\partial\nu/\partial P)_{P=0}=85$ cps/(kg/cm^2), and $\nu_{P=0}=$ 226.398 Mc/sec.

D) *Potassium Bromate* $KBrO_3$

The sample is the assembly of fine crystals which were recrystallized from aqueous solution. In Fig. 6, *ν-versus-P* curves are plotted at three temperatures, −77°, 0°, and 97.5°C, respectively. At the liquid oxygen temperature the frequency increases linearly with pressure up to 1000 kg/cm^2, and it was found that $(\partial\nu/\partial P)_{P=0}=86$ cps/(kg/cm^2), and $\nu_{P=0}=$ 149.212 Mc/sec.

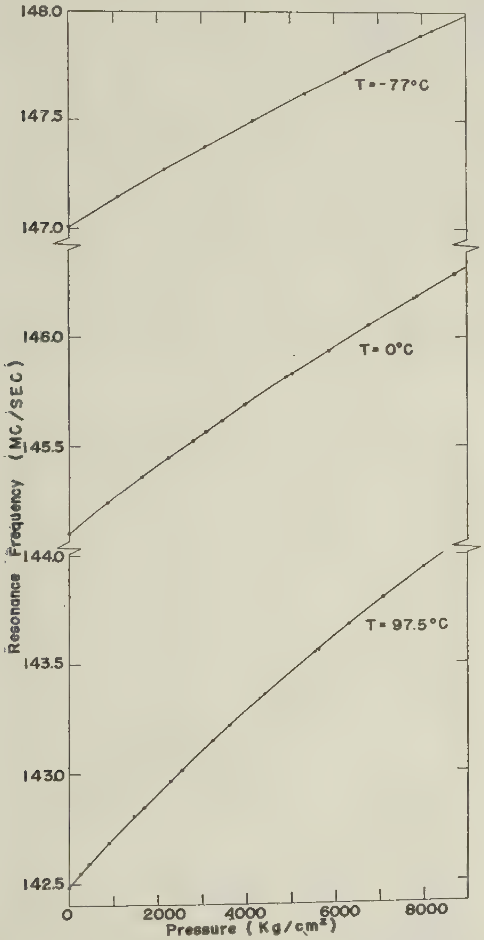

Fig. 6. The resonance frequency of the Br^{81} nucleus in $KBrO_3$ as a function of pressure at three temperatures.

The pressure experiment was also tried for $NaBrO_3$, but this material reacted with the transmitting fluid explosively at about 2000 atmos. The similar explosion was reported by KBB[5] for $NaClO_3$.

§ 4. Analysis of experimental data

Since the experimental results were analyzed on the basis of KBB, theory[5], its essential points will be summarized here.

The pure quadrupole resonance frequency is expressed by

$$\nu=\nu_0(1-3/2\langle\theta^2(t)\rangle_{AV})\ , \qquad (1)$$

where ν_0 is the resonance frequency when the effect of lattice vibration does not exist, $\theta(t)$ is the tipping angle of the maximum principal axis of field gradient tensor caused by the lattice vibration, and $\langle\ \rangle_{AV}$ denotes the average over the time. If $\langle\theta^2(t)\rangle_{AV}$ is expanded with respect to normal modes of vibration, and the energy of each normal mode thus obtained is equated to that of corresponding harmonic oscillator we obtain.

$$\nu=\nu_0\left[1-\frac{3}{2}\sum_{i=1}^{N}\frac{A_i}{\omega_i^2}\hbar\omega_i\times\left(\frac{1}{2}+\frac{1}{\exp(\hbar\omega_i/kT)-1}\right)\right]. \qquad (2)$$

Here the summation ought to be carried out over all the normal modes, but actually the effect of higher-frequency modes can be neglected due to the factor $1/\omega_i$. And Eq. (2) is reduced to the following equations, if the relation $x\equiv\hbar\omega/(kT)\leq 2$ holds,

$$\nu=a(1+bT+c/T)\ , \qquad (3)$$

were

$$a=\nu_0=\frac{eQq_0}{2I(2I-1)}\left(3m_z-\frac{3}{2}\right), \qquad (3a)$$

$$b=-\frac{3}{2}\,k\sum_{1}^{M}\frac{A_i}{\omega_i^2}\ , \qquad (3b)$$

$$c=-\frac{\hbar^2}{8k}\sum_{1}^{M}A_i\ . \qquad (3c)$$

Here a, b, and c, which generally depend of volume, can be obtained as a function of volume, if the $\nu(V, T)$ is measured experimentally. Since the measured value in the present experiment is, however, $\nu(P, T)$, equation of state, either empirical or theoretical, is necessary for this purpose. KBB[5] used the following semi-empirical equation for compressibility χ,

$$\chi(T, V)=-\frac{1}{V}\frac{\partial V}{\partial P}=\frac{V_0}{V}\chi_{00}\Big/\left[1-\zeta\left(\frac{V-V_0}{V_0}\right)\right], \qquad (4)$$

where ζ is a constant, whose value is 3.33 for wide range of solids, if use is made of Birch-Murnagham law[16]. And V_0, χ_{00} denote, respectively, the equilibrium volume and the compressibility at $T=0°K$ and $P=0$ atmos. The integral of Eq. (4) determines P-V isotherms with integration constants determined by thermal expansion coefficient.

Thus a, b, and c can be determined as a function of volume, from ν-*versus*-V isotherms at three different temperatures. Hence, the volume dependence of q_0, ω_i, and A_i can also be deduced respectively, and they can be written as

$$\left.\begin{aligned} q_0(V)&=q_0(V_0)(V/V_0)^{n(V)}\,, && \text{(A)}\\ \omega_i(V)&=\omega_i(V_0)(V/V_0)^{-\gamma_i}\,, && \text{(B)}\\ A_i(V)&=A_i(V_0)(V/V_0)^{+\sigma_i}\,, && \text{(C)}\end{aligned}\right\} \quad (5)$$

If the average over i is taken, one obtains

$$\left.\begin{aligned} d\ln a/d\ln V&=n(V)\,, && \text{(A)}\\ d\ln|b|/d\ln V&=2\gamma+\sigma\,, && \text{(B)}\\ d\ln|c|/d\ln V&=\sigma\,. && \text{(C)}\end{aligned}\right\} \quad (6)$$

When an asymmetry parameter η of the field gradient tensor is small enough, which is the case treated by KBB, the volume change of the resonance frequency can be devided into two parts as follows:

$$\frac{\partial\ln\nu}{\partial\ln V}=\frac{d\ln q_0}{d\ln V}+\frac{\partial\ln\nu}{\partial\ln\langle\theta^2\rangle_{AV}}\frac{\partial\ln\langle\theta^2\rangle_{AV}}{\partial\ln V} \qquad (7)$$

$$=\frac{d\ln a}{d\ln V}+\left[\frac{db}{(d\ln V)}T+\frac{dc}{(d\ln V)}\frac{1}{T}\right]$$
$$/(1+bT+c/T)\,. \qquad (8)$$

These relations can be extended to the case of $\eta\neq0$ by slight modifications in b and c in Eq. (3).

For instance, if tipping motions about x and y axes which are perpendicular to the direction of q, are *assumed* to be sole normal modes of vibration which are responsible to the reduction in resonance frequenny, the following equation is obtained[17),

$$q=q_0\left\{1-\frac{3}{2}\hbar\left[\frac{1+\eta/3}{\Theta_y\omega_y}\left(\frac{1}{2}+\frac{1}{\exp(\hbar\omega_x/kT)-1}\right)\right.\right.$$
$$\left.\left.+\frac{1-\eta/3}{\Theta_y\omega_y}\left(\frac{1}{2}+\frac{1}{\exp(\hbar\omega_y/kT)-1}\right)\right]\right\}, \qquad (9)$$

where Θ_x and Θ_y are moments of inertia of the normal modes along x and y axes, and ω_x and ω_y are their vibration frequencies, respectively.

In this case, therefore, b and c are expressed by

$$b=-\frac{3k}{2}\left(\frac{1}{\Theta_x\omega_x{}^2}+\frac{1}{\Theta_y\omega_y{}^2}\right)$$
$$-\frac{\eta k}{2}\left(\frac{1}{\Theta_x\omega_x{}^2}-\frac{1}{\Theta_y\omega_y{}^2}\right), \qquad (10)$$

$$c=-\frac{\hbar^2}{8k}\left(\frac{1}{\Theta_x}+\frac{1}{\Theta_y}\right)-\frac{\eta}{24}\frac{\hbar^2}{k}\left(\frac{1}{\Theta_x}-\frac{1}{\Theta_y}\right). \qquad (11)$$

The effect of η can usually be neglected, except for the case with a large η, where its temperature and volume dependence ought to be determined experimentally.

A) SnI_4

Thermal expansion coefficient of SnI_4 was measured by Biltz *et al*[18) in the range −195° to 0°C, whereas its compressibility has not been measured yet, so far as the author

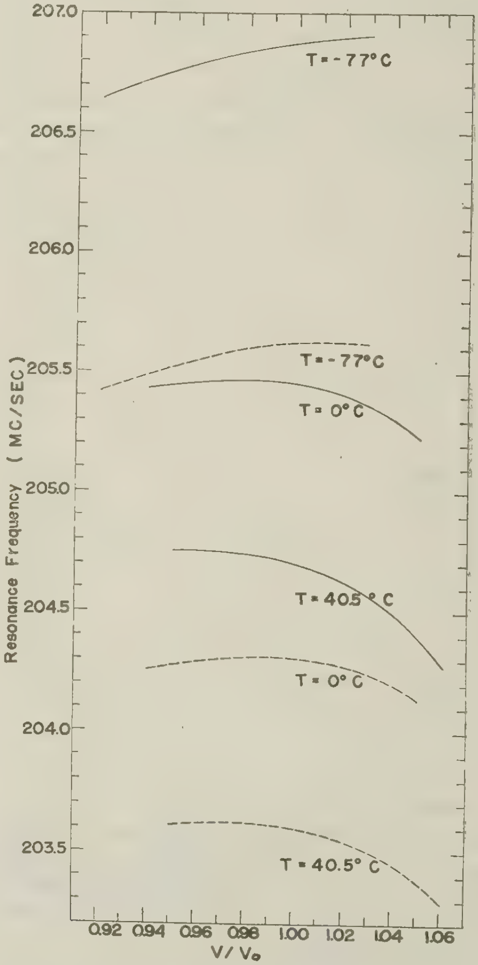

Fig. 7. The ν-*versus-volume* isotherms for SnI_4 derived from the experimental data using an equation of state. The solid curves show the results for the higher-frequency line of the doublet, and the dashed curves show those for the lower-frequency line.

knows. Therefore its compressibility was measured here with a lever piezometer which is the same as was used by Bridgman[9], and the result is $16\times10^{-6}/(\mathrm{kg/cm^2})$ at room temperature (12°C).

By using Eq. (4), the *P-versus-V* isotherms for this sample were determined with these values of thermal expansion coefficient and compressibility, in conjunction with the value 3.33 for ζ. And ν*-versus-P* curves which were obtained experimentally, were transferred into ν*-versus-V* curves as shown in Fig. 7.

First it was tried to determine the value of c at $V/V_0=1$, but the experimental error did not allow this value to be determined definitely. Its value is, however, very small, as is evidenced by the fact that ν*-versus-T* relation at constant volume is almost linear. Therefore, the moment of inertia $\langle\Theta\rangle=1/\langle A\rangle$ has large value. This is compatible with the following estimate of the moment of inertia, namely if one evaluates the moment of inertia of a tetrahedral molecule SnI_4 about an axis which passes through its center of gravity, one obtains $\Theta=3900\times10^{-40}\,\mathrm{g\,cm^2}$, which corresponds to $c=0.005$.

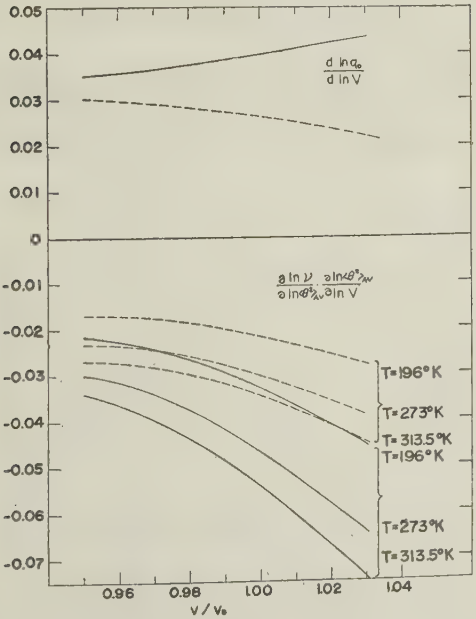

Fig. 8. The contribution from the volume dependence of the static field gradient q_0 and that of the lattice vibration, to the volume dependence of the resonance frequency for SnI_4. The solid and the dashed curves are those for the higher and the lower frequency lines, respectively.

In Fig. 8 are plotted the contributions to $\partial \ln\nu/\partial \ln V$ from q_0 and $\langle\theta^2\rangle_{AV}$, respectively. These two contributions have opposite signs with each other as shown there. This is similar to the results for $p\text{-}C_6H_4Cl_2$ obtained by KBB[5], but here the $\langle\theta^2\rangle_{AV}$ contribution depends more strongly on the volume than the case of $p\text{-}C_6H_4Cl_2$, and this tendency is more striking for the higher-frequency line. The volume dependence of the $\langle\theta^2\rangle_{AV}$ contribution is rather similar to those for $KClO_3$ than to those for $p\text{-}C_6H_4Cl_2$, and its temperature dependence at constant volume is almost linear, indicating $dc/d\ln V$ in Eq. (8) to be negligibly small.

Now let us compare the higher-frequency line (solid curve) with the lower-frequency line (dashed curve). Both the q_0 and the $\langle\theta^2\rangle_{AV}$ contributions for the higher-frequency line are larger in magnitude and stronger in their volume dependence than those for the lower-frequency line, and the differences between the curves for the two lines have the tendency to decrease to zero at a smaller volume. The same tendency is seen for the *b-versus-V* and the $1/2\cdot\partial \ln b/\partial \ln V$*-versus-V* curves in Fig. 9.

It is necessary to estimate the value of σ in order to obtain the value of γ (a modified Grüneisen's constant) from the volume dependence of b. The accuracy of experiment is, however, generally insufficient for the accurate estimate of σ[5]. Although SnI_4 is not an ideal molecular crystal[21], it may be safe to assume that σ is very small as is the case for a typical

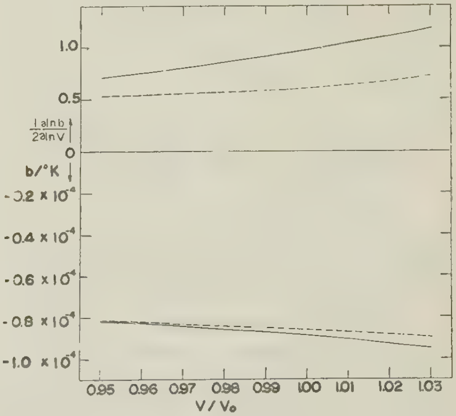

Fig. 9. The volume dependence of $1/2\cdot\partial\ln b/\partial\ln V$ and b for SnI_4. The solid and the dashed curves correspond to the higher and the lower frequency lines for the doublet, respectively.

molecular crystal. And if this assumption is admitted, it is concluded that there is considerable difference between the values of γ for the two resonance lines, and this difference decreases in magnitude with decreasing volume. This deduction is compatible with the following observation in the low-frequency Raman lines in molecular crystals: Ichishima[19] investigated their temperature dependence and found that $1/\omega \cdot d\omega/dT$ is different for different components of multiple lines.

The different behaviors of the doublet lines in SnI_4 stated above may be explained as follows: Stannic iodide crystal[20] consists of SnI_4 tetrahedrons, and each tetrahedron is slightly distorted so that only one I atom (I_I) is at a position with three fold symmetry, and the other three (I_{II}) lie at slightly less symmetric positions, as has been pointed out by Dehmelt[12]. Therefore, the resonance line due to I_{II}'s has non vanishing asymmetry parameter, which amounts to 0.8%. The two SnI_4 tetrahedrons are situated so that the base planes of the tetrahedrons, each of which consists of three I_{II}'s, face each other with the relation of a screw rotation by 60° about an axis of three-fold symmetry, and they have a slight tendency to form a kind of associated molecule Sn_2I_8[21]. The separation of the doublet resonance lines in SnI_4 is caused by an inter-molecular effect as was discussed by Schawlow *et al*[13,14], and the I_{II} atoms which are responsible for the lower-frequency line, must be influenced by neighboring molecules more strongly than the I_I atoms, because inter-molecular hybridization usually decreases the value of q, as is evidenced by the observed positive value of $\partial \ln q/\partial \ln V$ for this specimen. Therefore. it is natural to assume that the relative displacement between the pair of tetrahedrons stated above behave differently from the displacements among the other neighboring tetrahedrons, when the sample is subjected to a hydrostatic pressure. And this assumption enables the explanation of the facts that $\partial \ln q/\partial \ln V$, $\partial \ln \nu/\partial \ln \langle\theta^2\rangle_{AV} \cdot \partial \ln \langle\theta^2\rangle_{AV}/\partial \ln V$, b, and $\partial \ln b/\partial \ln V$ are all larger in magnitude for the higher-frequency line than for the lower one, and the differences between the values for the two lines have a tendency to decrease with decreasing volume.

In another word, it may be concluded that the distance between the pair tetrahedrons is slightly more rigid under the hydrostatic compression than the distances between the other tetrahedrons, therefore, the resonance line originated from I_I atoms is influenced more strongly under the pressure than I_{II} line, and with the increase of the degree of compression, this difference decreases and all the molecular distances would be compressed more homogeneously with the further compression. It should be noted that the effect of asymmetry parameter itself is negligible as stated before.

It is suggested that the study of the pressure dependence of multiplet lines in general would give an important clue for the understandings of the origin of the multiplets and of a detailed behavior of the molecules in a unit cell as well. For instance, the pressure dependence of triplet Cl lines in chloral hydrate $CCl_3CH(OH)_2$ would be interesting, because only two components of the triplets are believed to have hydrogen bonds[17].

B) As_4O_6

Thermal expansion coefficient for As_4O_6 is[22],

$$41.2\times10^{-6}-67.9\times10^{-9}(T-313),$$

and its compressibility at 30°C is[23], 9.29×10^{-6}. P-V isotherms for this specimen were determined with these values in conjunction with the value of 4.8 for ζ.

Since the pressure coefficient of the resonance frequency at liquid oxygen temperature was so small that it was not determined ac-

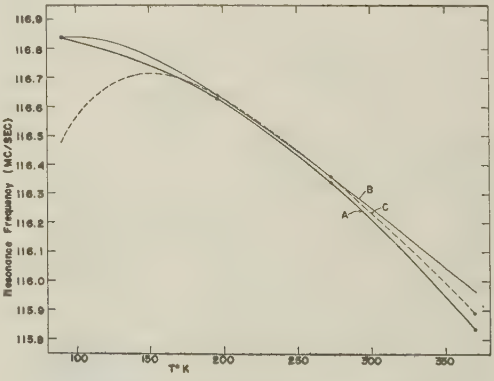

Fig. 10. The ν-*versus-temperature* curves for As_4O_6. Curve (A) is the temperature dependence of ν at atmospheric pressure. Curves (B) and (C) are $a(1+bT+c/T)$ curves calculated from the three lower and the three higher temperatures, respectively, at the constant volume which corresponds to liquid oxygen temperature and atmospheric pressure.

curately enough, $\nu(T)$ curve at constant volume was determined only at the volume which corresponds to the temperature of liquid oxygen and to the atmospheric pressure. This volume was estimated with the thermal expansion coefficient. The resonance frequency at the same volume at −77°, 0°, and 97°C, and the frequency at liquid oxygen temperature under the atmospheric pressure were tried to be fitted to Eq. (3), which is expected from the high temperature approximation of the Bayer type theories. The results are, however, unsatisfactory as are shown in Fig. 10. In this figure curve (B) represents Eq. (3) with the values of a, b, and c determined with the use of the three lower-temperature points, and curve (C) is the similar curve with the same parameter determined at the three higher-temperatures. This discrepancy indicates that the approximate equation (3) at high temperature fails to hold at about 90°K and the relation, $x \equiv \hbar\omega/(kT) < 2$, does not hold at this temperature, because the value of Θ is small and hence ω is large. Therefore, one ought to return to the original equation Eq. (2). Assuming $N=2$, $\omega_1=\omega_2=\omega$, and $A_1=A_2=A=1/\Theta$ on the basis of the crystal structure, one obtains,

$$(\nu_{90}-\nu_{196}):(\nu_{196}-\nu_{273}):(\nu_{273}-\nu_{370})$$

$$=\left(\frac{1}{\exp(\hbar\omega/196k)-1}-\frac{1}{\exp(\hbar\omega/90k)-1}\right)$$

$$:\left(\frac{1}{\exp(\hbar\omega/273k)-1}-\frac{1}{\exp(\hbar\omega/196k)-1}\right)$$

$$:\left(\frac{1}{\exp(\hbar\omega/370k)-1}-\frac{1}{\exp(\hbar\omega/273k)-1}\right).$$

And the best choice for the value of the lattice vibration frequency $\tilde{\nu}$ is in wave number unit, $\tilde{\nu} \equiv \omega/2\pi c = 370\,\mathrm{cm}^{-1}$ at the lower three temperatures, and it is $440\,\mathrm{cm}^{-1}$ at the higher three temperatures. In any case the value of x is greater than 5 at 90°K.

The moment of inertia deduced from the value ω is 17×10^{-40} and $11\times10^{-40}\,\mathrm{g\,cm}^2$ in the two temperature regions respectivly, volume which corresponds to liquid oxygen temperature and atmospheric pressure.

There are two points to be noted. First, the value of the moment of inertia thus obtained is much smaller than that of As_4O_6 molecule about its center of gravity, which amounts to about $1700\times10^{-40}\,\mathrm{g\,cm}^2$. The second point is that the value of ω thus determined appears to depend explicitely on the temperature.

The first point can be explained only by assumming that the dominant mode of lattice vibration which is responsible to the reduction in the resonance frequency, is intramolecular vibration instead of tipping motion of the molecule as a whole as in the case for usuall molecular crystals.

Although a unique explanation for the second point does not seem to be possible from the present experiment, either unharmonicity of the vibration considered above, or some distribution of the intra-molecular vibrations (or both) could account for this point.

The pressure dependence of the resonance frequency in this sample will be considered now. Although negative pressure dependence of ν is usually observed at low temperature in such molecular crystals as p-$C_6H_4Cl_2$ and p-$C_6H_4Br_2$ and even in SnI_4, no such tendency is observed even at liquid oxygen temperature for this specimen.

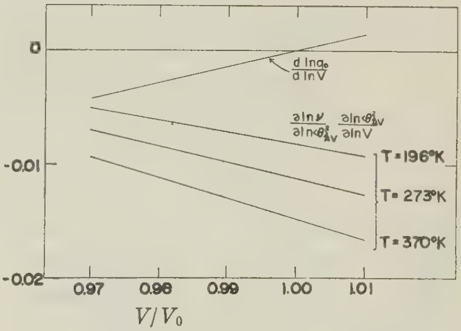

Fig. 11. The contribution of the volume dependence of q_0 and that of the lattice vibration to the volume dependence of the resonance frequency for As_4O_6 at three temperatures.

In spite of the ambiguity mentioned above in applying KBB's analysis to this sample, the volume dependence of the resonance frequency is analyzed along the KBB method. The result thus obtained is shown in Fig. 11, where the contributions to $\partial\ln\nu/\partial\ln V$ from the q_0 and the $\langle\theta^2\rangle_{AV}$ terms are shown. The volume dependence of b is also small, and the value of γ at $V/V_0=1.00$ is only 0.3. This can be explained in terms of the fact that the intramolecular bending motions play the most important role to the temperature dependence of the resonance line.

C) p-$C_6H_4Br_2$ and $KBrO_3$

Mean thermal expansion coefficient of p-$C_6H_4Br_2$ in the temperature ranges 20° to −77°C and 20° to −183°C are 138×10^{-6} and 98×10^{-6} deg^{-1}, respectively. Its compressibility is found to be 15.5×10^{-6}/(kg/cm^2) at room temperature (12°C). From Eq. (4), the equation of state was obtained using these values as well as the value of 3.33 for ζ.

The result of the analysis is shown in Figs. 12 and 13. The contributions of q_0 and $\langle\theta^2\rangle_{Av}$ to $\partial\ln\nu/\partial\ln V$, which are similar to the case of SnI_4, are drawn in the former figure, and the volume dependence of b and γ are shown in the latter one, where the value of γ is found to be roughly equal to that of isomorphic p-$C_6H_4Cl_2$. Using the data of two low-frequency Raman lines[24], the value of b is estimated as $b=-0.55\times10^{-4}$/°K. The agreement between this value and the value shown in Fig. 13 can be regarded as reasonable, if it is taken into account that the compression under the pressure could not be isotropic because of less symmetric crystal structure.

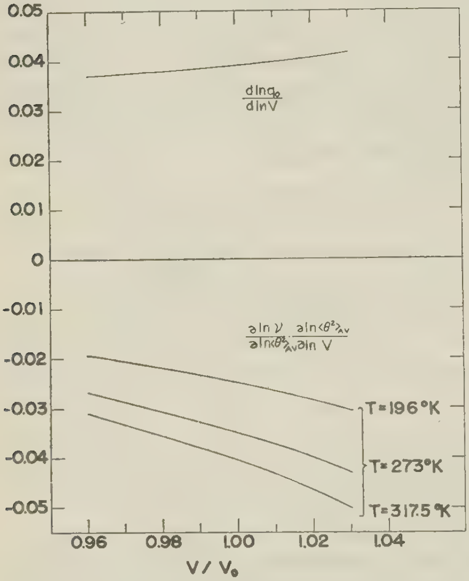

Fig. 12. The contribution of the volume dependence of q_0 and that of the lattice vibration to the volume dependence of the resonance frequency for p-$C_6H_4Br_2$ at three temperatures.

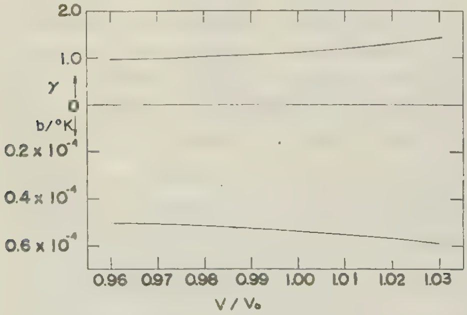

Fig. 13. The volume dependence of b and γ for p-$C_6H_4Br_2$.

The pressure dependence of $KBrO_3$ is found to be quite similar to that of $KClO_3$ which was extensively investigated by KBB already, and therefore, the result will not be shown here.

Acknowledgement

The author wishes to express his sincere thanks to Professor Y. Kôi at Tokushima University for suggestting this investigation and for his guidance throughout this experiment. He also appreciates valuable discussions with Professor T. Kushida at Hiroshima University and Professor J. Itoh at Osaka University. He is grateful to Mr. A. Tsujimura for his cooperation in the earlier stage of this experiment. The present investigation has partly been supported by the fund of the Ministry of Education.

Magnetic Anisotropy of Chromium Antimonide and its Manganese Substitites

By Ichiro TSUBOKAWA*

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received September 21, 1960)

Magnetic anisotropy of compounds of CrSb, $(Cr_{0.9}Mn_{0.1})Sb$ and $(Cr_{0.8}Mn_{0.2})Sb$ was investigated by using their single crystals. From the measurements of torque curves by means of torsion pendulum magnetometer, the difference between the susceptibilities parallel and perpendicular to the c-axis of the hexagonal crystal lattice was obtained for each specimen. It was confirmed that the magnetic spin axis lies along the c-axis for each compound. (also in the ferrimagnetic region of $(Cr_{0.8}Mn_{0.2})Sb$) The magnetic anisotropy constant K of CrSb was estimated to be about 10^5 erg/gr. at room temperature.

§ 1. Introduction

The magnetic properties of chromium antimonide and its manganese substitutes in powder form were studies by Lotgering and Gorter[1] and Hirone et al.[2] It has been known from these studies that these compounds have either antiferromagnetic spin ordering or both ferromagnetic and antiferromagnetic spin ordering with a temperature transition between them. Snow[3] showed by neutron diffraction experiments that the spin magnetic moment of each cation in chromium antimonide orients along the c-axis of the hexagonal crystal lattice. In order to study the magnetic anisotropy of these compounds and the interesting magnetic behavior, the present author measured the magnetic anisotropy by using single crystals of these compounds.

§ 2. Specimens and the Method of Measurement

Single crystals of chromium antimonide and the manganese substitutes were prepared in the following way. First, the powders of these compounds, CrSb, $(Cr_{0.9}Mn_{0.1})Sb$ and $(Cr_{0.8}Mn_{0.2})Sb$ were made by the ceramic method as described in the pervious paper.[2] The compounds perpared in this way were then pressed into a rectangular rod with a pressure of six tons per square centimeter. These compressed bars were sealed in evacuated silica tubes, heated at temperatures several degrees above the melting points of each specimen, and cooled in a furnace at a rate of a few degrees per minute. The size of single crystals obtained were about 4×4 millimeters square and 10 millimeters in length.

The crystallographic orientation was determined by means of Laue photographs within an accuracy of a few degrees. A magnetic torsion pendulum magnetometer was used to measure the anisotropy of magnetic susceptibility. The difference of principal magnetic susceptibilities can be expressed by the following equation,

---

* Present address is Totsuka Works, Hitachi, Ltd. Yokohama, Japan.

$$\chi_a-\chi_c=\frac{2L}{mH^2\sin 2\theta}\,, \tag{1}$$

where m is the mass of the specimen, L the torque in the specimen due to the magnetic field H and θ the angle between the c-axis and the applied field.

§ 3. Experimental Results

First, an example of the torque curve in the $a-c$ plane for a single crystal of chromium antimonide at various temperatures in a magnetic field with a field strength of 6420 Oe are shown in Fig. 1. Each curve shows that the torque changes nearly as sin 2θ with the angle θ, and its amplitude decreases with a rise of temperature. It was also confirmed that the torque value changes linearly with the square of the applied magnetic field strength, and example at liquid nitrogen temperature being shown in Fig. 2. On the basis of equation, (1) the difference of susceptibilities perpendicular and parallel to the c-axis of the crystal, $(\chi_a-\chi_c)$, are obtained as shown in Fig. 3. On the other hand, the powder susceptibility may be expressed as an average of parallel and perpendicular susceptibilities by the well-known formula

$$\chi_p=\frac{1}{3}\chi_c-\frac{2}{3}\chi_a\,. \tag{2}$$

Using the previous data of powder susceptibility and the difference $(\chi_a-\chi_c)$ obtained by the present experiments, the values of χ_a and χ_c were calculated. The results are shown in Fig. 4. To confirm the results, the author

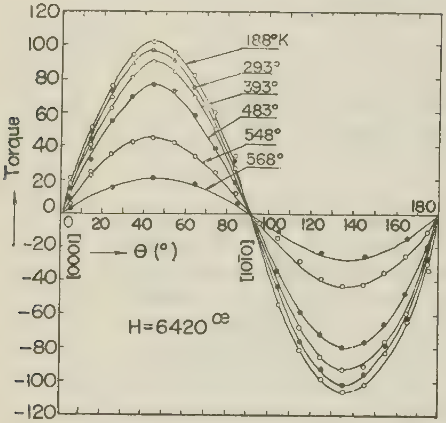

Fig. 1. Torque curves of a single crystal of CrSb in a–c plane.

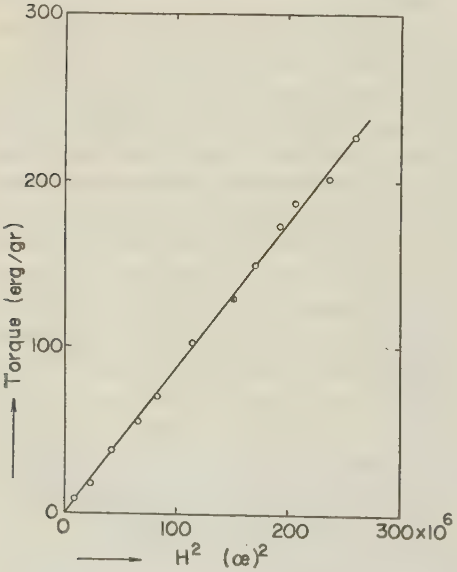

Fig. 2. Torque versus H^2 relation of CrSb.

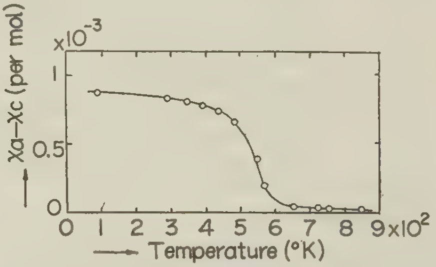

Fig. 3. $(\chi_a-\chi_c)$ of CrSb.

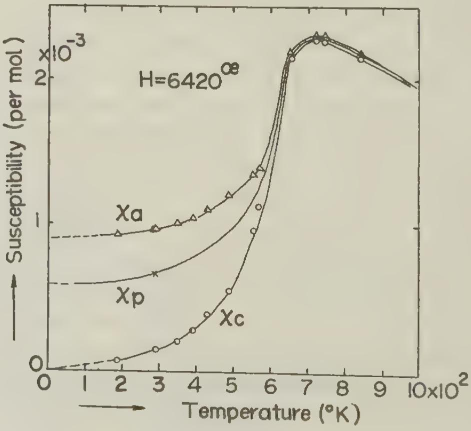

Fig. 4. χ_a, χ_c and χ_p of CrSb. ▲ and × are the values of χ_a and χ_p obtained by using the magnetic balance.

measured χ_a and χ_p of the same crystal at room temperature using a magnetic balance. The powder specimen was prepared from the original single crystal. The results are shown in Fig. 4 by the marks ▲ and ×. Each value agrees very well with the former curves.

The same measurements were also made for the compounds $(Cr_{0.9}Mn_{0.1})Sb$ and $(Cr_{0.8}Mn_{0.2})Sb$. It is known from the measurement of the powder susceptibility that the compounds are antiferromagnetic in a certain range below the Néel temperature, but become ferrimagnetic in the lower temperature range. In the antiferromagnetic region, the torque curves were represented nearly by sin 2θ as shown in Fig. 5 and Fig. 6. However, for the compound $(Cr_{0.8}Mn_{0.2})Sb$ at liquid nitrogen temperature, which is just below the ferrimagnetic transition point, the maximum points of the torque curves are displaced to the side of the c-plane (about 15° at the maximum field strength of 25.2 kOe) (Fig. 7). The relation of the maximum torque value versus the square of the magnetic field at several temperatures are shown in Fig. 8. As shown in Fig. 8, the maximum values of torque at the higher temperatures of the antiferromagnetic region change in proportion to the square of the magnetic field strength, however, at the lower temperature of the

region it increases more rapidly than the linear relation. As in the previous case of chromium antimonide, we obtained $(\chi_a-\chi_c)$ as shown in Fig. 9 and 10. χ_a and χ_c obtained with combining the previous data of powder susceptibilities[2] are shown in Fig. 11 and 12.

§ 4. Discussions

It is concluded from the torque measurement that the antiferromagnetic easy direction of CrSb is along the c-axis of the crystal. This fact is consistent with the results of neutron diffraction experiments by Snow.[3] In such a case, it is to be expected that the perpendicular susceptibility will be independent of temperature below the Néel point. Contrary to this expectation, present results show that the perpendicular susceptibility of chromium antimonide decreases with falling temperature from the Néel point to 400°K. This fact may be explained by a weakening of the antiferromagnetic interaction which is accompanied by the change of the lattice constant c (according to Snow's X-ray work,[4] the lattice constant c expands several percent during the temperature rise of these ranges). According to a molecular field approximation, the Néel point and the susceptibility of antiferromagnet are expresses as

$$T_N=\frac{2}{3}|J|zk^{-1}S(S+1)\,, \tag{3}$$

$$\chi_N=Ng^2\mu_B^2/4|J|z \tag{4}$$

where J is the exchange integral, z number of the nearest neighbour, K Boltzman's constant, S spin quantum number, χ_N the susceptibility at the Néel point, N Loschmit number, g Landé factor and μ_B Bohr magneton. The same consideration can be applied also to the other two compounds, since the same kind of behaviour appears in χ_a below the Néel point in these and, at the same time the measurement of the dilatation performed by Hirone et al[5] gives the change of lattice constants of the same order of magnitude. It is noticed for $(Cr_{0.8}Mn_{0.2})Sb$, that the torque versus H^2 curve at 15°C displaced from straight line appreciablly at above $H=20000$ Oe. This anomalous behaviour is considered to be based on the induced ferromagnetism of this crystal in the stronger field strengths. (At room temperature, the compound is antiferromagnetic from the previous susceptibility data and present torque measurement.)

Torque curves at liquid nitrogen temperature show that saturation could not be obtained at 13000 Oe. Ferrimagnetic easy direction is in the *c*-axis of the hexagonal crystal and coincide with the antiferromagnetic easy direction at higher temperatures.

Finally, we will show the results of the magnetic anisotropy constant for CrSb. Introducing the anisotropy constant, K, we can express the powder susceptibility by the formula[6]

$$\chi_p=\frac{1}{3}\chi_{||}-\frac{2}{3}\chi_{\perp}-\frac{2}{15K}(\chi_{||}-\chi_{\perp})^2H^2\,. \quad (5)$$

Thus, if we measure the χ_p as a function of H^2, then we can calculate K combining with the observed χ_a and χ_c. The obtained value of K is of the order of magnitude of 10^5 erg/gr at just below room temperature.

Extension of High Polymer Molecule and Energy Change by Mixing

By Hiroshi MIZUTANI

Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received September 28, 1960)

The change in intermolecular potential energy produced by mixing some low molecular liquids, which are considered as the substitute for the chain elements of polystyrene molecule, with several non-polar solvents and the extension of polystyrene molecule in these solvents were measured, and the obtained results were compared with the theory⁽¹⁾. Determination of the energy change was made by means of calorimetric method and that of the extension of polystyrene by measuring the intrinsic viscosity of the solution. We found that the variation of the extensions of polystyrene in different non-polar solvents is mainly determined by the difference in the energy change effected by the mixing of benzene, the side group of polystyrene, with the solvents.

§1. Introduction

The fact that the extension of high polymer molecule in solution depends on the kind of solvent may be ascribed to the difference in potential energies between chain elements of the high polymer molecule and solvent molecules. Since many properties of high polymer solution have an intimate relationship with the degree of the extension of high polymer molecule in solution, the investigation on the relation between the molecular extension in solution and the intermolecular potential energies between chain elements and solvent molecules must be of importance not only to the problem of moleculor extension but also to the study of the physical properties of high polymer solution.

According to the theoretical treatment⁽¹⁾, the mean square end-to-end distance $\langle r^2\rangle$ of the high polymer molecule in solution is given by

$$\langle r^2\rangle=\frac{\displaystyle\int \exp\left\{\frac{\sigma N^2}{\nu\tau}\frac{\Delta E}{kT}r^{-3}-\frac{3r^2}{2CN^\gamma}\right\}r^4dr}{\displaystyle\int \exp\left\{\frac{\sigma N^2}{\nu\tau}\frac{\Delta E}{kT}r^{-3}-\frac{3r^2}{2CN^\gamma}\right\}r^2dr}, \cdots\cdots(1)$$

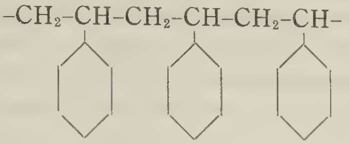
with

$$\Delta E=\frac{E_{pp}+E_{ss}}{2}-E_{ps}, \cdots\cdots\cdots\cdots(2)$$

where $-E_{pp}$, $-E_{ss}$ and $-E_{ps}$ are the mutual potential energies for chain element-chain element, solvent molecule-solvent molecule, and chain element-solvent molecule, respectively, σ the number of the nearest neighbors around a lattice point, N the number of chain elements, ν the number density of lattice points, τ a constant number $[(4\pi/3)\cdot(1/6^{3/2})]$, k Boltzmann constant, and CN^γ the end-to-end distance of high polymer molecule when the volume exclusion effect of chain element is taken into account, C and γ being constants. Eq. (1) is the formula for the end-to-end distance of high polymer molecule in solution obtained with due consideration for the interaction between the chain elements and the solvent molecules as well as for the volume exclusion effect of chain elements. From this equation we see that the end-to-end distance of high polymer molecule in solution is a monotone decreasing function of ΔE, the energy change produced when the chain element and a solvent molecule come in contact with each other (cf. Fig. 5). The problem thus reduces to the experimental investigation into the relation between $\langle r^2\rangle$ and ΔE for different solutions of a high polymer substance.

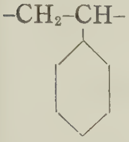
Since it is practically impossible to measure ΔE directly for high polymer solutions, we had instead recourse to the use of low molecular substance, which might be regarded as the equivalent to the chain element of the polymer. As the chain element we may assume the monomer of high polymer molecule or the units whose size are larger or smaller than monomer.

If we take polystyrene as a high polymer substance:

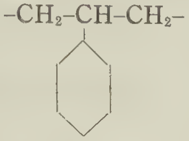


$-CH_2-CH-CH_2-CH-CH_2-CH-$

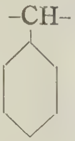
the conceivable chain elements are:



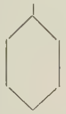
$-CH_2-CH-$



$-CH_2-CH-CH_2-$

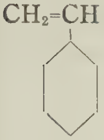


$-CH-$



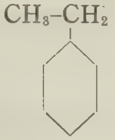
The corresponding stable molecules which might possibly behave in the same manner as these units are:

styrene



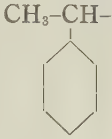
$CH_2=CH$

ethylbenzene



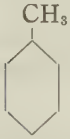
CH_3-CH_2

isopropylbenzen



$CH_3-CH-CH_3$

toluene



CH_3

benzene

Which molecule of these can be considered as the suitable substitute for the chain element of polystyrene may be judged by determining ΔE-values for that molecule in various solvents and trying to see if the ΔE-values thus determined and the $\langle r^2 \rangle$ -values, which can be obtained from the intrinsic viscosity $[\eta]$ of polystyrene solutions (see later), satisfy Eq. (1). The ΔE-value can be derived, as will be described in § 4, from the energy change ΔU, which in its turn can be determined from the mixing heat ΔH evolved (or absorbed) in the process of mixing the molecules with the solvent by the use of the relation[(2)]

$$\Delta U=\Delta H-T(\alpha/\beta)\Delta V. \cdots\cdots\cdots\cdots(3)$$

Here T is the absolute temperature, α the thermal expansion coefficient, β the isothermal compressibility, and ΔV the volume change brought about by mixing. The methods of measuring ΔH, ΔV and $[\eta]$ will be described in detail in the following sections.

§ 2. Measurement of Mixing Heat ΔH

The easiest and most accurate method of obtaining the mixing heat is perhaps to measure the heat transferred from an electric heater to the mixture of two liquids, which is required for componsation or reproduction of the temperature change according as heat is absorbed or evolved.

I) Apparatus

Employing this method, we constructed an apparatus which is an improved type of that devised by G. H. Cheesman and A. M. Beryl Whitaker[(3)] (Figs. 1 and 2). Main points of improvement are as follows:

i) Up-and-down motion of iron rod for mixing and stirring liquids is drived by an electro-magnet set outside the glass tube. D. C of constant voltage is used for the magnet to prevent the heating of the mixing vessel due to the electric induction. Make and break of circuit of the magnetic coil is performed by a rotary switch connected to a synchronous motor.

ii) As is shown in Fig. 1, a cylindrical piece of copper (indicated by D in the figure) with large heat capacity is used as temperature standard, with reference to which the temperature change in the mixing vessel is to be measured. In this way the measure-

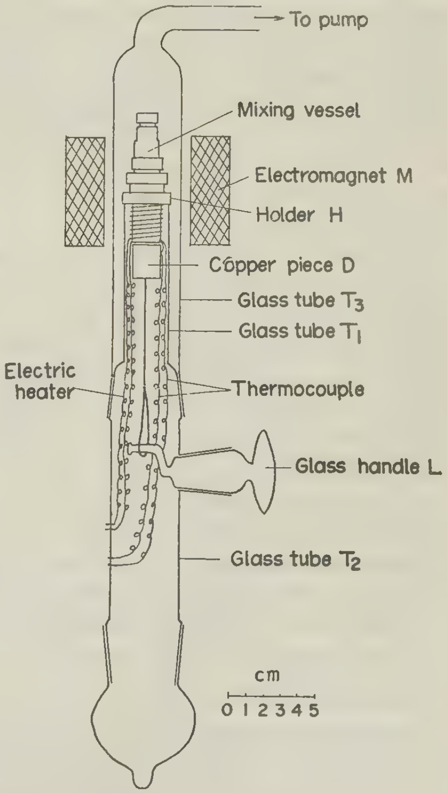


Fig. 1. Scheme of the whole apparatus.

ment is markedly simplified.

As seen in Fig. 1, the mixing vessel supported on a ring holder *H*, which in turn is supported on top of a glass tube T_2, is set in a glass tube T_3. There are several holes in the upper part of the ring holder through which the tube T_2 is evacuated. In order to prevent radiant heat transfer between the mixing vessel and the outer space, inner surface of glass tube T_3 is coated with aluminium by means of vacuum-evaporation technique. Glass handle *L* is used for pulling down the copper piece *D* stated above so that it may be released from contact with the bottom of the mixing vessel.

The heating coil is an enamel-coated constantan wire 0.2 mm in diameter, about 1 meter long, and with resistance of 13 ohms. Voltage applied to the coil ranged from 0.65 volt to 1.3 volt. These values of the current were selected so that the plotting of the "heating curve", as will be illustrated in Fig. 3, may be made easily and quickly.

M is a magnet coil designed so as to let the iron rod move up and down and to break the tinfoil diaphragm (described below). The magnet coil is made of an enamel-coated copper wire 0.4 mm in diameter, total number of turns being 8000. 100 volt D. C. voltage is applied to this magnet coil and the current is closed and cut off at regular intervals of one second by a rotary switch drived by a synchronous moter. The duration of time while the switch is on is 0.01 sec.

Fig. 2 gives the details of the mixing vessel. It is composed of two parts *B* and *C* with respective volumes 2.7 cm³ and 3.4 cm³, into which the liquids to be mixed are introduced. *B* and *C* are separated from each other by a tinfoil diaphragm 0.005 mm in thickness, which is hold tightly by gaskets G_1 made of annular polyethylene sheet 1 mm thick.

In *C* there is an iron rod with a sharp point which is used for breaking the tinfoil diaphragm and mixing the two liquids by its up-and-down motion. Around the vessel *C* are wrapped two sheets of insulating paper *P*, with a heating coil *E* in between.

II) Experimental Procedure

Accurately measured quantities of the two liquids to be mixed are introduced into the vessels *B* and *C*, and the whole apparatus is evacuated down to pressure 10^{-4} mm Hg.

Now, we start the motor which drives the rotary switch. If the readings of galvanometer are found constant we commence mixing and stirring the liquids. The results obtained in endothermic and exothermic cases are shown in Fig. 3a and Fig. 3b, respectively.

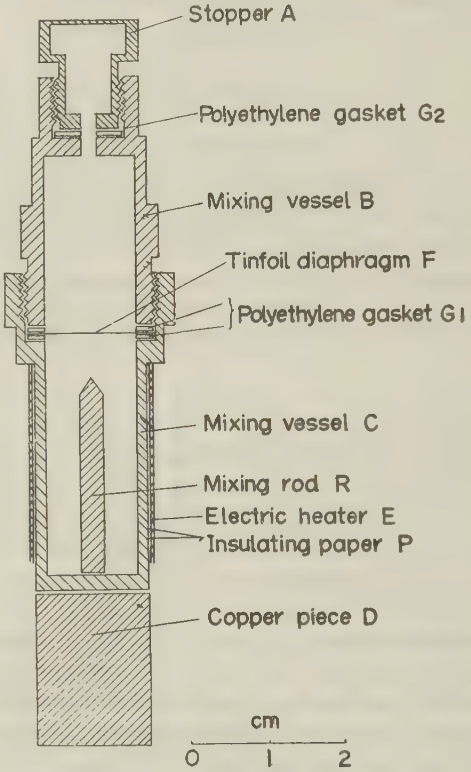

Fig. 2. Mixing vessel.

A in Fig. 3a indicates the point where the mixing is started. The galvanometer reads from *A* to *C* and finally to *D*. The net temperature change due to mixing corresponds to the height *AB* which is obtained by extrapolation of the curve *DC* leftwards down to *B*. In order to obtain the mixing heat ΔH (see section (III)), we close the heater circuit at the moment when the curve arrives at the point *D* (which can be selected arbitrarily*. The "heating curve" *DEF* is then plotted, and the tangent is drawn at *E* which is at the same level as *A*. This tangent means a heating curve which would have been obtained if the heating were solely due to heater current*.

---

* Only, the curve *C D* must be long enough to be extrapolated.

In the case of exothermic mixing (Fig. 3b), the height $A'B'$ corresponding to the net temperature elevation brought about by mixing is obtained by extrapolation of the curve $D'C'$. The plotting of the "heating curve" $E'F'$ is started from the room temperature. The tangent of the curve $E'F'$ at E', is, as before, nothing but the heating curve which would have been obtained, if the heating were only due to the heating coil.

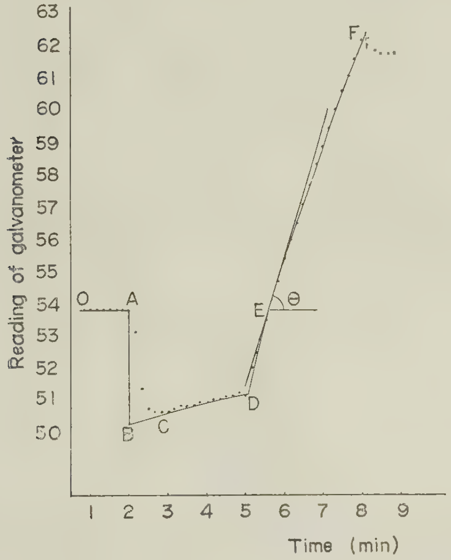

Fig. 3a. Mixing curve of benzene and isopropylbenzene.

III) Calculation of Mixing Heat

i) Endothermic Mixing

In Fig. 3a, AB measures the net temperature depression caused by mixing, and the gradient $\tan\theta$ of the tangent drawn to the curve DEF at E means the temperature elevation of the mixture per unit time when the heat is transferred from none other than the heating coil. Thus the mixing heat ΔH (joule) is given by

$$\Delta H = I^2 R \times \frac{AB}{\tan\theta}\,, \tag{4}$$

where I (ampere) is the heater current, and R (ohm) the resistance of the heating coil.

ii) Exothermic Mixing

From Fig. 3b, and following the same procedure as in the case of endo-thermic mixing, we get the mixing heat

$$\Delta H' = I^2 R \times \frac{A'B'}{\tan\theta'}\,. \tag{5}$$

§ 3. Measurement of the Volume Change Caused by Mixing

A pycnometer with stoppers, as shown in Fig. 4, is used for the measurement of volume change produced by mixing. The stoppers serve for preventing the liquids from evaporation. Measurements of the densities ρ_A and ρ_B of the liquids A and B and of ρ_{AB} of equi-

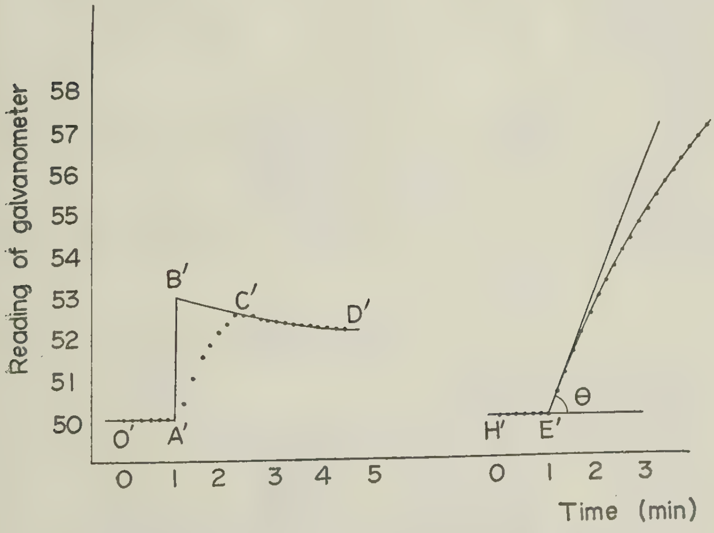

Fig. 3b. Mixing curve of benzene and methylethylketone.

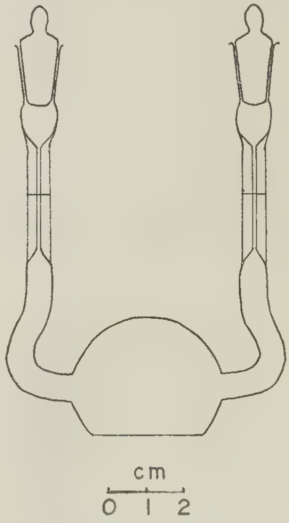

Fig. 4. Pycnometer.

---

* In constructing the heating curve, due corrections must be made by subtracting the heat developed within the mixture (heat of kinetic energy origin), which can be measured by the blank test.

Table I. Volume change by mixing. (cm³/mol. mixt.)

Solvent \ Chain element equivalent	Styrene	Ethylbenzene	Isopropyl-benzene	Toluene	Benzene
Benzene	+0.0504	+0.1193	−0.0583	+0.0715	0
Toluene	−0.2896	−0.0163	+0.1120	0	+0.0715
Xylene	+0.0231	+0.0422	+0.0323	+0.2070	+0.2797
Styrene	0	−0.0136	+0.0478	−0.2896	+0.0504
Ethylbenzene	−0.0136	0	−0.0876	−0.0163	+0.1193
Cyclohexane	+0.5694	+0.4792	+0.4699	+0.6348	+0.6412

molal mixture of A and B are determined by the ordinary manner. The volume change per unit equi-molal mixture is therefore given by

$$\Delta V=\frac{1}{2}\left[\frac{M_A+M_B}{\rho_{AB}}+\left(\frac{M_A}{\rho_A}+\frac{M_B}{\rho_B}\right)\right], \qquad (6)$$

where M_A and M_B are the molecular weights of A and B respectively. Experimental results obtained are shown in Table I.

§ 4. Calculation of Energy Change Due to Mixing

In this section we shall derive the mixing energy of two liquids A and B [$\Delta E=(E_{pp}+E_{ss})/(2)-E_{ps}$] from the change of the intermolecular potential energy ΔU brought about by mixing. We assume for simplicity that the quasicrystalline lattice model for liquid is allowed to use and that the size and shape of molecules of A and B are so similar to each other that the probability for a molecule to occupy a lattice point is the same in both liquids.

Let the numbers of molecules of A and B be N_A and N_B, respectively, the number of the nearest neighbor sites around a lattice point be σ, and the potential energies of molecular pairs $A-A$, $B-B$ and $A-B$ be $-E_{AA}$, $-E_{BB}$ and $-E_{AB}$, respectively. Then the sum of the potential energies of two liquids A and B before mixing is

$$U_A+U_B=-\frac{\sigma N_A}{2}E_{AA}-\frac{\sigma N_B}{2}E_{BB}\,. \qquad (7)$$

Table II.

Solvent	Thermal expansion coefficient α	Isothermal compressibility β cm²/dyne
Benzene	1.229×10^{-3}	0.953×10^{-3}
Toluene	1.051 〃	0.9147 〃
Xylene	0.994 〃	0.798 〃
Styrene	0.738 〃	0.74 〃
Ethylbenzene	1.018 〃	0.833 〃
Cyclohexane	1.20 〃	1.20 〃

Since the numbers of the molecular pairs $A-A$, $B-B$ and $A-B$ are respectively given by

$$\left.\begin{aligned} N_{AA}&=\frac{\sigma N_A^2}{2(N_A+N_B)}\,,\\ N_{BB}&=\frac{\sigma N_B^2}{2(N_A+N_B)}\,,\\ N_{AB}&=\frac{\sigma N_A N_B}{N_A+N_B}\,, \end{aligned}\right\} \qquad (8)$$

we have, for the total intermolecular potential energy of the mixture,

$$\begin{aligned} U_{\text{mix}}&=-N_{AA}E_{AA}-N_{BB}E_{BB}-N_{AB}E_{AB}\\ &=-\frac{\sigma N_A^2}{2(N_A+N_B)}E_{AA}-\frac{\sigma N_B^2}{2(N_A+N_B)}E_{BB}\\ &\quad-\frac{\sigma N_A N_B}{N_A+N_B}E_{AB}\,. \end{aligned} \qquad (9)$$

Thus the change in intermolecular potential energy of the two liquids produced by mixing is, from Eqs. (7) and (9),

$$\Delta U=U_{\text{mix}}-(U_A+U_B)=\frac{\sigma N_A N_B}{N_A+N_B}\Delta E\,, \qquad (10)$$

with

$$\Delta E=\frac{E_{AA}+E_{BB}}{2}-E_{AB}\,, \qquad (11)$$

so that

$$\Delta E=\frac{N_A+N_B}{\sigma N_A N_B}\Delta U\,. \qquad (12)$$

If no change of volume accompanies mixing, ΔU is equal to the mixing heat ΔH, or we have

$$\Delta E=\frac{N_A+N_B}{\sigma N_A N_B}\Delta H\,. \qquad (13)$$

In the case where the volume change $\varDelta V$ is not zero, the system of mixture undergoes a change in energy corresponding to the work done in a form of mechanical work of expansion or contraction. Theory⁽²⁾ requires that

$$\varDelta U=\varDelta H-T(\alpha/\beta)\varDelta V \\ +(\text{higher terms of } \varDelta V)\,, \qquad (3)$$

in which α, thermal expansion coefficient, and β, isothermal compressibility of the mixture, are given in terms of corresponding values of the component liquids, by

$$\left.\begin{aligned}\alpha&=\phi_1\alpha_1+\phi_2\alpha_2\,,\\ \beta&=\phi_1\beta_1+\phi_2\beta_2\,,\end{aligned}\right\} \qquad (14)$$

ϕ_s' being the volume fractions of the components. Eqs. (3) and (12) yield

$$\varDelta E=\frac{N_A+N_B}{\sigma N_A N_B}\{\varDelta H-T(\alpha/\beta)\varDelta V\}\,. \qquad (15)$$

In the special case where unit molal mixture is made of equi-molal liquids A and B, we have

$$N_A=N_B=\frac{N_{AV}}{2}\,,$$

N_{AV} being Avogadro's number. If we put

$$\sigma=12\,,$$

Eq. (15) becomes

$$\varDelta E=\frac{1}{3N_{AV}}\{\varDelta H-T(\alpha/\beta)\varDelta V\}\,. \qquad (16)$$

Observed values of ΔH for equi-molal mixing and calculated values of ΔE are given in Tables III–VII.

Procedure of deriving the equi-molal mixing heat from the experimental results for non-equi-molal mixing is as follows. Neglecting the effect of volume change ΔV and putting ΔU equal to ΔH, we obtain from Eq. (13) the expression for equi-molal mixing heat per unit molal mixture;

$$\Delta H_{\text{equi-mol. mix.}}/\text{mole} = \frac{N_{AV}}{4}\left(\frac{N_A+N_B}{N_A N_B}\right)\Delta H_{\text{obs.}}\,, \qquad (17)$$

or, introducing the molal fractions of liquids A and B;

$$\left.\begin{aligned} x_A &= \frac{N_A}{N_{AV}}\,, \\ x_B &= \frac{N_B}{N_{AV}}\,, \end{aligned}\right\} \qquad (18)$$

$$\Delta H_{\text{equi-mol. mix.}}/\text{mole} = \frac{x_A+x_B}{4x_A x_B}\Delta H_{\text{obs.}}\,. \qquad (19)$$

§ 5. Measurement of Extension of High Polymer

The end-to-end distance of polystyrene of molecular weight 200,000 in various solutions has been measured. Between the intrinsic viscosity $[\eta]$ of the high polymer solution and the molecular weight M of the high polymer molecule there is an empirical relation

$$[\eta] = KM^{a}\,, \qquad (20)$$

where K and a are constants. For the benzene solution of polystyrene, Eq. (20) becomes(4)

$$[\eta] = 2.7\times10^{-4}\times M^{0.66}\,. \qquad (21)$$

This equation enables one to determine the molecular weight of any fractionated sample of polystyrene. The values of K and a for solvents other than benzene are then obtained from the measurement of $[\eta]$ by using polystyrene of known molecular weight.

With these values of K and a, $[\eta]$ of the solutions of polystyrene with molecular weight 200,000 can be calculated, so that finally the extension of polystyrene in these solutions can be derived from the values of $[\eta]$ and a(5). The measurement of viscosity was carried out by the use of a viscometer of Ostwald type. The concentration of the solution was determined by weighing the high polymer residue after a known quantity of solution was dried by evacuation and

Table VIII. Intrinsic viscosity $[\eta]$ and root mean square end-to-end distance $(\langle r^2\rangle)^{1/2}$ of polystyrene with molecular weight 200,000.

Styrene	84.5	0.62	303
Ethylbenzene	77.5	0.50	256

heating. Experimental results are shown in Table VIII.

§ 6. Discussion

As already stated (§ 1), the mean square end-to-end distance $\langle r^2\rangle$ of high polymer molecule in solution must be a monotone decreasing function of ΔE. As can be seen from Tables III–VII, it is only the case where benzene is assumed as the chain element equivalent that $\langle r^2\rangle$ comes out a monotone decreasing function of ΔE (cf. Tables VII and VIII). It may therefore be inferred that, in so far as the solvent molecules are non-polar, the extension of polystyrene is determined mainly by the intermolecular interaction between the benzene group, which is bound on the side of the main chain of polystyrene, and solvent molecules.

That the benzene group acts as a substitute for the chain element of polystyrene may be interpreted as follow; If the structural chain element of polystyrene were free, its nearest neighbor sites (usually 12) should be all equivalent to one another and capable of admitting any other element (chain element or solvent molecule) into them: But the nearest neighbor sites of actual chain element are not all equivalent with respect to the chain element, since some of them are already occupied. The remaining sites which are capable of admitting any other element are perhaps for the most part identical in character with the nearest neighbors of benzene. This may probably be the reason why benzene molecules show a behavior similar to the chain elements of polystyrene.

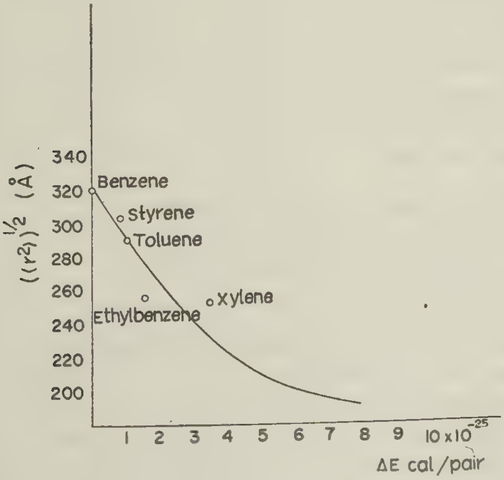

Fig. 5. Relation between root mean square end-to-end distance and energy change by mixing for polystyrene (M.W.: 200,000).
Full line: Theoretical curve ($\sigma=12$, N=1923)
Circle : 1/40 of observed values

The next step to be taken is to compare the relation between ΔE and $\langle r^2\rangle$ with the theory quantitatively. In Fig. 5 the full line gives the theoretical curve and circles give the observed values of ΔE multiplied by 1/40. Theoretical values are those calculated numerically from Eq. (1), where as the lower limit of integration is taken the value of r which is computed from the radius R of a hypothetical sphere considered to consist of close-packed chain elements by the relation based on the random fleight model

$$\langle R^2\rangle=\frac{1}{6}\langle r^2\rangle\,, \tag{22}$$

and as the upper limit is taken the value of the end-to-end distance of the chain with the elements lined up straight. The constants in Eq. (1) are estimated to be: $\sigma=12$, $N=1923$, $\nu=2{,}566\times10^{21}$ and $\tau=0.285$.

The fact that the experimental values of ΔE multiplied by 1/40 come out to fit the theoretical curve fairly well may be interpreted as follows:

(1) For the chain elements constituting a chain some of the configurations of the pairs of "chain element-chain element" and of "chain element-solvent molecule" will be frustrated on account of the steric hindrance by the neighboring chain elements, so that the effective number of the nearest neighbors around a chain element must be less than $\sigma=12$. The diminution in σ-value causes theoretical value of ΔE as calculated by Eq. (1) to increase so that the curve in Fig. 5 should be displaced to the right.

(2) It is generally regarded as true that

the high polymer molecule in solution assumes the form of a thread ball, the density of the chain elements at a point within the ball being the larger, the nearer it approaches the center. Thus, the solvent molecules are more or less prevented from penetrating into the ball; that is to say, it becomes impossible for the chain elements near the center to make free contact with solvent molecules. Consequently, the effective number of chain elements should be considered to be less than $N=1923$. The decrease in N-value also leads to the displacement of the curve in Fig. 5 to the right.

(3) The steric hindrance stated in (1) will cause the destruction of low energy configurations along with the diminution in the number of geometrical nearest neighbors. This implies that the values of ΔE to be observed when the high polymer (polystyrene) is dissolved in various solvents should be smaller than those observed in the present experiment.

Acknowledgments

The author wishes to express his hearty thanks to prof. T. Hori and Prof. J. Furuichi for kind discussion on the present subject. He is also indebted to Mr. I. Asai, Mr. K. Nemoto, Mr. M. Akiyama and Mr. T. Abe for kind assistance and to Mr. T. Noguti and Mr. Y. Kabashima for laborious preparation of the apparatus.

Proton Magnetic Resonance of Ice Single Crystal

By Kiyoshi KUME

University of Tokyo, Tokyo
and Ryosuke HOSHINO
Department of Physics, Faculty of Science,
Hokkaido University, Sapporo

(Received September 10, 1960)

The single crystal of ice was examined by proton magnetic resonance method, and the result was shown to be consistent with Pauling model. The problem of whether the arrangements of protons is ordered or not is, however, still open to the question.

The structure of heavy ice has been investigated by Peterson and Levy[1] by neutron diffraction and the result is found to be consistent with Pauling model[3]. We examined the ice single crystal by proton magnetic resonance method and obtained the result which is again consistent with the model.

The sample was kindly provided by Dr. K. Arakawa. The crystal was examined by the etch-pit method[2]. The etch-pits developed on the surface perpendicular to the c-axis are reproduced in Fig. 1. All of them are regular hexagonal as is expected from the hexagonal crystal lattice of ice. It may safely be concluded that the crystal is quite single and the c-axis is almost parallel throughout the crystal. A cylindrical specimen about 10 mm in diameter and 15 mm in height, the axis of which was perpendicular to the c-axis, was cut from the central part of the original single crystal of

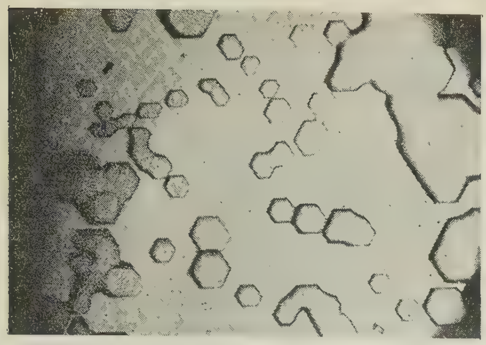

Fig. 1. Ech-pits on the ice single crystal.

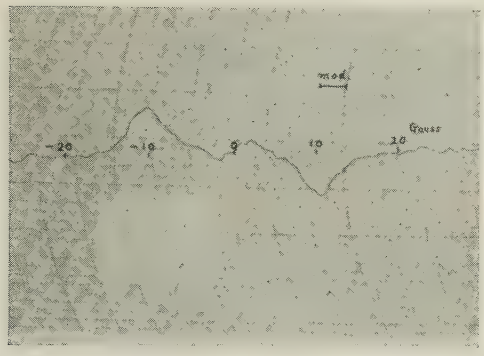

Fig. 2. Derivative of absorption curve of ice single crystal when the magnetic field is applied parallel to the c-axis ($\theta=0°$).
Sample: Ice single crystal, see the text for details
Field: 5630 Gauss
Field sweep: about 3 Gauss/min
Frequency: 24.0 MC
R.f. Field within sample coil: about 50 microgauss
Time constant: about 10 sec
Temperature: 93°K

about 200 mm in diameter and 70 mm in height.

Fig. 2 shows an example of the results. The external magnetic field was applied parallel to the c-axis, within the accuracy of 5 degrees. The temperature was kept as low as $-180°C$, and H_1 was cut down to as low as about 50 microgauss to avoid saturation. A Twin-T bridge-type detector was used throughout this experiment. The upper part of Fig. 3 shows the angular dependence of the absorption, where the external field makes the angle θ from the c-axis in the plane which contains the c-axis and a direction that makes the angle of about 20 degrees with an a-axis in the c-plane.

The calculations of line shapes were based upon Pauling model[3]: first, protons occupy the two among the four possible positions surrounding each oxygen, secondly, the protons lie on the lines connecting two oxygens, and thirdly, only one proton can exist on any oxygen-oxygen line closer to either of the two oxygen atoms at both ends. The assumption of the microscopic random occupation of protons among possible arrangements, however, are immaterial here, because the contribution to the second moment from neighboring protons, which must be used in the calculation of the actual line shape, is practically the same, whether these protons take random or ordered arrangements[4]. Then the number of possible interproton vectors are 18 in all; 6 of them are contained in a c-plane, the remaining 12 being contained in the cone, which is shown in Fig. 4. These interproton vectors were assumed to be equally

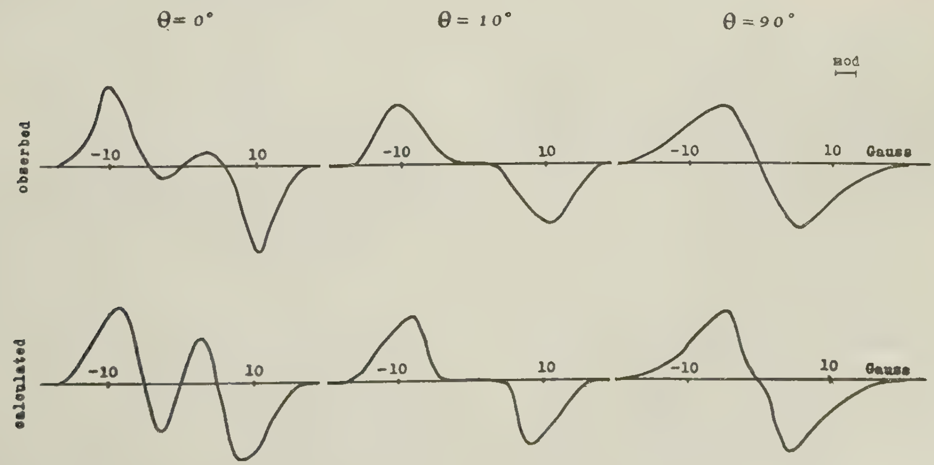

Fig. 3. Derivative of absorption curves of an ice single crystal. For the meaning of θ see text.

occupied throughout the whole specimen. Then the line shapes were able to be calculated by using the data on the interproton distance as well as the intermolecular contribution which were obtained by the powder experiment[4]. The results are shown in the lower part of Fig. 3. In view of the fact that the angular precision was rather poor, the agreement between observed and calculated curves is considered to be satisfactory.

Fig. 5 shows the motional narrowing. Although the experiment is rather qualitative, the general tendency is consistent with the powder experiment[4].

The authors express their hearty thanks to Prof. Y. Kakiuchi, who showed much interest on the experiment, and offered a chance to conduct it. We wish to thank Dr. K. Arakawa who kindly supplied the ice single crystal. We also thank Mr. H. Shimizu for his assistance in taking the etch-pits.

Microwave Attenuation by Cyclotron Resonance in a Slightly Ionized Gas

By Taro DODO

Hitachi Central Research Laboratory, Kokubunji, Tokyo

(Received Oct. 25, 1960)

The Boltzmann equation is solved for the distribution function of electrons in a static uniform magnetic field $\boldsymbol{B}_0$ and a high frequency electric field. The tensor of dielectric constant and the propagation constant $\boldsymbol{k}$ are obtained from this solution. The calculations are made by neglecting the square of the amplitude of electric field for two cases: (1) $\boldsymbol{k}//\boldsymbol{B}_0$, (2) $\boldsymbol{k}\perp\boldsymbol{B}_0$.

The attenuation spectrum for the case (2) is not a Lorentzian type and its maximum occurs at the microwave frequency

$$\omega\simeq(\omega_c^2+\omega_p^2+\nu_m^2)^{1/2}\ .$$

If the electron density is high, the attenuation spectrum differs from a Lorentzian type even for the case (1).

§ 1. Introduction

For the measurement of plasma temperature (collision frequency), the electron cyclotron resonance method gives more accurate means than the usual microwave diagnostic technique[1], because the half width of the resonance spectrum gives directly the collision frequency. It is then desirable to establish the theory, which would enable us to analyse the results obtained by cyclotron resonance technique. Several works[2][3][4] pertaining to this topic have been published. They are, however, neither rigorous nor convenient for the comparison with the experiment.

Kelly, Margenau and Brown[2] had obtained the cyclotron resonance absorption spectrum by calculating the quantity $\langle \boldsymbol{J}\cdot\boldsymbol{E}\rangle_{time\ average}$. Because the electric field $\boldsymbol{E}$ used in the theory of K. M. B. is the incident external field, which does not include the induced electric field produced by the plasma current $\boldsymbol{J}$, their theory can be applied only to a dilute plasma, i.e. $\omega_p^2\ll\omega^2$. Drummond[3] had carried out more detailed calculations, but his analytical results were complicated and difficult to be interpreted intuitively. Also he had shown many numerical results about the refractive index, but he had aimed at a very dense and hot plasma, so his results were not appropriate to apply to a slightly ionized cold plasma used in ordinary laboratory experiments. Also both authors had introduced phenomenologically the collision frequency, the relation between the collision frequency and the differential collision cross section* had not been clarified. Recently, Kelly[4] has derived conductivity tensors including electron-electron collision, but he has not derived propagation constant. The quantities that should be compared with experiments are propagation constants and these are different for propagation directions in relations to the static magnetic field. K. M. B. and Kelly have assumed without any discussion that the distribution function is uniform in spatial coordinates. When an electromagnetic wave polarized normal to a static magnetic field propagates in normal direction to the static field, a longitudinal current and a longitudinal field are induced. By these longitudinal components the electron density will be made inhomogeneous in the propagation direction.

The "absorption" of the electromagnetic energy can be obtained by calculating the quantity σE^2, where $\boldsymbol{E}$ should include the field induced by the current flowing in the plasma. On the other hand, for the plasma diagnostics, we get the information about the density and the collision frequency of the plasma from the measurement of the "attenuation constant" and the phase shift. The

---

* Desloge, Matthysse and Margenau[5] had made some errors in the treatment of collision term in the Boltzmann equation. They had used the collision frequency instead of the momentum transfer collision frequency, which should be used in such a problem. Recently, Desloge and Matthysse[6] has carried out the correct treatment in this point.

"absorption" and the "attenuation" are not the same. Consider the propagation of microwave of frequency ω through a collision-free plasma without static magnetic field. If $\omega_p>\omega$, as is well known, the amplitude of the wave attenuates, although there is no absorption of the wave energy. Usual plasma diagnostic method is based on the measurement of this attenuation. From this reason, we aimed to derive the "attenuation constant". The attenuation constant is more complicated than the conductivity tensors when the wave propagates perpendicularly to the static field.

§ 2. Distribution Function

The Boltzmann equation is solved for the distribution function f of electrons in a static uniform magnetic field $\boldsymbol{B}_0$ directed in z-axis and a high frequency electromagnetic field, whose electric vector $\boldsymbol{E}$ is in the $x-y$ plane. The Boltzmann transfer equation is

$$\frac{\partial f}{\partial t}+\boldsymbol{v}\frac{\partial f}{\partial \boldsymbol{r}}+\boldsymbol{F}\frac{\partial f}{\partial \boldsymbol{v}}=\left(\frac{\partial f}{\partial t}\right)_{coll}, \tag{1}$$

where $\boldsymbol{F}$ is the Lorentz force and $(\partial f/\partial t)_{coll}$ is the change of distribution function by collisions. Taking the non-relativistic approximation and neglecting the quantities of the order of v/c, $\boldsymbol{F}$ is given by

$$\boldsymbol{F}=-\frac{e}{m}\boldsymbol{E}-\frac{e}{mc}(\boldsymbol{v}\times\boldsymbol{B}_0)\,. \tag{2}$$

In a slightly ionized gas, collisions of the electrons are mainly electron-neutral atom encounters. We neglect the electron-ion and electron-electron collisions and assume that $(\partial f/\partial t)_{coll}$ comes from the electron-neutral elastic collision only and the relative velocity of collision can be replaced by the electron velocity because of (atomic mass)$\gg$(electron mass). By these assumptions $(\partial f/\partial t)_{coll}$ becomes very simple in form. We can assume safely that ions are not influenced by the high frequency microwave field because of their large inertia. Further we neglect the quantities of the order of $\boldsymbol{E}^2$. This is the most essential and severe assumption* in this paper. This means that the increase of mean kinetic energy of electrons by the absorption of microwave energy is not taken into consideration. Actually, for the plasma diagnostics by the measurement of microwave attenuation, we must use the microwave of small amplitude in order that the plasma is not disturbed by the measuring means. Therefore, the neglect of the quantities of the order of $\boldsymbol{E}^2$ is a natural assumption.

With these assumptions we can treat rigorously the problem without ambiguity. To the first order of $\boldsymbol{E}$, we can put the distribution function f into the form

$$f=f_e+f_{odd}=f_e+v_xG_1+v_yG_2\equiv f_e+\boldsymbol{v}\boldsymbol{G}\,, \tag{4}$$

where f_e, G_1, and G_2 are functions of electron speed v. Since

$$\frac{\partial}{\partial \boldsymbol{v}}(f_e+\boldsymbol{v}\boldsymbol{G})=\frac{\boldsymbol{v}}{v}\left(\frac{\partial f_e}{\partial v}+\boldsymbol{v}\frac{\partial \boldsymbol{G}}{\partial v}\right)+\boldsymbol{G}\,, \tag{5}$$

substituting (4) into (1) gives

$$\frac{\partial f_e}{\partial t}+\boldsymbol{v}\frac{\partial \boldsymbol{G}}{\partial t}+\boldsymbol{v}\left(\frac{\partial f_e}{\partial \boldsymbol{r}}+\boldsymbol{v}\frac{\partial \boldsymbol{G}}{\partial \boldsymbol{r}}\right)-\frac{e}{m}\boldsymbol{E}\boldsymbol{G}$$
$$-\frac{e}{m}\boldsymbol{E}\frac{\boldsymbol{v}}{v}\left(\frac{\partial f_e}{\partial v}+\boldsymbol{v}\frac{\partial \boldsymbol{G}}{\partial v}\right)-\frac{e}{mc}(\boldsymbol{v}\times\boldsymbol{B}_0)\boldsymbol{G}=\left(\frac{\partial f}{\partial t}\right)_{coll}. \tag{6}$$

Substracting from (6) the expression obtained by replacing $\boldsymbol{v}$ with $-\boldsymbol{v}$ in (6), we obtain

$$\boldsymbol{v}\left[\frac{\partial \boldsymbol{G}}{\partial t}+\frac{\partial f_e}{\partial \boldsymbol{r}}-\frac{\partial \boldsymbol{E}}{m}\frac{1}{v}\frac{\partial f_e}{\partial v}-\frac{e}{mc}(\boldsymbol{B}_0\times\boldsymbol{G})\right]$$
$$=\left[\left(\frac{\partial f}{\partial t}\right)_{coll}\right]_{odd}, \tag{7}$$

where $[(\partial f/\partial t)_{coll}]_{odd}$ is the odd function part of $(\partial f/\partial t)_{coll}$ with respect to $\boldsymbol{v}$. Neglecting the terms containing (electron mass/neutral atom mass)$^{1/2}$, the right hand side of (7) becomes, as shown in Appendix I,

$$-\nu_m\boldsymbol{v}\boldsymbol{G}\,,$$

where ν_m is the collsion frequency for momentum transfer and is generally a function of v,

$$\nu_m=2\pi\iint(1-\cos\theta)f_n(\boldsymbol{v}_n)g\sigma(g,\theta)\sin\theta d\theta d\boldsymbol{v}_n\,, \tag{8}$$

where $f_n(\boldsymbol{v}_n)$ is the distribution function of neutral atoms, g is the relative velocity given by $g=|\boldsymbol{v}-\boldsymbol{v}_n|\simeq v$, and $\sigma(g,\theta)$ is the differential scattering cross section. Then (7) reduces to a simpler expression

$$\frac{\partial \boldsymbol{G}}{\partial t}-\frac{e}{mc}(\boldsymbol{B}_0\times\boldsymbol{G})+\nu_m\boldsymbol{G}=\frac{e\boldsymbol{E}}{m}\frac{1}{v}\frac{\partial f_e}{\partial v}-\frac{\partial f_e}{\partial \boldsymbol{r}}\,. \tag{9}$$

The solution of (9) is easily obtained by the change of variables

$$E_x+iE_y=E_+,\ E_x-iE_y=E_-,\ G_1+iG_2=G_+,\cdots\,. \tag{10}$$

---

[*] If the collision frequency ν_m is independent of the electron velocity, this assumption is unnecessary for the results derived in § 3(i).

By use of (10), (9) becomes

$$\frac{\partial G_\pm}{\partial t}\mp i\omega_c G_\pm+\nu_m G_\pm =\frac{e}{m}E_\pm\frac{1}{v}\frac{\partial f_e}{\partial v}-\left(\frac{\partial f_e}{\partial x}\pm i\frac{\partial f_e}{\partial y}\right), \tag{11}$$

where ω_c is the cyclotron frequency

$$\omega_c=eB_0/mc\ .$$

If E_+ and E_- vary as
$E_+=e_+\exp(-i\omega t)$, $E_-=e_-\exp(-i\omega t)$, (ω : real), (E_+ : ordinary wave, E_- : extraordinary wave), we obtain the soltuions of (11):

$$G_\pm=\left[\frac{eE_\pm}{m}\frac{1}{v}\frac{\partial f_e}{\partial v}-\left(\frac{\partial f_e}{\partial x}\pm i\frac{\partial f_e}{\partial y}\right)\right]\frac{1}{\nu_m-i(\omega\pm\omega_c)}, \tag{13}$$

and

$$G_1=\left[\frac{e}{m}\frac{1}{v}\frac{\partial f_e}{\partial v}\left\{(\nu_m-i\omega)E_x-\omega_c E_y\right\} -\frac{\partial f_e}{\partial x}(\nu_m-i\omega)+\frac{\partial f_e}{\partial y}\omega_c\right]\frac{1}{(\nu_m-i\omega)^2+\omega_c^2}, \tag{15}$$

$$G_2=\left[\frac{e}{m}\frac{1}{v}\frac{\partial f_e}{\partial v}\left\{\omega_c E_x+(\nu_m-i\omega)E_y\right\} -\frac{\partial f_e}{\partial x}\omega_c-\frac{\partial f_e}{\partial y}(\nu_m-i\omega)\right]\frac{1}{(\nu_m-i\omega)^2+\omega_c^2}. \tag{16}$$

$\partial f_e/\partial v$ of the first term on the right hand side of these expressions can be replaced under our assumption by $\partial f_0/\partial v$, f_0 being the zero-order quantity with respect to the perturbation $\boldsymbol{E}$, i.e. the Maxwell distribution in equilibrium.

§ 3. Propagation Constants (Dispersion Relations)

Calculations are carried out for two different cases, namely (i) when the propagation vector $\boldsymbol{k}$ is parallel to the z-axis, $\boldsymbol{k}//\boldsymbol{B}_0$, and (ii) when $\boldsymbol{k}$ is parallel to the x-axis, $\boldsymbol{k}\perp\boldsymbol{B}_0$. In both cases we treat a plane wave, so that $\partial f_e/\partial y=0$.

(i) $\boldsymbol{k}//\boldsymbol{B}_0$

In this case, $\partial f_e/\partial r\equiv 0$ because the electromagnetic wave propagates as a transverse wave. Using (13), we obtain the current $J_\pm$:

$$J_\pm=-e\int(v_x\pm iv_y)f dv=-(e/3)\int v^2 G_\pm dv =\frac{e^2E_\pm}{3kT}\int\frac{v^2}{\nu_m-i(\omega\pm\omega_c)}f_0 4\pi v^2 dv =\frac{ne^2}{3kT}E_\pm\left\langle\frac{v^2}{\nu_m-i(\omega\pm\omega_c)}\right\rangle. \tag{17}$$

When ν_m is independent* of v, we have, because of $\langle v^2\rangle=3kT/m$, from (17) the relationship

$$J_\pm=\frac{\omega_p^2}{4\pi}E_\pm\frac{1}{\nu_m-i(\omega\pm\omega_c)},\quad \omega_p^2=4\pi ne^2/m\ . \tag*{(17)$'$}$$

When ν_m is proportional to v, i.e. the collision cross section (mean free path) is independent of v, we can obtain an analytical expression and the result is shown in Appendix II. The numerical results is nearly the same as (17)$'$.

By use of (10), the Maxwell equations are rewritten as follows:

$$\left.\begin{aligned} i\frac{\partial H_\pm}{\partial z}&=\frac{1}{c}\frac{\partial E_\pm}{\partial t}+\frac{4\pi}{c}J_\pm\ ,\\ i\frac{\partial E_\pm}{\partial z}&=-\frac{1}{c}\frac{\partial H_\pm}{\partial t}\ .\end{aligned}\right\} \tag{20}$$

Eliminating $H_\pm$ from these equations and substituting (17) into $J_\pm$, we obtain the scalar dielectric constants ε_+ and ε_- for the ordinary and extraordinary waves:

$$\frac{\partial^2 E_\pm}{\partial z^2}=\frac{1}{c^2}\left(\frac{\partial^2 E_\pm}{\partial t^2}+4\pi\frac{\partial J_\pm}{\partial t}\right)\equiv\frac{\varepsilon_\pm}{c^2}\frac{\partial^2 E_\pm}{\partial t^2}\ . \tag{21}$$

As stated at the begining of this subsection, in the case of $\boldsymbol{k}//\boldsymbol{B}_0$ the electron density is independent of the spatial coordinates and so $\partial n/\partial t=0$, $\partial J_\pm/\partial t\propto n(\partial E_\pm/\partial t)$. Then we obtain

$$\varepsilon_\pm=1-\frac{1}{3\lambda_D^2}\frac{1}{\omega}\left\langle\frac{\omega\pm\omega_c-i\nu_m}{(\omega\pm\omega_c)^2+\nu_m^2}v^2\right\rangle, \tag{22}$$

where λ_D is the Debye length and $\lambda_D=(kT/4\pi ne^2)^{1/2}$. When ν_m is independent of v, the above expression comes to

$$\varepsilon_\pm=1-\eta\frac{1\pm\gamma-i\beta}{(1\pm\gamma)^2+\beta^2}, \tag*{(22)$'$}$$

where $\eta=\omega_p^2/\omega^2$, $\gamma=\omega_c/\omega$, $\beta=\nu_m/\omega$.

Substituting

$$\left.\begin{aligned} E_\pm&=E_{\pm 0}\exp i(k_\pm z-\omega t)\ ,\\ k_\pm&=k_{\pm r}+ik_{\pm i}\end{aligned}\right\} \tag{24}$$

into (21), we obtain the real and imaginary parts of propagation constants:

$$\begin{aligned} k_{\pm r}&=k_0(|\varepsilon_\pm|+\varepsilon_{\pm r})^{1/2}/(2)^{1/2}\ ,\\ k_{\pm i}&=k_0(|\varepsilon_\pm|-\varepsilon_{\pm r})^{1/2}/(2)^{1/2}\ ,\quad k_0=\omega/c\ .\end{aligned} \tag{25}$$

---

* If ν_m is independent of v, we get (17)$'$ by the partial integration:

$$\int v\frac{\partial f_e}{\partial v}\frac{1}{\nu_m-i(\omega\pm\omega_c)}4\pi v^2 dv =-\frac{3}{\nu_m-i(\omega\pm\omega_c)}\int f_e 4\pi v^2 dv =-3n/[\nu_m-i(\omega\pm\omega_c)]\ .$$

Therefore, f_e is not necessarily the Maxwell distribution, namely the assumption stated at the last section, the neglect of quantities of the order of $\boldsymbol{E}^2$, is unnecessary.

The attenuation constant $k_{//}$ of wave energy for the linearly polarized wave propagating parallel to the static magnetic field is

$$k_{//}=-\frac{1}{|E_{+}E_{-}|}\frac{\partial}{\partial z}|E_{+}E_{-}|=k_{+i}+k_{-i}\quad \text{nepers/cm.} \tag{26}$$

In the case of a plasma of extremely low density ($\omega_p^2\ll\omega^2$), we expand the square root of (25) into a power series of ω_p^2/ω^2 and take the first term only, then we get the well-known Lorentzian spectrum:

$$k_{//}=\frac{1}{6\lambda_D^2 c}\left[\left\langle\frac{\nu_m}{(\omega+\omega_c)^2+\nu_m^2}v^2\right\rangle+\left\langle\frac{\nu_m}{(\omega-\omega_c)^2+\nu_m^2}v^2\right\rangle\right]\quad \text{for } \omega_p^2\ll\omega^2\,. \tag{27}$$

When ν_m is independent of v, (27) becomes

$$k_{//}=\frac{\omega_p^2}{2c}\left[\frac{\nu_m}{(\omega+\omega_c)^2+\nu_m^2}+\frac{\nu_m}{(\omega-\omega_c)^2+\nu_m^2}\right]\quad \text{for } \omega_p^2\ll\omega^2\,. \tag{27$'$}$$

This expression is already given by K. M. B.[2] from the calculation of conductivity tensor σE^2.

When the value of ν_m is not extremely large, the attenuation spectrum (27)′ has the maximum at $\omega=\omega_c$ and has a symmetrical shape about $\omega=\omega_c$. For a plasma of not extremely low density ($\omega_p^2\gtrsim\omega^2/10$), the attenuation spectrum numerically calculated from (22)′ and (25) has a maximum at $(\omega)_{\max}>\omega_c$ and has an assymmetrical shape about $(\omega)_{\max}$. A numerical example is shown in Fig. 1.

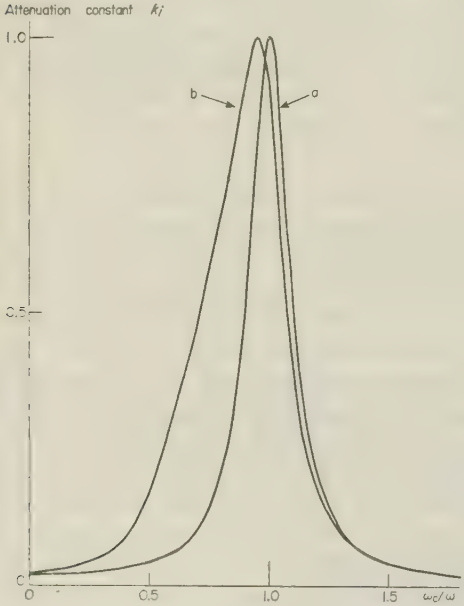

Fig. 1. Attenuation spectra of a Lorentzian type and an exact one as a function of magnetic field strength ω_c/ω.
(a): Calculated by (27)′. $\omega_p^2\ll\omega^2$, $\nu_m/\omega=0.1$.
(b): Calculated by (22)′ and (25). $\omega_p^2=0.5\omega^2$, $\nu_m/\omega=0.1$.
The collision frequency is the same for both cases. The normalization factors are adjusted so as to give the same peak height.

(ii) $\boldsymbol{k}\perp\boldsymbol{B}_0$

In this case, even when the incident microwave has E_y component only, a longitidinal component E_x is produced in the plasma by the current J_x produced by E_y and $\boldsymbol{B}_0$.

The first term of the current obtained by using (15) is a current J_E produced by the electric field and its second term containing $\partial f_e/\partial x$ is a current J_D produced by diffusion. One can prove (as shown in Appendix III*)

$$(J_E/J_D)\propto(\lambda'/\lambda_D)^2\,, \tag{28}$$

where λ' is the wave length of the microwave. Therefore, in case of $(\lambda'/\lambda_D)^2\gg1$, the term containing $\partial f_e/\partial x$ can be neglected. In laboratory experiments, λ_D is usually of the order of 10^{-2} cm and so the condition $(\lambda'/\lambda_D)^2\gg1$ is well established.

On these grounds, calculations are carried out neglecting the term containing $\partial f_e/\partial x$. Currents J_x and J_y are obtained from (15) and (16):

$$\begin{aligned}J_x&=-e\int v_x f dv=-e\int v_x^2 G_1 dv\\&=\frac{ne^2}{3kT}\left[\left\langle\frac{\nu_m-i\omega}{(\nu_m-i\omega)^2+\omega_c^2}v^2\right\rangle E_x-\left\langle\frac{\omega_c}{(\nu_m-i\omega)^2+\omega_c^2}v^2\right\rangle E_y\right],\end{aligned} \tag{29}$$

$$J_y=\frac{ne^2}{3kT}\left[\left\langle\frac{\omega_c}{(\nu_m-i\omega)^2+\omega_c^2}v^2\right\rangle E_x+\left\langle\frac{\nu_m-i\omega}{(\nu_m-i\omega)^2+\omega_c^2}v^2\right\rangle E_y\right]. \tag{30}$$

Substituting these expressions into the Maxwell equation

$$(\Delta^2-\text{grad div})\boldsymbol{E}=\frac{1}{c^2}\left(\frac{\partial^2\boldsymbol{E}}{\partial t^2}+4\pi\frac{\partial\boldsymbol{J}}{\partial t}\right), \tag{31}$$

we obtain the dielectric tensor $\overleftrightarrow{\varepsilon}$. In this calculation, the term $\partial\boldsymbol{J}/\partial t$ is composed of two terms:

$$\frac{\partial\boldsymbol{J}}{\partial t}\propto\frac{\partial n}{\partial t}\boldsymbol{E}+n\frac{\partial\boldsymbol{E}}{\partial t}\,.$$

---

* This discussion was suggested by Professor T. Kihara of Tokyo University.

The first term $(\partial n/\partial t)\boldsymbol{E}$ is the quantity of the order of $\boldsymbol{E}^2$ and can be neglected from our assumption. Then

$$\frac{1}{c^2}\left(\frac{\partial^2 \boldsymbol{E}}{\partial t^2}+4\pi\frac{\partial \boldsymbol{J}}{\partial t}\right)\equiv\frac{\overset{\leftrightarrow}{\varepsilon}}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2}\,, \tag{32}$$

$$\left.\begin{aligned}
&\varepsilon_{xx}=\varepsilon_{yy}=1-\frac{1}{3\lambda_D^2}\frac{1}{\omega}\left\langle\frac{\omega+i\nu_m}{(\omega+i\nu_m)^2-\omega_c^2}v^2\right\rangle,\\
&\varepsilon_{xy}=-\varepsilon_{yx}=i\frac{1}{3\lambda_D^2}\frac{\omega_c}{\omega}\left\langle\frac{v^2}{(\omega+i\nu_m)^2-\omega_c^2}\right\rangle,\\
&\varepsilon_{xz}=\varepsilon_{yz}=\varepsilon_{zx}=\varepsilon_{zy}=0\,,\\
&\varepsilon_{zz}=1-\frac{1}{3\lambda_D^2}\frac{1}{\omega}\left\langle\frac{v^2}{\omega+i\nu_m}\right\rangle.
\end{aligned}\right\} \tag{33}$$

In the case of plane wave propagating along the x-axis, i.e. $\partial\boldsymbol{E}/\partial y=\partial\boldsymbol{E}/\partial z=0$, (31) and (32) are

$$0=\frac{1}{c^2}\left[\varepsilon_{xx}\frac{\partial^2 E_x}{\partial t^2}+\varepsilon_{xy}\frac{\partial^2 E_y}{\partial t^2}\right],$$

$$\frac{\partial^2 E_y}{\partial x^2}=\frac{1}{c^2}\left[\varepsilon_{yx}\frac{\partial^2 E_x}{\partial t^2}+\varepsilon_{yy}\frac{\partial^2 E_y}{\partial t^2}\right].$$

Eliminating E_x from these equations, we obtain the effective scalar dielectric constant ε for E_y propagating along the x-axis:

$$\frac{\partial^2 E_y}{\partial x^2}=\frac{\varepsilon}{c^2}\frac{\partial^2 E_y}{\partial t^2}\,,$$

$$\begin{aligned}
\varepsilon&=\varepsilon_{yy}-\varepsilon_{yx}\varepsilon_{xy}/\varepsilon_{xx}\\
&=1-\frac{1}{3\lambda_D^2}\frac{1}{\omega^2}\left[\left\langle\frac{1+i\beta}{(1+i\beta)^2-\gamma^2}v^2\right\rangle\right.\\
&\qquad\left.+\frac{\dfrac{1}{3\lambda_D^2}\dfrac{\gamma^2}{\omega^2}\left\langle\dfrac{v^2}{(1+i\beta)^2-\gamma^2}\right\rangle^2}{\left\{1-\dfrac{1}{3\lambda_D^2}\dfrac{1}{\omega^2}\left\langle\dfrac{1+i\beta}{(1+i\beta)^2-\gamma^2}v^2\right\rangle\right\}}\right].
\end{aligned} \tag{34}$$

If ν_m is independent of v, the above expression becomes

$$\varepsilon=1-\eta\frac{1-\eta+i\beta}{(1-\eta-\beta^2-\gamma^2)+i\beta(2-\eta)}\,. \tag{34$'$}$$

Substituting this dielectric constant (34) or (34)′ into (25) instead of $\varepsilon_\pm$, we obtain the propagation constant for E_y. Because this expression is lengthy*, we show the numerical results for the cases of $\eta=0.1$, 0.3, 0.5, 2.0: $\beta=0.1$ in Fig. 2, as an example. The attenuation spectra were calculated numerically by using (34)′ for various combinations of η and β. From these calculations, we found that the half width was given by $2\nu_m$ in good accuracy when $\eta\lesssim 0.3$ and $\beta\lesssim 0.3$. And the maximum of attenuation spectrum occured, as expected from (34)′, at $(\gamma)_{\max}$;

$$(\gamma)_{\max}\simeq(1-\eta-\beta^2)^{1/2}\,. \tag{35}$$

From another point of view, the microwave frequency $(\omega)_{\max}$ at which the attenuation spectrum attains a maximum is given by, instead of ω_c,

$$(\omega)_{\max}\simeq(\omega_c^2+\omega_p^2+\nu_m^2)^{1/2}\,. \tag{36}$$

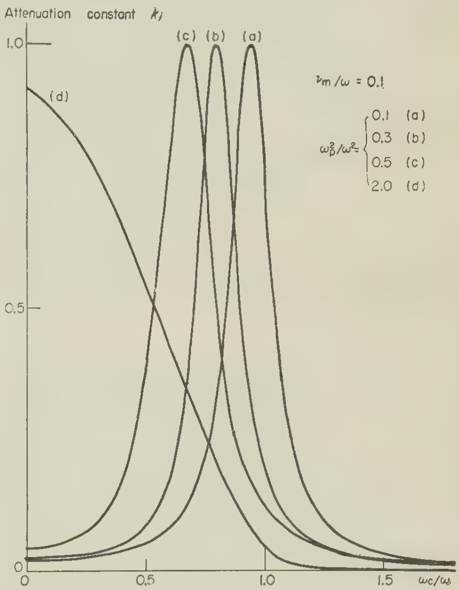

Fig. 2. Attenuation spectra of the microwave propagating normal to the static magnetic field. In this figure the microwave frequency ω is fixed and the cyclotron frequency (field strength) ω_c is varied. The resonance maximum $(\omega_c)_{\max}$ is given by

$$(\omega_c)_{\max}\simeq(\omega^2-\omega_p^2-\nu_m^2)^{1/2}\,.$$

The normalization factors of (a), (b), (c) are adjusted so as to give the same peak height.

The appearance of ω_p^2 in the denominator of the expression (34)′ of the dielectric constant results from the fact that in the case of $\boldsymbol{k}\perp\boldsymbol{B}_0$ the electric field has a longitudinal component leading to fluctuation of the electron density. This density fluctuation is in close connection with the plasma oscillation.

In order to see a characteristic feature for the case of $\boldsymbol{k}\perp\boldsymbol{B}_0$, the relation between the phase velocity V and the frequency ω is shown in Fig. 3 for the particular case of $\nu_m=0$.

---

* Mr. S. Tanaka[7] of Kyoto University has shown an approximate expression for the case of $\omega_p^2\ll\omega^2$ and he has given many numerical examples for this case.

The phase velocity V is given by the relation

$$\left(\frac{V}{c}\right)^2=\varepsilon^{-1}\fallingdotseq\left(1-\frac{\omega_p{}^2}{\omega^2}\frac{\omega^2-\omega_p{}^2}{\omega^2-\omega_p{}^2-\omega_c{}^2}\right)^{-1}. \quad (37)$$

This figure should be compared with the Figures 4.1 and 4.2 in Spitzer's text[8]. In the case of $\omega_p>\omega_c$ (Fig. 3(a)), the phase velocity is similar to that of an ordinary wave. In the case of $\omega_c>\omega_p$ (Fig. 3 (b)), the difference between $\boldsymbol{k}//\boldsymbol{B}_0$ and $\boldsymbol{k}\perp\boldsymbol{B}_0$ is remarkable and the phase velocity has the characteristics of both an ordinary wave and an extraordinary wave. With regard to experiments, if an experiment is carried out by changing the microwave frequency and fixing the static magnetic field strength, a maximum of attenuation occurs at very low frequency $\omega\simeq\omega_p{}^2/\omega_c$ as well as at $\omega\simeq(\omega_c{}^2+\omega_p{}^2)^{1/2}$. On the other hand, the maximum occurs at only one point $\omega_c\simeq(\omega^2-\omega_p{}^2)^{1/2}$ when the magnetic field is varied keeping the frequency constant.

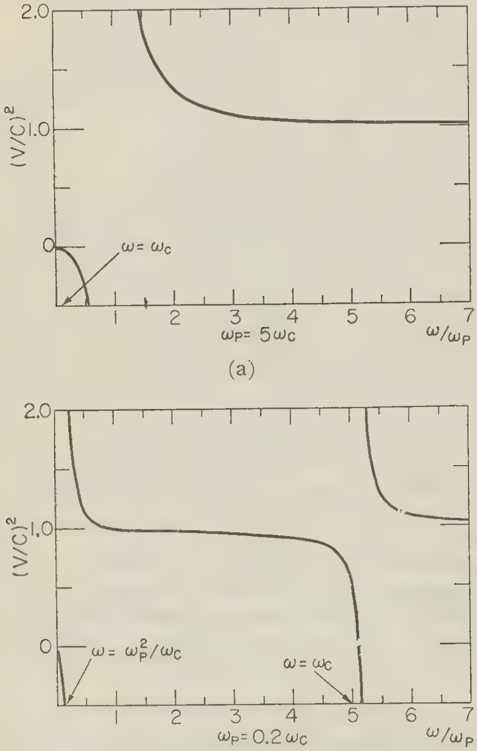

Fig. 3. Dispersion curves for $\nu_m=0$ for the electromagnetic wave propagating normal to the static field. (a): $\omega_p=5\omega_c$, (b): $\omega_p=0.2\omega_c$

§ 4. Conclusion

In this article a theory of cyclotron resonance appropriate to the plasma diagnostics is constructed rigorously with the definite assumption which should be reasonable for the ordinary diagnostic experiments.

The main results are the following two. First, the dielectric tensor is derived from the Boltzmann equation without ambiguity. The collision frequency ν_m, which is treated ambiguously by many authors, is clearly defined and an analytical expression for dielectric tensor is derived when ν_m depends on the electron velocity. It is clarified that the dependence of distribution function on the space coordinates, which is in usual treatment ignored without comment, can be neglected when the wave length of the electromagnetic wave is larger than the Debye length.

Second, the "attenuation spectrum" of microwave is represented as a function of the magnetic field strength. In a rather dense plasma, even for an extraordinary wave, the attenuation spectrum is considerably different from the absorption spectrum calculated by Kelly, Margenau and Brown[2] using the conductivity tensor. (See Fig. 1.) This difference becomes even more pronounced for the wave propagating normal to the magnetic field. This is attributed to the fact that the electromagnetic wave has a longitudinal component. The main feature is the shift of resonance maximum point of attenuation spectrum from $\omega=\omega_c$ as shown in (35) and (36). Nevertheless, for the case of $\boldsymbol{k}\perp\boldsymbol{B}_0$ the collision frequency is found to be given by the half width of attenuation spectrum in good accuracy. The density of plasma can be determined by the peak position using expression (35) as well as by the ordinary method where the peak height is used.

This theory is in good agreement with experiments.[9] [10]

The author is greatly indebted to Mr. S. Tanaka of Kyoto University who suggested this problem and gave valuable discussions. He wishes also to express his sincere thanks to Professor T. Kihara of Tokyo University for his valuable advices and suggestions on the rigorous treatment of the Boltzmann equation. He is deeply obliged to Miss. Y. Nakamura for her performance of numerical calculations and to Mr. K. Matsuoka for his discussions.

Appendix I Change of the Distribution Function by Collisions

As is well known, when the electron-neutral atom collision alone is taken into account, $(\partial f/\partial t)_{coll}$ is

$$\left(\frac{\partial f}{\partial t}\right)_{coll} = \iint [f_n(\boldsymbol{v}_n')f(\boldsymbol{v}')-f_n(\boldsymbol{v}_n)f(\boldsymbol{v})]g\sigma(g,\theta)d\Omega d\boldsymbol{v}_n\,. \tag{A. I. 1}$$

Let $W(\boldsymbol{v},\boldsymbol{v}')d\boldsymbol{v}'$ be the probability that an electron having a velocity $\boldsymbol{v}$ gets a velocity between $\boldsymbol{v}'$ and $\boldsymbol{v}'+d\boldsymbol{v}'$ after a collision. Using W, (A. I. 1) is rewritten as follows:

$$\left(\frac{\partial f}{\partial t}\right)_{coll} = \int [f(\boldsymbol{v}')W(\boldsymbol{v}',\boldsymbol{v})-f(\boldsymbol{v})W(\boldsymbol{v},\boldsymbol{v}')]d\boldsymbol{v}'\,. \tag{A. I. 2}$$

There is no anisotropy of space with respect to collision:

$$W(\boldsymbol{v},\boldsymbol{v}')=W(-\boldsymbol{v},-\boldsymbol{v}') \tag{A. I. 3}$$

The right hand side of (7) is

$$\left[\left(\frac{\partial f}{\partial t}\right)_{coll}\right]_{odd} = \frac{1}{2}\int [f(\boldsymbol{v}')\{W(\boldsymbol{v}',\boldsymbol{v})-W(\boldsymbol{v}',-\boldsymbol{v})\} -f(\boldsymbol{v})W(\boldsymbol{v},\boldsymbol{v}')+f(-\boldsymbol{v})W(-\boldsymbol{v},\boldsymbol{v}')d\boldsymbol{v}]' \tag{A. I. 4}$$

Using the decomposition (4) and (A. I. 3), we get for each term in (A. I. 4)

$$\begin{aligned}\int f_e(v')\{W(\boldsymbol{v}',\boldsymbol{v})-W(\boldsymbol{v}',-\boldsymbol{v})\}d\boldsymbol{v}' &= \int f_e(v')\{W(\boldsymbol{v}',\boldsymbol{v})-W(-\boldsymbol{v}',\boldsymbol{v})\}d\boldsymbol{v}' \\ &= \int f_e(v')\{W(\boldsymbol{v}',\boldsymbol{v})-W(\boldsymbol{v}',\boldsymbol{v})\}d\boldsymbol{v}' \\ &\qquad (\because \text{change of variable}) \\ &= 0\,,\end{aligned}$$

$$\int f_e(v)\{W(\boldsymbol{v},\boldsymbol{v}')-W(-\boldsymbol{v},\boldsymbol{v}')\}d\boldsymbol{v}'=0\,,$$

$$\frac{1}{2}\int \boldsymbol{v}'\boldsymbol{G}(v')\{W(\boldsymbol{v}',\boldsymbol{v})-W(\boldsymbol{v}',-\boldsymbol{v})\}d\boldsymbol{v}' = \int \boldsymbol{v}'\boldsymbol{G}(v')W(\boldsymbol{v}',\boldsymbol{v})d\boldsymbol{v}'\,,$$

$$-\frac{1}{2}\int \boldsymbol{v}\boldsymbol{G}(v)\{W(\boldsymbol{v},\boldsymbol{v}')+W(-\boldsymbol{v},\boldsymbol{v}')\}d\boldsymbol{v}' = -\int \boldsymbol{v}\boldsymbol{G}(v)W(\boldsymbol{v},\boldsymbol{v}')d\boldsymbol{v}'\,.$$

Then, (A. I. 4) becomes

$$\left[\left(\frac{\partial f}{\partial t}\right)_{coll}\right]_{odd} = -\int [\boldsymbol{v}\boldsymbol{G}(v)W(\boldsymbol{v},\boldsymbol{v}')-\boldsymbol{v}'\boldsymbol{G}(v')W(\boldsymbol{v}',\boldsymbol{v})]d\boldsymbol{v}'\,, \tag{A. I. 5}$$

$$= -\int [\boldsymbol{v}\boldsymbol{G}(v)f_n(\boldsymbol{v}_n)-\boldsymbol{v}'\boldsymbol{G}(v')f_n(\boldsymbol{v}'_n)]g\sigma(g,\theta)d\Omega d\boldsymbol{v}_n. \tag{A. I. 6}$$

In a slightly ionized plasma, the temperature of neutral atoms equals to at most the electron temperature, i.e.

$$|\boldsymbol{v}_n| \lesssim (m/M)^{1/2}|\boldsymbol{v}|\,. \tag{A. I. 7}$$

$(m/M)^{1/2}$ is the order of 10^{-2}, we expand $\boldsymbol{v}'$ and $\boldsymbol{v}_n'$ into a power series of $(m/M)^{1/2}$:

$$\boldsymbol{v}_n'=\boldsymbol{v}_n[1+\mathrm{O}(m/M)^{1/2}]\,, \tag{A. I. 8}$$

$$\boldsymbol{v}'=\boldsymbol{v}[\cos\theta+\mathrm{O}(m/M)^{1/2}] +|\boldsymbol{v}|\sin\theta[\boldsymbol{h}\cos\varphi+\boldsymbol{i}\sin\varphi]\,, \tag{A. I. 9}$$

where $\boldsymbol{h}$ and $\boldsymbol{i}$ are the unit vectors normal to $\boldsymbol{v}$. Substituting (A. I. 8) and (A. I. 9) into (A. I. 6) and neglecting the quantities of the order of $(m/M)^{1/2}$, we obtain

$$\left[\left(\frac{\partial f}{\partial t}\right)_{coll}\right]_{odd} = -\boldsymbol{v}\boldsymbol{G}\iint (1-\cos\theta)f_n(\boldsymbol{v}_n)g\sigma(g,\theta)d\Omega d\boldsymbol{v}_n\,, \tag{A. I. 10}$$

$$= -\boldsymbol{v}\boldsymbol{G}\nu_m(v)\,, \tag{A. I. 10$'$}$$

where we have used the fact that the second term of (A. I. 9) after integration by solid angle $d\Omega$ is zero. The quantity ν_m is the momentum transfer collision frequency, and is equal to the collision frequency only when the forward scattering is equal to the backward scattering, i.e. $\sigma(g,\theta)=\sigma(g,\pi-\theta)$.

Appendix II $J_\pm$ When ν_m is Proportional to v

If the cross section $\sigma(g,\theta)$ is independent of the relative velocity g and we neglect the terms containing $(m/M)^{1/2}$, ν_m becomes proportional to the electron velocity:

$$\nu_m = g\iint (1-\cos\theta)f_n(\boldsymbol{v}_n)\sigma(\theta)d\Omega d\boldsymbol{v}_n = N\sigma_m v = v/\lambda_m\,, \tag{A. II. 1}$$

where N is the number of neutral atoms per unit volume and σ_m and λ_m are the total cross section and the mean free path for momentum transfer, respectively. The integral (17) can be carried out analytically:

$$J_\pm = \frac{ne^2E_\pm}{3kT}\int \frac{\nu_m+i(\omega\pm\omega_c)}{\nu_m{}^2+(\omega\pm\omega_c)^2}\left(\frac{\alpha}{\pi}\right)^{3/2} \times \exp(-\alpha v^2)4\pi v^4 dv \tag{A. II. 2}$$

$$= \frac{\omega_p{}^2}{4\pi}E_\pm\frac{2}{3}\tau\left[\frac{2}{\pi^{1/2}}\{1-x^2+x^4\exp(x^2)E_1(x^2)\} +ix\{1-2x^2+4|x^3|\exp(x^2)\,\mathrm{Erfc}(|x|)\}\right], \tag{A. II. 3}$$

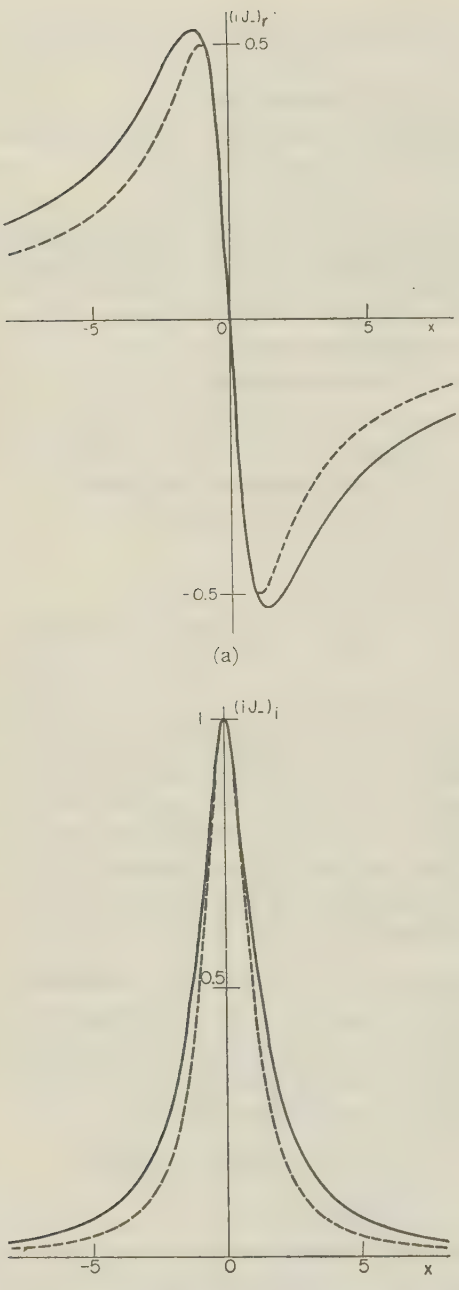

Fig. 4. The current J_- induced by the extraordinary wave is represented as a function of $x=\tau(\omega-\omega_c)$.

(a) Real part of iJ_-
Solid line: constant cross section, $x[1-2x^2+4|x^3|\exp(x^2)\,\mathrm{Erfc}(|x|)]$
Broken line: constant collision frequency, $x/(x^2+1)$

(b) Imaginary part of iJ_-
Solid line: constant cross section, $1-x^2+x^4\exp(x^2)\mathrm{E}_1(x^2)$
Broken line: constant collision frequency, $1/(x^2+1)$

where $\alpha=m/2kT$, mean collision time

$$\tau=\lambda_m/(2kT/m)^{1/2}\ ,$$

$$x=\tau(\omega\pm\omega_c)\ ,\quad \mathrm{E}_1(x)=\int_x^\infty \exp(-t)t^{-1}dt\ ,$$

$$\mathrm{Erfc}\,(x)=\int_x^\infty \exp(-t^2)dt\ .$$

The real and imaginary parts of iJ_- are plotted against $x=\tau(\omega-\omega_c)$ in Fig. 4 (a), (b). The current iJ_-' in the case of constant collision frequency (17)$'$ is also shown by a broken line in the same figure:

$$iJ_-'=-\frac{\omega_p{}^2}{4\pi}E_-\tau\frac{\tau(\omega-\omega_c)-i}{\tau^2(\omega-\omega_c)^2+1}\ ,\quad \tau=1/\nu_m\ .$$

From this figure, we can see that J_- in the case of constant cross section is almost the same as J_-' in the case of constant collision frequency.

Appendix III Current due to grad *f*

Let us compare J_E produced by the longitudinal field E_x with J_D produced by the density gradient $\partial f_e/\partial x$. By use of (15), J_E and J_D are given as follows:

$$J_E=-e\int v_x{}^2\frac{e}{m}\frac{1}{v}\frac{\partial f_0}{\partial v}E_x\frac{\nu_m-i\omega}{(\nu_m-i\omega)^2+\omega_c{}^2}4\pi v^2dv$$

$$=\frac{ne^2}{3kT}\left\langle\frac{\nu_m-i\omega}{(\nu_m-i\omega)^2+\omega_c{}^2}v^2\right\rangle E_x=ne\mu E_x\ , \tag{A. III. 1}$$

$$J_D=\frac{e}{3}\left\langle\frac{\nu_m-i\omega}{(\nu_m-i\omega)^2+\omega_c{}^2}v^2\right\rangle\frac{\partial n}{\partial x}$$

$$=e\frac{kT}{e}\mu\frac{\partial n}{\partial x}=eD\frac{\partial n}{\partial x}\ . \tag{A. III. 2}$$

We can see from the above equations that the Einstein's relation is valid in microwave region. Let the wave length of microwave be λ', we have relations of order estimation:

$$\frac{E_x}{\lambda'}\simeq\mathrm{div}\,\boldsymbol{E}=4\pi e(n-n_0)\ ,$$

$$\frac{\partial n}{\partial x}\simeq\frac{n-n_0}{\lambda'}\ ,$$

where n_0 is the equilibrium value of the density. Finally, we obtain the relation

$$J_E/J_D\simeq n_0e^2\mu4\pi(n-n_0)\lambda'/[kT\mu(n-n_0)/\lambda']$$

$$=4\pi e^2n_0\lambda'^2/kT=\lambda'^2/\lambda_D{}^2\ .$$

Optical Image Formation in Terms of Entropy Transformations*

Edward L. O'NEILL** Toshimitsu ASAKURA

Information Technology Department, ITEK Corporation
Lexington, Massachusetts U. S. A.

(Received October 10, 1960)

Three major developments have been associated with problems in image formation optics in the last decade. They are the application of Communication and Information Theory concepts to optics, the theory of partial coherence and finally the matrix approach to image formation. In this report it is shown that these three developments are intimately related. Starting with E. Wolf's general theory of image formation in terms of the mutual coherence function, it is shown that both the matrix and communication approaches flow naturally from it. In addition, these latter two are themselves closely related. Finally, some new results showing the change in entropy loss as a function of focal position are presented both from a geometrical and physical optics point of view.

The appeal is one of unity. The arguments presented are confined to the special but important case of quasi-monochromatic illumination. For sources of arbitrary spectral width and time varying fields, the generalized theory has not yet been fully developed.

§1. Introduction

The field of opitical image formation has undergone a renaissance in the last decade or so, the impetus for this renewed interest coming from several distinct sources. First, the fact that the equations describing the formation of an optical image could be cast into a form already well known to circuit engineers gave rise to the speculation that optical image formation could be treated from the standpoint of linear filter theory. With certain slight, but important, modifications, the techniques developed in electric filter theory were applied to optical systems with so much success and appeal that today they are an accepted way of treating problems in image formation.

In addition to this stimulating influence, a number of workers began to examine carefully the naive concepts associated with the terms "coherent" and "incoherent" light. By a process of inductive investigation, much of the ambiguity and vagueness of the earlier work was removed from the theory. Culminating in the outstanding work of Emil Wolf in recent years, the theory of partial coherence stands as a self-consistent, conceptually clear, and logical extension of the classical Maxwell description of electromagnetic wave propaga-

** Now at Department of Physics, Boston University, Boston 15, Mass., U. S. A.

tion. A similar treatment has been and is being carried on for vector waves in the theory of partial polarization.

Finally, Gamo[1)] and Gabor,[2)] simultaneously and independently, demonstrated that image formation could be treated by matrix methods in complete analogy to the wave versus matrix formalism of the early days of modern quantum mechanics. Gamo has developed the theory of the point where it now appears that the "illumination matrix" will play a role in statistical optics similar to that played by the density matrix of statistical mechanics.

This paper, in addition to presenting some new results of the application of statistical communication theory concepts to optics, will attempt to demonstrate the the connections among these three approaches. For reasons of logical consistency, a phenomenological treatment of the theory of partial coherence based on Wolf's approach will be given in section 2, while section 3 will develop the two extreme cases of this general approach, emphasizing the notation of linear filtering. The part that entropy plays in image formation will also be presented in section 3, together with illustrations and discussions of the connection between the entropy criterion and the more classical descriptions of image quality. Section 4, will demonstrate the relation between the Gamo matrix description and the partial coherence factors outlined in section 2.

§ 2. Generalized theory of image formation

An excellent historical review of the work in the theory of partial coherence has been given in a recent publication[3)] by Born and Wolf. For our purposes here, we accept the final results of the theory on the basis of the phenomena it is capable of explaining in a logically consistent way. Taking the deductive approach, we start with the most general relation[4)] between observable quantities over the object and image planes and deduce the equation describing the formation of an image in quasi-monochromatic light for the two extreme cases of fully coherent and fully incoherent illumination. It is with these two extreme cases that the remainder of the paper is concerned.

A few definitions, will be needed. Following Wolf† let $\Gamma_{12}(\tau)=\Gamma(\vec{x}_1, \vec{x}_2; \tau)$ represent the mutual coherence of the light vibrations at two points in the wave field at times separated by τ and let $\Gamma(\vec{x}_1, \vec{x}_2; \nu)$ represent its temporal Fourier transform. In terms of the scalar disturbance over the wave field, $\Gamma_{12}(\tau)$ is defined as

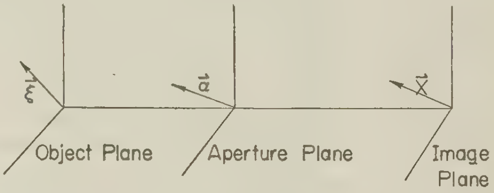
$$\Gamma_{12}(\tau)=\langle V(\vec{x}_1, t+\tau)V^*(\vec{x}_2, t)\rangle=\langle V_1(t+\tau)V_2^*(t)\rangle \tag{1}$$

the brackets indicating a time average.

In terms of the sketch below, the relation between the Fourier transforms of $\Gamma_{12}(\tau)$ over the object and image planes is given by

$$ {}_i\hat{\Gamma}(\vec{x}_1, \vec{x}_2; \nu)=\iiiint_{-\infty}^{+\infty} {}_0\hat{\Gamma}(\vec{\xi}_1, \vec{\xi}_2; \nu)K(\vec{\xi}_1-\vec{x}_1; \nu) K^*(\vec{\xi}_2-\vec{x}_2; \nu)d\vec{\xi}_1 d\vec{\xi}_2 \tag{2}$$

where $K(\vec{x}_1, \nu)$ represents the complex amplitude distribution in the image plane due to a monochromatic point source of frequency ν in the object plane. In (2) it is assumed that this distribution does not change appreciably over the region being explored.



The mutual coherence function itself, it must be recalled, is given by

$$\Gamma_{12}(r)=\int_{-\infty}^{+\infty}\Gamma_{12}(\nu)e^{-2\pi i\nu\tau}d\nu \tag{3}$$

and the actual intensity variations over the object and image planes by

$$ {}_0I(\vec{\xi})={}_0\Gamma_{11}(0)={}_0\Gamma(\vec{\xi}_1, \vec{\xi}_1; 0) \tag{4}$$

$$ {}_iI(\vec{x})={}_i\Gamma_{11}(0)={}_i\Gamma(\vec{x}_1, \vec{x}_2; 0)$$

respectively. Taking the temporal Fourier transform of (2) yields a direct relation between the mutual coherence function over the object and image planes in the form,

$$ {}_i\Gamma(\vec{x}_1, \vec{x}_2; \tau)=\iiiint_{-\infty}^{+\infty} K(\vec{\xi}_1-\vec{x}_1; \nu) \times K^*(\vec{\xi}_2-\vec{x}_2; \nu) {}_0\Gamma(\vec{\xi}_1, \vec{\xi}_2, \nu)e^{-2\pi i\nu\tau}\vec{d}\xi_1\vec{d}\xi_2 d\nu \tag{5}$$

---

† The authors wish to express their gratitude to Dr. G. Parrent for permission to consult a manuscript based on his Doctoral Dissertation at Manchester University.

The time and space Fourier transforms of $\Gamma_{12}(\tau)$ have interesting physical significance[3] in terms of the fringe contrast produced in the Michelson two-beam and stellar interferometers respectively. In the former case, information is obtained about the spectral energy density of the source; while in the latter, information is obtained which describes the brightness of the source as a function of its geometry.

Turning now to the special case of *quasi-monochromatic* illumination over the object plane defined by the set of (5)

a. ${}_0\Gamma_{12}(\tau)={}_0\Gamma_{12}(o)e^{-2\pi i\bar{\nu}\tau}$

b. ${}_0\hat{\Gamma}_{12}(\nu)=-\Gamma_{12}(o)\delta(\nu-\bar{\nu})$

assuming

c. $|\tau|\ll\frac{1}{\Delta\nu}$

equation (5) becomes

$$\Gamma(x_1, x_2; \tau)=\iiiint_{-\infty}^{+\infty}K(\vec{\xi}_1-\vec{x}_1; \bar{\nu})K^*(\vec{\xi}_2-\vec{x}_2; \bar{\nu}) \times {}_0\Gamma(\vec{\xi}_1, \vec{\xi}_2; o)d\vec{\xi}_1 d\vec{\xi}_2 e^{-2\pi i\bar{\nu}\tau} \tag{7}$$

The actual intensity variation over the image plane is then, by (4)

$${}_iI(x)={}_i\Gamma(\vec{x}_1, \vec{x}_1; o)=\iiiint_{-\infty}^{+\infty}K(\vec{\xi}_1-\vec{x}_1, \bar{\nu}) \times K^*(\vec{\xi}_2-\vec{x}_1; \bar{\nu}){}_0\Gamma(\vec{\xi}_1, \vec{\xi}_2; o)d\vec{\xi}_1 d\vec{\xi}_2 \tag{8}$$

We now specialize still further. From *incoherent* illumination over the object plane, for example a self-luminous object, ${}_0\Gamma_{12}(o)$ takes the form

$${}_0\Gamma(\vec{\xi}_1, \vec{\xi}_2; o)={}_0I(\vec{\xi}_1)\delta(\vec{\xi}_1-\vec{\xi}_2) \tag{9}$$

Substituting this into (7) and capitalizing on the sifting property of the δ-function, we arrive at an equation which emphasizes the linear filtering aspect of incoherent image formation:

$${}_iI(x)=\iint_{-\infty}^{+\infty}{}_0I(\vec{\xi})s(\vec{\xi}-\vec{x}, \bar{\nu})d\vec{\xi} \tag{10}$$

where $s(x)=|K(x)|^2$ is the intensity impulse response or spread function for the system. Taking the two dimentional spatial Fourier transform of (10) results in the well known multiplication equation in frequency space for the object and image spatial spectra

$${}_i\hat{I}(\vec{\omega})=\tau(\omega){}_0\hat{I}(\vec{\omega}) \tag{11}$$

where $\tau(\omega)$ is the spatial frequency response or transfer function of the optical system in incoherent light. Because, in practice, most optical instruments are confronted with incoherently illuminated objects, a great deal of attention has been paid to (10) and (11) in the last decase—so much so, in fact, that today a number of industrial instruments are available which yield $\tau(\vec{\omega})$ for lens systems.

At the other extreme, for fully *coherent* illumination over the object plane we must make an appeal to a theorem recently demonstrated by Parrent[5] which states that "in the quasi-monochromatic approximation a coherent field is completely characterized by a complex wave function U which depends on the coordinates of one point only and in terms of it the mutual coherence function is given by

$$\Gamma_{12}(\tau)=U(P_1)U^*(P_2)e^{-2\pi\bar{\nu}\tau}, \ |\tau|\ll\frac{1}{\Delta\nu}.\text{"} \tag{12}$$

Applying this theorem to the mutual coherence function over the object plane in (8), we find for the intensity distribution in the image plane

$${}_iI(x)=\left|\int_{-\infty}^{+\infty}{}_0U(\vec{\xi})K(\vec{\xi}-\vec{x}; \bar{\nu})d\vec{\xi}\right|^2 \tag{13}$$

or in terms of the complex amplitudes over the object and image planes, the system behaves as a linear filter governed by the equation

$${}_iU(\vec{x})=\int_{-\infty}^{+\infty}{}_0U(\vec{\xi})K(\vec{\xi}-\vec{x}; \bar{\nu})d\vec{\xi}. \tag{14}$$

Again, taking the spatial Fourier transform of both sides, we derive the multiplication relation in frequency response

$${}_i\hat{U}(\vec{\omega})=\hat{\tau}(\omega){}_0\hat{U}(\vec{\omega}) \tag{15}$$

where $\hat{\tau}(\omega)$ is here the coherent transfer function.

Before closing this section it is important to emphasize again that this material is being used as both a base and a connecting link for the remainder of the paper. From the standpoint of image formation as linear filtering we are concerned with the extreme cases of fully coherent and incoherent illumination. For the more general case of partially coherent illumination these concepts have been extended considerably in Dr. Parrent's thesis.

§ 3. Entropic Description of Image Formation

Section 2 indicate that, at least in principle, under conditions which are frequently satisfied in practice, it is always possible to predict the variation in intensity over the final image plane in terms of the parameters describing the optical system, the intensity variation over the object plane, and the mode of illumination. In practice, however, most optical systems are required to image incoherently illuminated or self-luminous objects. For this special but important case the equations simplify considerably, leading to the relatively simple relations shown in (10) and (11). In this section, attention will be focused on the problem of image formation in incoherent quasi-monochromatic light with emphasis on the aspect of linear filtering. Many of the results will be directly applicable to systems linear in complex amplitude (coherent).

A study of (10) and (11) shows that $\tau(\vec{\omega})$ and $s(\vec{x})=|K(\vec{x})|^2$ are Fourier transform pairs. A direct application of the Convolution Theorem results in the interesting relation

$$\tau(\vec{\omega})=\frac{\iint_{-\infty}^{+\infty}\hat{K}(\vec{\alpha})\hat{K}^*(\vec{\alpha}+\vec{\omega})d\vec{\alpha}}{\iint_{-\infty}^{+\infty}|\hat{K}(\vec{\alpha})|^2d\vec{\alpha}} \tag{16}$$

But it is well known in scalar diffraction theory that the complex amplitude variations over the aperture plane and Fraunhofer image plane are Fourier transform pairs. Hence, the space frequency response in incoherent light is given by the normalized self-convolution of the complex aperture distribution with its complex conjugate. For a circular aperture with unit amplitude and zero phase (aberrations) over it, $\tau(\omega)$ in (16) is given by the common area of two circles as one slides over the other as a function of the distance between their centers. In this way, the picture of an optical system as a two-dimensional low-pass filter of spatial frequencies is sharpened.

All of this is well known,[6] of course. For periodic objects or for isolated objects on a dark background, (10) and (11) have been used with considerable success to determine the Fourier structure of the image. For random detail in the object plane, the multiplicative relation in frequency space must be written in terms of the Wiener spectra

$${}_i\Phi(\vec{\omega})=|\tau(\vec{\omega})|^2{}_0\Phi(\vec{\omega}) \tag{17}$$

where ${}_0\Phi(\vec{\omega})$ and ${}_i\Phi(\vec{\omega})$ are the spatial Fourier transforms of the auto-correlation of the object and image intensity variations respectively. If, in addition, the object structure is bandlimited to W lines per millimeter then by the Sampling Theorem[7] it is possible to write

$${}_0I(\vec{\xi})=\sum_{n=-\infty}^{+\infty}\sum_{m=-\infty}^{+\infty}{}_0I\left(\frac{m}{2w},\frac{n}{2w}\right)T_{mn}(\vec{\xi}) \tag{18}$$

where $T_{mn}(\xi)$ is the two-dimensional sampling function given by

$$T_{mn}(\vec{\xi})=\frac{\sin(2\pi w\xi-m\pi)}{(2\pi w\xi-m\pi)}\frac{\sin(2\pi w\eta-n\pi)}{(2\pi w\eta-n\pi)} \tag{19}$$

If, in addition, the object is confined to an area L^2, then the Sampling Theorem can be applied directly in frequency space, yielding

$${}_0\hat{I}(\vec{\omega})=\sum_{j=-\infty}^{+\infty}\sum_{k=-\infty}^{+\infty}{}_0\hat{I}\left(\frac{j}{2L},\frac{k}{2L}\right)L_{jk}(\vec{\omega})\,. \tag{20}$$

The relation between the sampled values in the space and frequency planes can be described through the matrix equation

$${}_0\hat{I}_{jk}=\sum_m\sum_n F_{jk,mn}\,{}_0J_{mn} \tag{21}$$

where $F_{jk:mn}$ are the elements of a unitary matrix describing the Fourier transformation between the planes in the form

$$F_{jk:mn}=\exp\left\{i2\pi\left(\frac{jm+kn}{4WL}\right)\right/4WL \tag{22}$$

and where $N=16W^2L^2$ represents the number of degrees of freedom. The complete transformation from the sampled points in object space to those in object frequency space, through the instrument to the image frequency space, and finally to the image sampling points themselves can be described by the matrix equation,

$${}_iI(\vec{x})=F^{-1}\tau F_0I(\vec{\xi}) \tag{23}$$

where τ is a diagonal matrix describing the sine wave response of the instrument and where the elements of the matrix on the left-hand side of (23) can be forced to yield the continuous function ${}_iI(\vec{x})$ by a further application of the Sampling Theorem.

If, further, the probability distribution for the statistically independent intensity values in object space which were sampled is given by $P({}_0I)$, then the entropy of the object set is given by

$$H_0=-\int P({}_0I)\log_2P({}_0I)d_0I \tag{24}$$

and a transformation from the $\vec{\xi}$ to an $\vec{\eta}$

representation results in the entropy

$$\hat{H}_0 = H_0 - \int P({}_0I) \log_2 J({}_0I/{}_0\hat{I}) d_0 I \tag{25}$$

For a linear transformation through the matrix A such that

$${}_0\hat{I} = A_0 I \tag{26}$$

$$J({}_0I/{}_0\hat{I}) = [A]^{-1} \tag{27}$$

where A is the determinant of the matrix A. For the transformation described by (21), $J({}_0I/{}_0\hat{I}) = 1$ so that $\hat{H}_0 = H_0$. In addition the image plane $J({}_iI/{}_i1) = 1$ so that

$$\varDelta H = H_i - H_0 = \hat{H}_i - \hat{H}_0\ . \tag{28}$$

By reasoning similar to that of Shannon[8] and Goldman[7] in two dimensions it is easily shown that

$$\varDelta H = \frac{1}{16\pi^2 w^2} \iint_0^w \log_2 |\tau(\vec{\omega})|^2 d\vec{\omega} \tag{29}$$

Since $0 \leqq |\tau(\omega)|^2 \leqq 1$ over the resolution limit of the system, this entropy change is always a loss. That is, the image is always a smoothed-over version of the object. To illustrate this effect the entropy loss as a function of the defocusing error has been calculated for a one-dimensional slit aperture and a circular aperture from both a physical optics point of view and from the corresponding geometrical approximation. The results are shown in Figures 1 and 2 where only the one-dimensional case is illustrated, while the two-dimensional case can be found in the report[15]. The expressions for the frequency response have been taken from reference 6. One sees that from a geometrical point of view, the image is perfect when properly focused in terms of zero entropy loss, while from the more accurate physical optics description, the entropy undergoes a loss even at best focus due to the finite spread of point image.

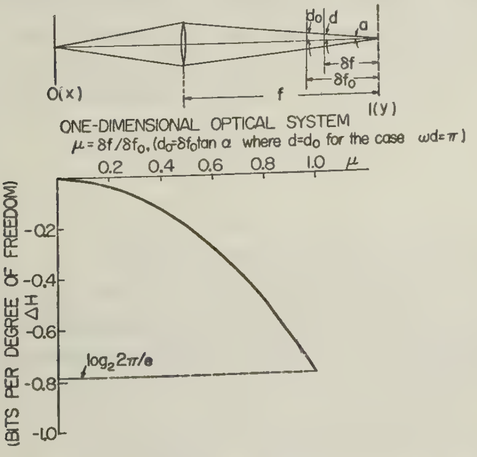


Fig. 1. Entropy loss versus defocusing (one-dimensional geometrical optics case).

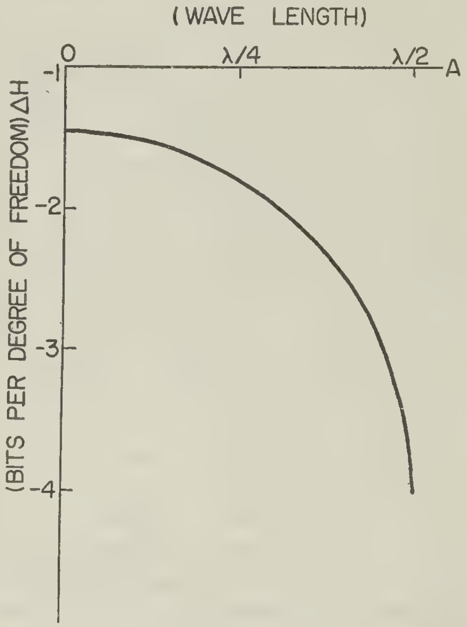
It is interesting to point out that, if one substitutes $|\tau(\vec{\omega})|^2$ in (17) into (29), there results a relation between the entropy difference in the object and image planes and the average value of the log $\varPhi(\vec{\omega})$ in the form

$$\varDelta H = \frac{1}{2} \log_{2i}[\varPhi(\bar{\omega})/{}_0\varPhi(\vec{\omega})] \tag{30}$$

indicating that for a number of systems in cascade, the entropy loss is given in terms of the logarithm of the ratio of the final Wiener spectrum to that of the original.



$$\varDelta H = \int_0^1 \log_2 \bigg/ \frac{\sin 4kA\eta(1-\eta)}{4kA\eta} \bigg/ d\eta \quad \{\text{Reference } 6\}$$

Fig. 2. Entropy loss versus defocusing (one-dimensional physical optics case).

Finally, it is important to see if this description of image formation is connected with the more classical and accepted descriptions. Recalling that $0 \leqq \tau(\vec{\omega}) \leqq 1$, a series expansion of (29) in the form

$$\varDelta H = \text{const.} \iint_0^w \Big\{ 1 - \tau(\vec{\omega}) + \frac{1}{2}[1 - \tau(\vec{\omega})]^2 + \frac{1}{3}[1 - \tau(\vec{\omega})]^3 + \cdots \Big\} d\vec{\omega} \tag{31}$$

shows that only the first few terms contribute appreciably to the integral. However, quality factors defined in terms of integrals over $\tau(\vec{\omega})$ and $\tau^2(\vec{\omega})$ have already been suggested and used[9] in optics with some success. It is not surprising, therefore, to find that minimizing the entropy loss between the object and image plane corresponds to maximizing such terms as Schade's equivalent passband N_e[10] or the Strehl Definition[11] of classical optics.

§ 4. Matrix Description of Image Formation

It remains now to relate the treatments in sections 2 and 3 to the recent matrix description which has already reached an advanced state of development at the hands of H. Gamo. For reasons of conceptual ecomony, one-dimensional variations only will be considered in this section. This will preserve the main features of the argument without introducing unwieldy notation. It should be pointed out, however, that the general theory in two dimensions, including the proof of the rotationally symmetric Sampling Theorem, has been given by both Gamo and Gabor. The emphasis here, however, is to demonstrate how this new formulation is related to that already presented. To this end, therefore, the one-dimensional equivalent of (8) can be written as

$$
{}_iI(x)=\iint_{-\infty}^{+\infty}K(\xi_1-x_1;\,\bar{\nu})K^*(\xi_2-x_2;\,\bar{\nu})\times{}_0\Gamma(\xi_1,\xi_2;\,o)\,d\xi_1 d\xi_2 \tag{32}
$$

Since $K(x)$ is the Fourier transform of the complex amplitude over the exit pupil of the optical system, it is certainly band-limited, allowing one to write

$$
\begin{aligned}
K(\xi-x)&=\sum_{m=-\infty}^{\infty}K\left(\xi-\frac{m}{2w}\right)T_m(x)\\
&=\sum_{m=-\infty}^{\infty}K_m(\xi)T_m(x)
\end{aligned} \tag{33}
$$

where $T_m(x)$ is the one-dimensional form of the sampling function defined in (19). Inserting the summations for K and K^* in (32) results in the following matrix expression of the quadratic form,

$$
{}_iI(x)=\tilde{T}AT=\sum_m\sum_n T_m(x)A_{mn}T_n(x) \tag{34}
$$

where A_{mn} are the elements of the "illumination matrix" defined as

$$
A_{mn}=\iint_{-\infty}^{+\infty}K_n(\xi_1)\,{}_0\Gamma(\xi_1,\xi_2;\,o)K_n^*(\xi_2)\,d\xi_1 d\xi_2 \tag{35}
$$

Since $A^*_{nm}=A_{mn}$ and ${}_iI(x)$ is positive, the matrix is of the positive definite Hermitian form. In addition, the total illumination in the image plane is fixed and is given by the integral over ${}_iI(x)$ in (34). Due to the orthogonality of the sampling functions there results the invariance principle for the trace of the matrix

$$
\int I_i(x)\,dx=\frac{1}{2w}\sum_n A_{nn}=\frac{1}{2w}\,\mathrm{trace}\,(A)=\mathrm{const.} \tag{36}
$$

Finally, there exists a transformation S in function space from the T to T' representation such that

$$
I(x)=\tilde{T}'\Lambda' \tag{37}
$$

Where Λ is given by the similarity transformation

$$
\Lambda=\tilde{S}AS\,. \tag{38}
$$

Conventionally now it is convenient to diagonalize Λ so that (37) reduces to a sum of pure square of the form,

$$
{}_iI(x)=\sum_n\lambda_n T_n'^2(x) \tag{39}
$$

where λ_n are the eigenvalues of the illumination matrix A obtained from setting the determinant $|A-\lambda|=0$. These eigenvalues λ_j can then be used to construct the eigenvectors from which the S matrix itself is determined.

From the standpoint of image formation it is an easy matter to show how these matrices reduce for the two extreme cases of fully coherent and incoherent illumination. First, for the coherent case, the insertion of the condition in (12) into A_{mn} results in

$$
A_{mn}=\int_{-\infty}^{+\infty}K_m(\xi_1)\,{}_0U(\xi_1)\,d\xi_1\int_{-\infty}^{+\infty}K_n^*(\xi_2)\,{}_0U^*(\xi_2)\,d\xi_2 \tag{40}
$$

or

$$
A_{mn}={}_iU\left(\frac{m}{2w}\right){}_iU^*\left(\frac{n}{2w}\right) \tag{41}
$$

Now, substituting this back into (34) and making use of the Sampling Theorem, there results an expression for the image intensity distribution

$$
{}_iI(x)=|{}_iU(x)|^2 \tag{42}
$$

which agrees, of course, with (13) and (14).

For the incoherent ${}_0\Gamma_{12}={}_0T(\xi_1)\delta(\xi_2-\xi_1)$ and again the elements of the illumination matrix take the form

$$A_{mn}=\int_{-\infty}^{+\infty}{}_0I(\xi)K_m(\xi)K_n^*(\xi)d\xi \tag{43}$$

and inserting this into (34) a little manipulation results in

$${}_iI(x)=\int_{-\infty}^{+\infty}{}_0I(\xi)\,|\,K(\xi-x)\,|^2d\xi \tag{44}$$

which, again, agrees with (10) and emphasizes the role of the optical system as a linear filter.

It should also be pointed out that for a series of systems in cascade, the multiple convolution integrals of the form in (44) can be replaced by Fourier space by a single equivalent multiplication relation for the equivalent frequency response of the whole chain as a product of the separate frequency responses of each link. Similarly, Gamo has demonstrated that there exists a matrix parallel to this which allows one to determine one equivalent illumination matrix as a product of matrices arising from each system in the chain. Finally, the sinusoidal test chart plays such as important role currently that the image of such an object has been calculated using the matrix method for the cases of coherent, incoherent, and partially coherent illumination. The rather lengthy and tedious manipulations can be found in reference12).

Turning now from the image forming aspect of the matrix description, it is interesting to note that the illumination matrix corresponds formally in many ways with the density matrix of statistical mechanics. Following von Neumann13) we now extend the analogy further and define the entropy of the light beam in terms of the eigenvalues of the diagonalized matrix; thusly

$$H=-\sum_i\left(\frac{\lambda_i}{\sum\limits_j \lambda_j}\right)\log_2\left(\frac{\lambda_i}{\sum\limits_j \lambda_j}\right) \tag{45}$$

which was mentioned by Gamo14). Since the trace is invariant under a unitary transformation, the sum in the denominators represents the total illumination by (36) and is constant. It is proven15), further, that in the coherent limit H goes to zero, while in the incoherent limit H reaches a maximum agreeing with the usual interpretation of the entropy of completely ordered and disordered arrangements respectively.

It is important to mention here that this entropy is not the same as the entropy of the object intensity distribution given in (24). In point of fact, the term "entropy" as used in thermodynamics, statistical mechanics and information theory has caused considerable confusion. Since its introduction by Clausius16), entropy in thermodynamics has been used to describe the irreversibility between equilibrium states. Starting with the pioneering work of Boltzmann17) in the form of his celebrated H theorem and the interpretations given by Gibbs18), entropy in statistical mechanics has came to be understood as a description of the overwhelming tendency for a non-equilibrium state to reach equilibrium. In a strikingly prophetic paper, Szilard19) pointed out in 1929 the similarity between entropy and information in treating the problem of Maxwell's demon. Later, Shannon,8) concerned with practical problems of message transmission, defined an entropy as a measure of the choice of a massage as well as of the average information in long messages. It is clear that these expressions for entropy are certainly not equivalent since they refer to basically different physical quantities. Much confusion can be avoided if it is agreed to define entropy first as a measure of uncertainty in the mathematical theory of probability. In the same way that the various moments, standard deviation, etc. are defined as weighted sums, it is often useful to employ a stronger measure of the unexpectance of an event than the linear measure P_1 itself, where $0\leqq P_i\leqq 1$. The suggested stronger measure is the $\log 1/P_i$ which covers the range $0\leqq\log 1/p_i\leqq\infty$. The average value of this quantity defined in the usual weighted sense is called the "entropy" of the set of probabilities p_i and is given by $H=-\sum_i p_i\log p_i$. One is now free to apply this notion to any fields in the same way that one applies such concepts as variance and standard deviation.

It is in this spirity that the entropy is a perfectly valid measure of the degree of coherence of a light beam. This is not an unexpected result, however. The value that H assumes is determined by the eigenvalues λ_i which in turn arise from elements of the illumination matrix. These elements in turn are derived from Wolf's mutual coherence function which itself, in normalized form, has been defined as the "degree of coherence." It, too, is a statistical description in the form of the complex cross correlation function of the disturbance at two points in space at different times (see (1)). Finally, it is interesting to point out that Planck[20] (1907) mentions Laue's[21] attempt to relate the thermodynamic entropy of the black body radiation field to the tate of partial coherence. The connection between the present work and Laue's has not as yet been demonstrated.

§ 5. Summary and Conclusions

An attempt has been made to relate the three major developments of theoretical optics in the last decade. Starting with the most general theory of scalar wave propagation in the form of Wolf's mutual coherence function, it has been possible to demonstrate how one can incorporate within this framework some of the more important applications of matrix techniques and statistical filter theory. For the most part, progress has been confined to the more restricted case of quasi-monochromatic illumination with special emphasis on the coherent and incoherent limits. It is to be expected that further attempts at unification will be directed toward treatments of polychromatic partially coherent fields. In addition, the similarity between the illumination matrix of statistical optics and the density matrix of statistical mechanics indicates that future research will exploit this analogy still further. Despite the often centrifugal effects of specialized investigation, it is encouraging to note that, in modern optics at least, there is now a tendency for more general formulations to approach a common focus.

Magnetic Hyperfine Structure in the Rotational Spectrum of H_2CO

By Hiroshi TAKUMA*

Department of Physics, Faculty of Science, University of Tokyo, Tokyo

(Received October 24, 1960)

The theory of magnetic hyperfine interaction of an asymmetric rotor molecule with C_{2v} symmetry in $^1\Sigma$ state was discussed, and the magnetic hyperfine structures in the low frequency rotational spectrum of formaldehyde were studied with a beam maser. The $\Delta F=0$ and the $\Delta F=\pm 1$ components in the $J=4$, $K_{-1}=3$ and the $J=5$, $K_{-1}=3$ Q-branch transitions were observed with good signal-to-noise ratio. The frequency of the $\Delta F=0$ component of the $J=5$, $K_{-1}=3$ line was measured as 18.275 ± 0.004 Mc. The observed hyperfine structures were analysed with the theory, and the hyperfine coupling constants were determined as $\alpha=-13.2\pm 3.4$ kc, $\beta=-3.0\pm 3.4$ kc and $\gamma=30.2\pm 2.7$ kc. The coupling constants were theoretically interpreted, and a proportionality of the hyperfine coupling constans and the rotational g factors for the asymmetric rotor molecule was found. $\langle r^{-3}_{\text{electron}}\rangle_{av}$ arround the proton in H_2CO was obtained as $1.5\times 10^{24}\,\text{cm}^{-3}$ from the comparison of these two quantities.

§1. Introduction

The magnetic hyperfine splittings in the rotational spectrum of a molecule in $^1\Sigma$ state are usually very small, and cannot be observed by a conventional absorption type spectrometer. Recently, the application of beam maser techniques in the field of microwave spectroscopy allowed the observation of the magnetic hyperfine structures of some kinds of molecules with sufficiently good resolutions and sensitivites.

Gordon[1] observed the magnetic hyperfine structures of inversion lines of ammonia, and determined the hyperfine coupling constants. Takuma, Shimizu and Shimoda[2] observed and analysed the magnetic hyperfine structure of the $3_{12}\rightarrow 3_{13}$ transition of H_2CO. Thaddeus, Loubser, Krisher and Lecar[3] observed and analysed the $2_{11}\rightarrow 2_{12}$ transition of H_2CO and HDCO. Shimoda and Kondo[4] observed the magnetic hyperfine structure of the $J=3$, $K=2$ inversion line of ammonia.

The magnetic hyperfine structure of NH_3 was discussed by Gunther-Mohr, Townes and Van Vleck,[4] and by Gordon[1], and experimental results are completely analysed except the anomaly of the hyperfine structure of the (3.2) line found by Shimoda and Kondo.[4]

The theory of magnetic hyperfine structures of asymmetric molecules in $^1\Sigma$ state with C_{2v} symmetry was discussed by Okaya,[7] but his theory and experiment were rather incomplete and did not agree well with the recent studies with masers. The observed patterns of the $3_{12}\rightarrow 3_{13}$ and the $2_{11}\rightarrow 2_{12}$ transitions were explained satisfactorily with the theory in TSS**. However, the hyperfine coupling constants were not obtained from the lack of sufficient number of experimental data.

The physical interpretation of the magnetic hyperfine coupling constants and their relation with rotational g factors were discussed by White[6] for diatomic, linear or symmetric rotor molecules. However, such discussion for asymmetric rotor molecules have not been published.

Thus the problems about the magnetic hyperfine structures are left unaccomplished for asymmetric rotor molecules. The purpose of this paper is to treat such subjects for an asymmetric rotor molecule, H_2CO.

The theory of the hyperfine interaction of H_2CO type molecule was discussed, and the hyperfine coupling constants were theoretically analysed. The hyperfine structures of the low frequency transitions of H_2CO, the $4_{31}\rightarrow 4_{32}$ and the $5_{32}\rightarrow 5_{33}$ transitions, were studied with a low frequency beam maser which was pioneered recently by Shimoda, Takuma and

---

* Present Address, Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo.

** The paper by Takuma, Shimizu and Shimoda[2] on the $3_{12}\rightarrow 3_{13}$ line of H_2CO is reffered as TSS in this paper for convenience.

Shimizu[8]. The magnetic hyperfine satellites in these two transitions were observed with a little improvement of the sensitivity of the spectrometer. From these observations and the experimental result on the $3_{12} \to 3_{13}$ line, the magnetic hyperfine coupling constants were determined.

The results were physically interpreted, and the relation between the magnetic hyperfine coupling constants and the rotational g tensor of the asymmetric rotor molecule was also discussed.

§ 2. Theory of Magnetic Hyperfine Interaction of H₂CO Type Molecules

The Hamiltonian of a formaldehyde type molecule with C_{2v} symmetry in $^1\Sigma$ state can be written as;[1,2,5,9]

$$\boldsymbol{H}=A(J_z-L_z)^2+B(J_y-L_y)^2+C(J_x-L_x)^2 \tag{1.0}$$

$$+(e\mu_N/c)\sum_{K=1,2}\sum_{i} r_{Ki}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)$$

$$\times\left\{\boldsymbol{v}_i-\left(1+\frac{Z_K}{g_H}\right)\boldsymbol{v}_K\right\}g_H\boldsymbol{I}_K \tag{1.1}$$

$$-(e\mu_N/c)\sum_{K=1,2}\sum_{L\neq K} Z_L r_{KL}^{-3}(\boldsymbol{r}_K-\boldsymbol{r}_L)$$

$$\times\left\{\left(1+\frac{Z_K}{g_H}\right)\boldsymbol{v}_K-\boldsymbol{v}_L\right\}g_H\boldsymbol{I}_K \tag{1.2}$$

$$+\mu_N{}^2r^{-3}g_H{}^2\{\boldsymbol{I}_1\cdot\boldsymbol{I}_2-3r^{-2}(\boldsymbol{I}_1\cdot\boldsymbol{r}_{12})(\boldsymbol{I}_2\cdot\boldsymbol{r}_{12})\}\ , \tag{1.3}$$

where J_g is the component of the rotational angular momentum along the molecular fixed $g(g=x, y, z)$ axis, L_g the electronic angular momentum, μ_N the nuclear magneton, r_{Ki} the distance between the K^{th} nucleus and the i^{th} electron, r_{KL} the distance between the K^{th} and the L^{th} nuclei, $\boldsymbol{r}_i$ and $\boldsymbol{v}_i$ the position vector and the velocity vector of the i^{th} electron, $\boldsymbol{r}_K$ and $\boldsymbol{v}_K$ the position vector and the velocity vector of the K^{th} nucleus, g_H the g factor of proton, Z_K or Z_L the effective charge of the K^{th} or the L^{th} nucleus, r the distance between the two protons, and I_K the spin of the K^{th} proton. The nuclei are numbered so that $K=1$ and 2 for the protons. The molecular fixed coordinate axes x, y, and z are chosen as the principal axes of the molecule.

The energy of the hyperfine interaction was given as a function of $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling constants A_{Kg} and spin-spin interaction terms, but the theoretical evaluation of A_{Kg} was not discussed in TSS. In order to obtain a theoretical background about the experimental values and to get informations about the electronic state of the rotating molecule, detailed discussions on A_{Kg} are given below. The electronic state must be excited by molecular rotation, because Eq. (1) contains the coupling terms between the electronic angular momentum and molecular rotation. The Hamiltonian $\boldsymbol{H}$ will be treated by the electronic wave function at first. The Hamiltonian is devided into two parts; $\boldsymbol{H}^{(1)}$ and $\boldsymbol{H}^{(2)}$, the one which is diagonal and the other which is off diagonal in electronic wave function as below;

$$\boldsymbol{H}^{(1)}=\sum_{g\ \ x,y,z} A_gJ_g{}^2 \tag{2.0}$$

$$-(e\mu_Ng_H/c)\sum_{K=1,2}\sum_{L\neq K} Z_L r_{LK}^{-3}(\boldsymbol{r}_K-\boldsymbol{r}_L)$$

$$\times\left[\left(1+\frac{Z_K}{g_H}\right)\boldsymbol{v}_K-\boldsymbol{v}_L\right]\cdot\boldsymbol{I}_K \tag{2.1}$$

$$+\mu_N{}^2r^{-3}g_H{}^2[\boldsymbol{I}_1\cdot\boldsymbol{I}_2-3r^{-2}(\boldsymbol{I}_1\cdot\boldsymbol{r}_{12})(\boldsymbol{I}_2\cdot\boldsymbol{r}_{12})]\ , \tag{2.2}$$

$$\boldsymbol{H}^{(2)}=\sum_{g=x,y,z} A_gL_g{}^2 \tag{2.3}$$

$$-2\sum_{g=x,y,z} A_gJ_gL_g \tag{2.4}$$

$$+(e\mu_Ng_H/c)\sum_{K}\sum_{i} r_{iK}^{-3}(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\boldsymbol{v}_{iK}\cdot\boldsymbol{I}_K\ , \tag{2.5}$$

where $A_x=C$, $A_y=B$, $A_z=A$, and $\boldsymbol{v}_{ik}=\boldsymbol{v}_i-(1+Z_K/g_H)\boldsymbol{v}_K$. The terms (2.0) is neglected because it is independent of rotational energy of the molecule. The second order perturbation calculation by Van Vleck's method can be written as[5]

$$\langle o|\boldsymbol{G}|o\rangle=\langle o|\boldsymbol{H}^{(1)}|o\rangle+\sum_{n\neq0}(E_0-E_n)^{-1}\langle o|\boldsymbol{H}^{(2)}|n\rangle\langle n|\boldsymbol{H}^{(2)}|o\rangle\ , \tag{3.0}$$

where o and n refer to the ground and the n^{th} excited electronic state of the molecule, and $\boldsymbol{G}$ is the effective Hamiltonian.

The first term in Eq. (3.0) is calculated as;

$$\langle o|\,\boldsymbol{H}^{(1)}|o\rangle=\sum_{g=x,y,z}A_gJ_g{}^2-(e\mu_N/c)\sum_{K=1,2}\sum_{L\neq K}Z_Lr_{LK}^{-3}(\boldsymbol{r}_K-\boldsymbol{r}_L)\times\left[\left(1+\frac{Z_K}{g_H}\right)\boldsymbol{v}_K-\boldsymbol{v}_L\right]\cdot g_H\boldsymbol{I}_K$$

$$+\mu_N{}^2g_H{}^2r^{-3}[\boldsymbol{I}_1\cdot\boldsymbol{I}_2-3(\boldsymbol{I}_1\cdot\boldsymbol{r}_{12})(\boldsymbol{I}_2\cdot\boldsymbol{r}_{12})\boldsymbol{r}^{-2}]\ , \tag{3.1}$$

and the second term is obtained as;

$$\sum_{n\neq0}(E_0-E_n)^{-1}\langle o|\boldsymbol{H}^{(2)}|n\rangle\langle n|\boldsymbol{H}^{(2)}|o\rangle$$

$$=\sum_{g}\sum_{g'}\boldsymbol{M}_{gg'}J_gJ_{g'}+\sum_{g}\sum_{g'}\sum_{K}\boldsymbol{N}_{Kgg'}J_g\boldsymbol{I}_{Kg'}+\sum_{g}\sum_{g'}\boldsymbol{S}_{gg'}\boldsymbol{I}_{1g}\cdot\boldsymbol{I}_{2g'}\ , \tag{3.2}$$

where

$$M_{gg'}=\sum_{n\neq 0}(E_0-E_n)^{-1}\cdot 4A_gA_{g'}\langle o|L_g|n\rangle\langle n|L_{g'}|o\rangle\,, \tag{3.3}$$

$$\begin{aligned}N_{Kgg'}=-(e\mu_N/c)\sum_{n\neq 0}(E_0-E_r)^{-1}\{&\langle o|L_g|n\rangle\langle n|\sum_i[(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\boldsymbol{v}_{iK}]_g r_{iK}^{-3}|0\rangle\\&+\langle o|\sum_i[(\boldsymbol{r}_L-\boldsymbol{r}_K)\times\boldsymbol{v}_{iK}]_{g'}r_{iK}^{-3}|n\rangle\langle n|L_g|o\rangle\}g_H\,,\end{aligned} \tag{3.4}$$

$$\begin{aligned}S_{gg'}=-(e\mu_N g_H/c)^2\sum_{n\neq 0}(E_0-E_n)^{-1}\cdot&\langle o|\sum_i[(\boldsymbol{r}_i-\boldsymbol{r}_1)\times\boldsymbol{v}_{iK}]_g r_{i1}^{-3}|n\rangle\\&\times\langle n|\sum_i[(\boldsymbol{r}_i-\boldsymbol{r}_2)\times\boldsymbol{v}_{iK}]_{g'}r_{i2}^{-3}|o\rangle\,.\end{aligned} \tag{3.5}$$

The first term in the right hand side of Eq. (3.2) is the increment of the rotational energy of the molecule due to the excitation of the electronic state, and can be neglected in the present discussion, because it is small compared with the rotational energy and has the same expression as the energy of the molecular rotation.

Because $\boldsymbol{v}_K=\boldsymbol{\omega}\times\boldsymbol{r}_K$, where $\boldsymbol{\omega}$ is the angular velocity of the molecule, and $\boldsymbol{\omega}_g$ is equivalent to $2A_gJ_g/\hbar$, terms such as $(\boldsymbol{r}_K-\boldsymbol{r}_L)\times\boldsymbol{v}_K$ can be substituted by[5]

$$[(\boldsymbol{r}_K-\boldsymbol{r}_L)\times\boldsymbol{v}_K]_g=\sum_{g'=x,y,z}\{\delta_{gg'}(\boldsymbol{r}_K-\boldsymbol{r}_L)\boldsymbol{r}_K-\boldsymbol{r}_{Kg'}(\boldsymbol{r}_K-\boldsymbol{r}_L)_g\}\times\frac{2A_{g'}J_{g'}}{\hbar}\,.$$

On the other hand, the directions of the principal axes of the diadic of $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling constants for each hydrogen nucleus must be parallel to the principal axes of the molecule from symmetry consideration. Therefore, cross products $J_gJ_{g'}$ between different g and g' must vanish in the final form of the effective Hamiltonian. Taking into account of these facts, and by putting $-I_{Kg}=\bar{I}_{Kg}$ in order to discuss with the molecular fixed coordinate axes, we obtain the Hamiltonian for the nuclear magnetic interaction;

$$\begin{aligned}\boldsymbol{G}=&-\sum_{K=1,2}(A_{Kx}\bar{I}_{Kx}J_x+A_{Ky}\bar{I}_{Ky}J_y+A_{Kz}\bar{I}_{Kz}J_z)\\&+\mu_N{}^2g_H{}^2r^{-3}[\sum_g\bar{I}_{1g}\bar{I}_{2g}-3(\sum_g\bar{I}_{1g}r_g)(\sum_g\bar{I}_{2g}r_g)r^{-2}]\,,\end{aligned} \tag{4}$$

which is the same as Eq. (4) in TSS. The hyperfine coupling constants, $A_{Kg}{}^{(1)}$ and $A_{Kg}{}^{(2)}$ are defined below.

$$\begin{aligned}A_{Kg}^{(1)}=-\frac{2e\mu_NA_gg_H}{c\hbar}\sum_{L\neq K}Z_Lr_{LK}^{-3}\Big\{&\Big(1+\frac{Z_K}{g_H}\Big)\\&\times[(\boldsymbol{r}_K-\boldsymbol{r}_L)\boldsymbol{r}_K-\boldsymbol{r}_{Kg}(\boldsymbol{r}_K-\boldsymbol{r}_L)_g]\\&-[(\boldsymbol{r}_K-\boldsymbol{r}_L)\boldsymbol{r}_L-\boldsymbol{r}_{Lg}(\boldsymbol{r}_K-\boldsymbol{r}_L)_g]\Big\}\end{aligned} \tag{5.1}$$

$$\begin{aligned}A_{Kg}^{(2)}=\frac{e\mu_Ng_HA_g}{c}\sum_{n\neq 0}(E_n-E_0)^{-1}&\\\times\{\langle o|L_g|n\rangle\langle n|\sum_i&[(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\boldsymbol{I}_{iK}]_g r_{iK}^{-3}|o\rangle\\+\langle o|\sum&[(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\boldsymbol{v}_{iK}]_g r_{iK}^{-3}|n\rangle\langle n|L_g|o\rangle\}\,.\end{aligned} \tag{5.2}$$

Then A_{Kg} in Eq. (4) is determined as

$$A_{Kg}=A_{Kg}^{(1)}+A_{Kg}^{(2)}\,. \tag{5.3}$$

For the convenience of later discussions, following constants are defined;

$$\left.\begin{aligned}\alpha&=A_{1x}+A_{2x}\\\beta&=A_{1y}+A_{2y}\\\gamma&=A_{1z}+A_{2z}\end{aligned}\right\} \tag{5.4}$$

The indirect spin-spin interaction term, $\sum_g S_{gg}I_{1g}I_{2g}$, is neglected in the above discussion, because it is of the order of $(e\mu_Ng_H/c)\cdot\langle r_{\text{electron}}^{-3}\rangle_{\text{av}}(1/mA_g)A_{Kg}^{(2)}\sim 10^{-12}A_{Kg}^{(2)}$, and $A_{Kg}^{(2)}$ is usually the same order of magnitude as the direct spin-spin interaction term (2.3) in $^1\Sigma$ state molecules.

The physical meanings of $A_{Kg}^{(1)}$ and $A_{Kg}^{(2)}$ are apparently shown in Eq. (5). The former is the part of $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling constant due to the rotation of nuclear charge, and the latter is that due to the excitation of the electrons by rotation. In general, the sign of the value of $A_{Kg}^{(1)}$ is negative, and that of $A_{Kg}^{(2)}$ is positive, as seen from Eqs. (5.1) and (5.2). Therefore, the sign of the value of A_{Kg} is positive if the greater parts of the electrons rotate with the molecular frame, because the electrons get angular momentum and $A_{Kg}^{(2)}$ predominates. On the contrary, the sign of the value of A_{Kg} is negative, when the greater parts of the electrons slip against the molecular frame.

§ 3. Measurement of Hyperfine Structures by a Low Frequency Beam Maser

The rotational spectrum of H_2CO lies in a very wide range. The greater part of the rotational transitions lie in rather short wave length microwave region, and it is difficult to study them by beam masers at the present stage. Only a few $\Delta J=0$ transitions are in centimeter ranges in which a beam maser is operated without difficulties. The $2_{11}\rightarrow 2_{12}$ and the $3_{12}\rightarrow 3_{13}$ transitions, which have already been studied, belong to such transitions. The hyperfine structures in $\Delta J=0$ transitions in microwave ranges consist of three strong $\Delta F=0$ components and weak $\Delta F=\pm 1$ components.[2,3] Therefore, it is difficult to observe a $\Delta F=+1$ or $=-1$ transition, because it overlaps one of $\Delta F=0$ components frequently. Only the value of $\alpha-\beta$ is obtained from the observation of $\Delta F=0$ transitions, as shown in TSS.

On the other hand, some $\Delta J=0$ transitions of H_2CO lie in low frequency ranges, and it has been shown by Shimoda, Takuma and Shimizu[8] that these transitions can be observed by a beam maser. The $\Delta F=0$ components in these transitions are separated by only a few cycles per second, while $\Delta F=\pm 1$ transitions are estimated to be separated from $\Delta F=0$ components by the order of 10 kc, as will be shown later. Therefore, the low frequency beam maser is suited to the study of $\Delta F=\pm 1$ transitions. The measurements in microwave and low frequency ranges give more accurate values of α, β and γ than the measurements in only one of these two ranges.

The low frequency measurements were made on the $4_{31}\rightarrow 4_{32}$ and the $5_{32}\rightarrow 5_{33}$ transitions. The experimental procedure was the same in principle as stated in the previous paper.[8] A high Q resonance circuit was used to improve the sensitivity. The noise figure of the spectrometer was 2 for the $4_{31}\rightarrow 4_{32}$ transition, and 1.5 for the $5_{32}\rightarrow 5_{33}$ transition. A long time constant and slow sweeps were used for the observation of hyperfine structure in the $4_{33}\rightarrow 4_{32}$ transition to improve the sensitivity. The time constant was 10 seconds and the sweep rate was about 3 kc/min. for the $4_{31}\rightarrow 4_{32}$ transition, while the time constant of 2.5 seconds and the sweep rate of about 10 kc/min. was used for the $5_{32}\rightarrow 5_{33}$ transition.

The observed patterns are shown in Fig. 1 and Fig. 2, and the measured values are

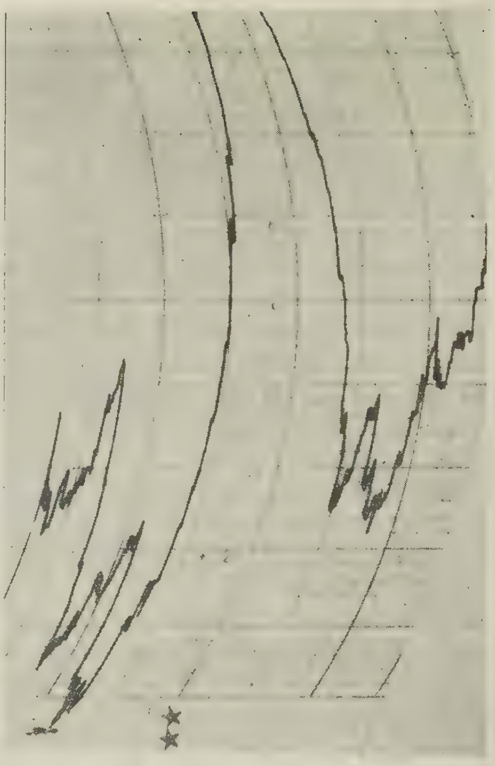

Fig. 1. Trace of the $4_{31}\rightarrow 4_{32}$ transition of H_2CO by beam maser.

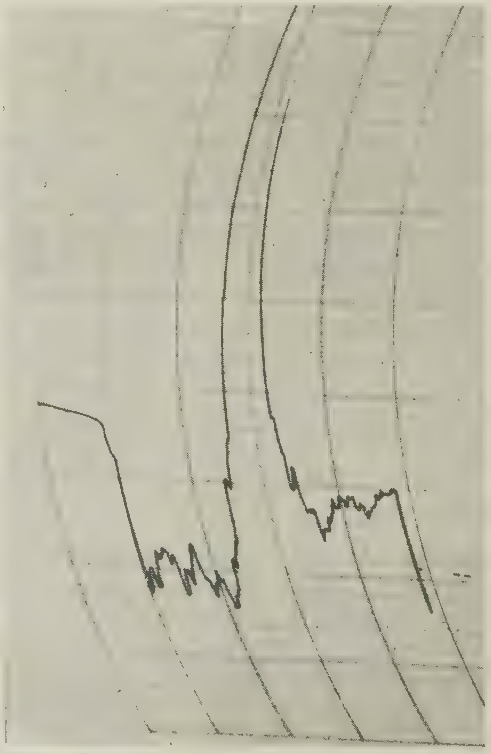

Fig. 2. Trace of the $5_{32}\rightarrow 5_{33}$ transition of H_2CO by beam maser.

Table I. Observed values of hyperfine splittings in the low frequency transitions of H_2CO.

Transitions $J_{K_{-1}K_1} \to J_{K_{-1}K_1}$	$F \to F'$	Splittings (kc)	Frequencies (Mc)
$4_{31} \to 4_{32}$	$\Delta F=0$	0.00	4.5769 ±0.0023*)
	$5 \to 4$ $4 \to 5$	$^{+}_{-}$ 25.7±0.9	
	$4 \to 3$ $3 \to 4$	$^{+}_{-}$ 15.5±1.1	
$5_{32} \to 5_{33}$	$\Delta F=0$	0.00	18.275 ±0.004
	$\left.\begin{matrix}6 \to 5\\ 5 \to 4\end{matrix}\right\}$ + $\left.\begin{matrix}5 \to 6\\ 4 \to 5\end{matrix}\right\}$ −	9.9±0.7	

*) Measured by Shimoda, Takuma and Shimizu.[8)]

listed in Table I.

The frequency shifts due to the magnetic hyperfine interaction for the $F \to F'$ component, $\Delta\nu_{F\to F'}$, are calculated from Eq. (10) of TSS;

$$\left.\begin{aligned}
&\Delta\nu_{F\to F}=0 \qquad (F=J+1,\ J,\ J-1)\,,\\
&\Delta\nu_{J+1\to J}=-\Delta\nu_{J\to J+1}\\
&\quad=\frac{1}{2J}[\alpha\langle J_x^2\rangle+\beta\langle J_y^2\rangle+\gamma\langle J_z^2\rangle]\\
&\quad-\frac{9\mu_N^2 g_H^2 r^{-3}}{2J(2J+3)}\left[\langle J_y^2\rangle-\frac{1}{3}J(J+1)\right],\\
&\Delta\nu_{J\to J-1}=-\Delta\nu_{J-1\to J}\\
&\quad=\frac{1}{2(J+1)}[\alpha\langle J_x^2\rangle+\beta\langle J_y^2\rangle+\gamma\langle J_z^2\rangle]\\
&\quad-\frac{9\mu_N^2 g_H r^{-3}}{2(2J-1)(J+1)}\left[\langle J_y^2\rangle-\frac{1}{3}J(J+1)\right],
\end{aligned}\right\} \qquad (6)$$

because $\Delta\langle J_g^2\rangle \ll 1$ for low frequency transitions.

Eq. (6) shows that the hyperfine spectrum of the low frequency transition of H_2CO consists of a strong center line which corresponds to the $\Delta F=0$ transitions and symmetrically arranged four satellites which correspond to the $\Delta F=\pm 1$ transitions. The $\Delta F=\pm 1$ satellites were completely resolved in the $4_{31}\to 4_{32}$ transition, while only one satellite was observed in the $5_{32}\to 5_{33}$ transition. In the latter case, $\Delta\nu_{6\to 5}$ and $\Delta\nu_{5\to 4}$ or $\Delta\nu_{5\to 6}$ and $\Delta_{4\to 5}$ are nearly equall and two satellites are unresolved.

From the observed values of $\Delta\nu_{5\leftrightarrow 4}$ in the $4_{32}\to 4_{32}$ transition, by putting the values of $\mu_N=5.050\times 10^{-24}$ erg/gauss, $g_H=5.585$ and $r=1.89$Å in Eq. (6), we obtain

$$\alpha\langle J_x^2\rangle+\beta\langle J_y^2\rangle+\gamma\langle {}_z^2\rangle$$
$$=5.500\alpha+5.500\beta+9.000\gamma=188.0\pm 7.2\ \text{kc}. \qquad (7.1)$$

Similary, from the observed value of $\Delta\nu_{3\leftrightarrow 4}$, we obtain

$$5.500\alpha+5.500\beta+9.000\gamma=183.0\pm 1.1\ \text{kc}\,. \qquad (7.2)$$

The right hand sides of Eqs. (7.1) and (7.2) agree will with each other. This is a check for the measurement of $\Delta\nu_{3\leftrightarrow 4}$ and $\Delta\nu_{4\leftrightarrow 5}$. Averaging the values of Eqs. (7.1) and (7.2).

$$5.500\alpha+5.500\beta+9.000\gamma=185.5\pm 9.1\ \text{kc}\,. \qquad (7.3)$$

On the other hand, in the $5_{32}\to 5_{33}$ transition, the average values of $\Delta\nu_{5\leftrightarrow 6}$ and $\Delta\nu_{4\leftrightarrow 5}$ give the frequency shifts of the unresolved satellites in the higher or lower frequency side, which are referred as $\Delta\nu_+$ or $\Delta\nu_-$ respectively. Thus we obtain from Eq. (6),

$$\Delta\nu_+=-\Delta\nu_-$$
$$=\frac{11}{120}(\alpha\langle J_x^2\rangle+\beta\langle J_y^2\rangle+\gamma\langle J_z^2\rangle)-0.07\ \text{kc}.$$

The observed value is put into the above equation, and it becomes;

$$10.50\alpha+10.50\beta+9.000\gamma=107.2\pm 7.6\ \text{kc}. \qquad (8)$$

The value of $\alpha-\beta$ is precisely determined from the observation of the $\Delta F=0$ components in microwave lines. The separation between the $F=4$ and $F=2$ components in the $3_{12}\to 3_{13}$ transition was measured as 23.0±0.6 kc. By putting this value into Eq. (9) in TSS[2)], we obtain*)

$$\alpha-\beta=-10.2\pm 0.9\ \text{kc}. \qquad (9)$$

Thus the values of α, β and γ are determined from Eqs. (7), (8) and (9);

$$\alpha=-13.2\pm 3.4\ \text{kc}$$
$$\beta=-3.0\pm 3.4\ \text{kc}$$
$$\gamma=30.2\pm 2.7\ \text{kc}$$

§ 4. Discussions

The hyperfine structures in the rotational spectrum of H_2CO have been calculated according to the theory and the hyperfine coupling constants determined above. The calculated values are listed in Table II, and compared with the experiments. The agreement between the calculated and the experimental values is very good. Thus the hyperfine structure in the rotational spectrum of H_2CO has been completely analysed, and the theories of hyperfine structure in the rotational spectrum of an asymmetric molecule by Posener[9] or TSS[2] have proved to be useful for a practical analysis.

---

*) The value of $\alpha-\beta$ was determined as −9.1± 0.6 kc in TSS. However, the measurement of the separation between the $F=3$ and the $F=4$ components might have some systematic error, because they were not resolved completely. Therefore, the experimental value of $\Delta\nu_{2\to 2}-\Delta\nu_{4\to 4}$ alone was used to determine the value of $\alpha-\beta$. More precise measurements on the $3_{12}\to 3_{13}$ and the $1_{10}\to 1_{11}$ transitions are now in progress.

The magnetic hyperfine coupling constants are closely related to the electronic state of the rotating molecule. The magnetic hyperfine coupling constant of proton had been determined with H_2, HD and NH_3.[6] It has a negative sign in all these molecules. That is, the magnitude of the magnetic field due to the rotation of nuclei exceeds that due to the excitation of the electronic state. This is because the distribution of the appreciable portion of the valence electrons is spherically symmetric about the center of mass of these molecule.

On the other hand, the hyperfine coupling constant γ in H_2CO has been obtained to have a positive sign. This is the first case in which the coupling constant of proton has been found to have a positive sign. The reason of the positive sign of the $\boldsymbol{I} \cdot \boldsymbol{J}$ coupling constant will be considered in the following.

A portion of the electrons in the CH bonding orbitals in H_2CO may be assumed to be spherically symmetric about each protons, but it is not spherically symmetric about the center of mass of the molecule. Because the electrons in sp^2 hybridized valence orbitals of the carbon atom and the lone pair electrons of the oxygen atom are fixed with respect to the molecular frame, they are easily excited by rotating the molecular frame.

Therefore, a large portion of the valence electrons does not slip about the center of mass of the molecule. The portion of electrons distributed with spherical symmetry around each proton exibits a kind of slippage about the proton and cancells partly the magetic field due to the proton. Moreover, HH distance r in H_2CO is larger than that of H_2 or NH_3, so the absolute value of $A^{(1)}_{Kg}$ is smaller, because it is proportional to r^{-3} as shown in Eq. (5.1).

Both α and β have small negative values. This shows that the magnetic field due to the nuclear charges exceeds that due to the electrons in the rotation along x or y axis, contrary to z direction. This is because the magnetic field due to the carbon and oxygen nuclei is less effective in producing a magnetic field by a revolution of the molecule along z axis compared with a revolution along x or y axis.

Table III. Magnetic hyperfine coupling constants of H_2CO.

Components	Nuclear (Calculated) (kc)	Electronic (kc)	Totals (Experimental) (kc)
α	−37.8	24.6	−13.2±3.4
β	−19.7	16.7	− 3.0±3.4
γ	−18.6	21.6	30.2±2.7

The nuclear parts of the $\boldsymbol{I} \cdot \boldsymbol{J}$ coupling constants α, β and γ, can be calculated from Eq. (5.1), and listed in Table III. Half an electron is assumed to be in the atomic orbital of each hydrogen in the average, slipping about the proton like the chair of Ferris wheel, in the calculation of these constants. The electronic parts are obtained by subtracting the nuclear parts from the experimentally obtained values of α, β and γ. They are also listed in Table III. The nuclear part or the electronic part of γ is much greater than that of the other components of $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling constants, because each diagonal component of the $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling diadic is proportional to the rotational constant along each axis as shown in Eqs. (5.1) and (5.2), and H_2CO has the largest rotational constant along z axis. Physically, this molecule rotates with a much larger angular velocity about z axis than the angular velocity along x or y axis.

In order to derive the relation between the $\boldsymbol{I}\cdot\boldsymbol{J}$ coupling constants and the rotational g factor of the molecule, Eq. (5.2) is somewhat modified.

$$m\sum_i(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\boldsymbol{v}_{iK}=m\sum_i\boldsymbol{r}_i\times\boldsymbol{v}_i+mN\boldsymbol{r}_K\times\boldsymbol{v}_K$$
$$-m\boldsymbol{r}_K\times\sum_i\boldsymbol{v}_i-m\left(1+\frac{Z_K}{g_H}\right)\sum_i\boldsymbol{r}_i\times\boldsymbol{v}_K\ ,$$

where N is the total number of the valence electrons in the molecule, and m the electron mass. The first term of the right hand side of the above equation is the electronic angular momentum of the molecule, and the order of magnitude of the remaining each term is equal to

$$\frac{m}{M}\times(\text{angular momentum of the molecule}),$$

where M is the mass of the molecule. Therefore, the last three terms are smaller than the first term, and $\sum(\boldsymbol{r}_i-\boldsymbol{r}_K)\times\boldsymbol{v}_{iK}$ in Eq. (5.2) can be substituted by $\hbar L_g/m$. Then following relation is derived;

$$A^{(2)}_{Kg}\cong 4\mu_B\mu_N g_H A_g\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}$$
$$\times\sum_{n\neq0}(E_n-E_0)^{-1}|\langle o|L_g|n\rangle|^2\ , \qquad (11)$$

where μ_B is the Bohr magneton. This is the extension of Eq. (19) in the paper by White[6] to an asymmetric top molecule H_2CO. $\sum_{n\neq0}(E_n-E_0)^{-1}|\langle o|L_g|n\rangle|^2$, which we shall abbreviate as $\sum_n(L_n)_g$, is a measure of the excitation of the electrons by a revolution of the molecule along g axis.

It was also shown by White that $\sum_n(L_n)_g$ was closely related to the rotational g factor for diatomic, linear or symmetric top molecules. The simillar relation to be satisfied for asymmetric molecules with C_{2v} symmetry in ${}^1\Sigma$ state is discussed in the appendix of this paper. From Eqs. (11) and (A10), we obtain the following relation;

$$-A^{(2)}_{Kg}/(g_H\mu_N{}^2g^{(2)}_{gg})\cong\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}\ . \qquad (12)$$

Thus the value of $\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}$ can be obtained from the value of $A^{(2)}_{Kg}$ calculated above, if the value of $g^{(2)}_{gg}$ is known.

The Zeeman effect of the microwave spectrum of H_2CO was studied by Kondo et al. with an absorption type spectrometer.[10] Their results are listed in Table IV. From Eq. (A10), nuclear parts of the rotational g tensor of H_2CO are calculated with the same assumptions as have been assumed in calculating $A^{(1)}_{Kg}$. The electronic parts are obtained by subtracting the nuclear parts from the experimental values. The results are listed in Table IV.

Table IV. Molecular g tensor of H_2CO.

Components	Nuclear (Calculated) (kc)	Electronic (kc)	Totals*) (Experimental) (kc)
g_{xx}	0.305	−0.285	0.02±0.10
g_{yy}	0.317	−0.667	−0.35±0.10
g_{zz}	0.503	−3.403	−2.90±0.05

*) Determined by K. Kondo et al.[10]

Putting the values of $A^{(2)}_{Kg}$ and $g^{(2)}_{gg}$ in Eq. (12), we obtain

$$-A^{(2)}_{Kx}/(g_H\mu_N{}^2g^{(2)}_{xx})=2.01\times10^{24}\ \text{cm}^{-3}\ ,$$
$$-A^{(2)}_{Ky}/(g_H\mu_N{}^2g^{(2)}_{yy})=0.58\times10^{24}\ \text{cm}^{-3}\ ,$$
$$-A^{(2)}_{Kz}/(g_H\mu_N{}^2g^{(2)}_{zz})=1.48\times10^{24}\ \text{cm}^{-3}\ .$$

These values should agree to give the value of $\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}$. Though they differ with each other, their differences are not significant because the relative errors for the experimental values of β and g_{xx} exceed 100 percent (See Table III and IV). The most precise value of $\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}$ is obtained from $A^{(2)}_{Kz}/(g_H\mu_N{}^2g^{(2)}_{zz})$, because the relative experimental errors of γ and g_{zz} are much smaller than that of α, β, g_{xx} and g_{yy}.

Then, the value of $\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}$ is determined as;

$$\langle r^{-3}_{\text{electron}}\rangle_{\text{av}}=1.5\times10^{24}\ \text{cm}^{-3}\ .$$

This is very much larger than that of pure $2p$ orbitals in hydrogen, and it shows that assuming the excited state as a p-electron is questionable. This is the same conclusion as

White[6] obtained for H_2, but the circumstances are more complicated in the present case, because the electrons in the bonding orbitals of the sp^2 hybridized carbon atom play a principal role in H_2CO.

Acknowledgements

The auther would like to express his hearty thanks to Professor K. Shimoda, for his encouragements, valuable advice and inspirations throughout this work. He also thanks to Messrs. T. Shimizu and K. Kondo for their assistances in experiment and discussions on this subject.

Appendix

Zeeman effect of the rotational spectrum of H_2CO by an absorption type spectrometer will be discussed here briefly.[*]

The hyperfine splittings are assumed to be negligibly small, and only the first order Zeeman effect is considered. The Hamiltonian for this problem is;

$$\mathscr{H}=C(J_x-L_x)^2+B(J_y-L_y)^2+A(J_z-L_z)^2$$
$$+\frac{e}{2c}\sum_i(\boldsymbol{r}_i\times\boldsymbol{v}_i)\cdot\boldsymbol{H}-\frac{e}{2c}\sum_K Z_K(\boldsymbol{r}_K\times\boldsymbol{v}_K)\cdot\boldsymbol{H}\,. \tag{A1}$$

In order to treat the Hamiltonian in the same way as that of the magnetic hyperfine structure, the external field H will be described by the molecular fixed coordinate system.

$$\left.\begin{aligned}H_x&=\lambda_{xZ}H\\H_y&=\lambda_{yZ}H\\H_z&=\lambda_{zZ}H\end{aligned}\right\}, \tag{A2}$$

where λ_{xZ}, λ_{yZ} and λ_{zZ} are the direction cosines of x, y and z axes with respect to the space fixed Z axis. The direction of the static field is chosen as the Z axis. Zeeman energy is then described as

$$\varDelta W_Z=-\mu_N\sum_g\sum_{g'}g_{gg'}J_gH_{g'}\,, \tag{A3}$$

where $g_{gg'}$ is the rotational g tensor of the molecule.

The Hamiltonian is devided into two parts in the same way as that of the magnetic hyperfine interaction: one which includes only diagonal terms in the electronic wave function and the other which includes off diagonal terms. The diagonal part $\boldsymbol{H}^{(1)}$ is given as

$$H^{(1)}=CJ_x^2+BJ_y^2+AJ_z^2$$
$$-\frac{e}{2c}\sum_K Z_K(\boldsymbol{r}_K\times\boldsymbol{v}_K)\cdot\boldsymbol{H}\,, \tag{A4}$$

After a little manipulation, we find

$$\langle o|\boldsymbol{H}^{(1)}|o\rangle$$
$$=-\mu_N(g_{xx}^{(1)}J_xH_x+g_{yy}^{(1)}J_yH_y+g_{zz}^{(1)}J_zH_z)\,, \tag{A5}$$
$$g_{gg}^{(1)}=\frac{eA_g}{\mu_N c\hbar}\sum_K Z_K(\boldsymbol{r}_K{}^2-r_{Ky}^2)\,,$$

where $g_{gg}^{(1)}$ is the rotational g tensor of the molecule due to the rotation of nuclear charges.

The effective part of the Hamiltonian which includes off diagonal terms is

$$\boldsymbol{H}^{(2)}=-2CJ_xL_x-2BJ_yL_y-2AJ_zL_z$$
$$+\frac{e}{2c}\sum_i(\boldsymbol{r}_i\times\boldsymbol{v}_i)\cdot\boldsymbol{H}\,. \tag{A6}$$

Thus the electronic part in the result of the perturbation calculation is written as

$$\sum_{n\neq0}(E_n-E_0)^{-1}\langle o|H^{(2)}|n\rangle\langle n|H^{(2)}|o\rangle$$
$$=\sum_g\sum_{g'}\mathfrak{M}_{gg'}J_{g'}J_g+\sum_g\sum_{g'}\mathfrak{H}_{gg'}J_gH_{g'}\,, \tag{A7}$$

where the second order terms on H are neglected, and

$$\mathfrak{M}_{gg'}=\sum_{n\neq0}4(E_0-E_n)^{-1}A_gA_{g'}\langle o|L_g|n\rangle\langle n|L_{g'}|o\rangle$$
$$\mathfrak{H}_{gg'}=-\frac{eA_g}{c}\sum_{n\neq0}(E_0-E_n)^{-1}[\langle o|L_g|n\rangle\langle n|\sum_i(\boldsymbol{r}_i\times\boldsymbol{v}_i)_{g'}|o\rangle \tag{48}$$
$$+\langle o|\sum(\boldsymbol{r}_i\times\boldsymbol{v}_i)_{g'}|n\rangle\langle n|L_g|o\rangle]$$

The term $\sum\sum\mathfrak{M}_{gg'}J_gJ_{g'}$, will not be considered here, because it is the same experssion as the rotational energy of the molecule, and included in it.

Therefore, the Zeeman energy due to the excitation of electrons is obtained as

$$\varDelta W_Z^{(2)}=-\mu_N\sum\sum g_{gg'}^{(2)}J_gH_g\,,$$
$$g_{gg'}^{(2)}=-\frac{eA_g}{\mu_N c}\sum_{n\neq0}(E_n-E_0)^{-1} \tag{A9}$$
$$\times[\langle o|L_g[n\rangle\langle n|\sum_i(\boldsymbol{r}_i\times\boldsymbol{v}_i)_{g'}|o\rangle+\langle o|\sum_i(\boldsymbol{r}_i\times\boldsymbol{v}_i)_{g'}|n\rangle\langle n|L_g|o\rangle]\,.$$

---

[*] Recently, after this work was finished, more detailed calculation of the magnetic interaction of $^1\Sigma$ state molecules including the second order Zeeman effect has been developed by K. Kondo.

As $m\sum r_i\times v_i$ is the electronic angular momentum of the molecule, the diagonal terms of the rotational g tensor of the molecule are obtained as below;

$$g_{gg}=g_{gg}^{(1)}+g_{gg}^{(2)}$$

$$g_{gg}^{(1)}=\frac{eA_g}{\mu_N c\hbar}\sum_K Z_K(r_K{}^2-r_{Kg}^2) \tag{A10}$$

$$g_{gg}^{(2)}=-\frac{4A_g\mu_B}{\mu_N}\sum_{n\neq 0}(E_n-E_0)^{-1}|\langle o|L_g|n\rangle|^2 ,$$

where μ_B is the Bohr magneton and m the electron mass. Eq. (A10) is the extension of Eq. (22) by White[6] to an asymmetric top molecule with C_{2v} symmetry.

Some Remarks on Hydrostatic Pressure and Maxwell Model

By Wataru SEGAWA

College of Humanities and Sciences, Nihon University, Tokyo

(Received October 7, 1960)

The difference between hydrostatic pressure and isotropic component of stress tensor was early mentioned by Reiner in his theory of dilatancy. In the recent development of the theory of viscoelasticity, however, it seems that this distinction becomes fade and is slightened. In this paper, this distinction is rigorously discussed in relation to Maxwell model.

It has been shown that as far as we stay at the assumption that actual stress is equivalent to elastic stress and also to viscous stress and the condition that viscous stress vanishes when viscous strain rate becomes zero, derived Maxwell's formulas can not contain hydrostatic pressure.

§ 1. Introduction

The extention of classical Maxwell's formula to three-dimensional case was initially done by T. Alfrey.[1] However, either the classical formula or Alfrey's formula are founded on the assumption that strain and strain rate are sufficiently small and so are not valid to the cases of large strain and strain rate. Recently, new theories have been developed by Yamamoto[2] and Segawa,[3] which are valid for non-linear viscoelasticity, basing on the extended Maxwell model. Now, we must remember that the classical Maxwell model is the series combination of a Hookeian spring and a Newtonian dashpot and the actual stress is equivalent to the elastic stress and also to the viscous stress. On the other hand, the Maxwell model in the theory of non-linear viscoelasticity is the series combination of a non-Hookeian spring and a non-Newtonian dashpot, though the assumption that the elastic stress is the same as the viscous stress is conserved, as far as we stand in the idea of the series combination of a spring and a dashpot.

The viscous stress is such stress as it vanishes when the viscous strain rate becomes zero. Thus, we can expect that either elastic stress or viscous stress becomes zero when the viscous strain rate vanishes, considering the property of the series combination of a spring and a dashpot. Then, hydrostatic pressure must also vanish because it is a kind of the elastic stress.

The difference between the hydrostatic pressure and the isotropic component of stress was early emphasized by Reiner in his mathematical theory of the dilatancy.[4] In the recent development of the theories of viscoelasticity, however, this distinction seems to have been treated carelessly. In this paper, we will discuss how this distinction is important, especially in relation to Maxwell's formula and some remarks will be done, relating to hydrostatic pressure and Maxwell model.

§ 2. Hydrostatic Pressure and Isotropic Component of Stress Tensor

After Reiner,[4] component of the stress, the strain and the strain rate tensor in the liquid are written as follows:

$$T^{*\lambda\mu}=T^*\delta_{\lambda\mu}+T'^{\lambda\mu}\ , \qquad (2.1)$$

$$e_{\lambda\mu}=e\delta_{\lambda\mu}+e'_{\lambda\mu}\ , \qquad (2.2)$$

$$f_{\lambda\mu}=f\delta_{\lambda\mu}+f'_{\lambda\mu}\ , \qquad (2.3)$$

respectively, where $\delta_{\lambda\mu}$ is the Kronecker's delta, and

$$T'^{\lambda\lambda}=e'_{\lambda\lambda}=f'_{\lambda\lambda}=0\ , \qquad (2.4)$$

$$T^{*\lambda\lambda}=3T^*\ ,\quad e_{\lambda\lambda}=3e\ ,\quad f_{\lambda\lambda}=3f\ . \qquad (2.5)$$

In Eq. (2.1), T^* and $T'^{\lambda\mu}$ express the isotropic components and the deviatoric components of the stress tensor, respecticely. Moreover, this equation can be rewritten as follows:

$$T^{*\lambda\mu}=(T-p)\delta_{\lambda\mu}+T'^{\lambda\mu} \qquad (2.6)$$

where p represents the hydrostatic pressure and is regarded as a function of the isotropic components of strain tensor e:

$$p=p(e) \qquad (2.7)$$

and T and $T'^{\lambda\mu}$ are the functions of isotropic components of the strain rate tensor and of components of the strain rate tensor, respectively:

$$T=T(f)\ ,\quad T(0)=0 \qquad (2.8)$$

$$T'^{\lambda\mu}=T'^{\lambda\mu}(f_{\lambda\mu}) \qquad (2.9)$$

Putting

$$T^{*\lambda\mu}+p\delta_{\lambda\mu}=T^{\lambda\mu}\ , \qquad (2.10)$$

Eq. (2.6) becomes

$$T^{\lambda\mu}=T\delta_{\lambda\mu}+T'^{\lambda\mu}\ , \qquad (2.11)$$

which in the case of liquid is a function of only components of strain rate tensor and just corresponds to $T_v^{\lambda\mu}$ in § 3. From Eq. (2.10), we have

$$T^*=T-p=T(f)-p(e)\ . \qquad (2.12)$$

From the above consideration, we can see that hydrostatic pressure p is not equivalent of the isotropic component of the stress tensor T^*, but such part of it as remains when $f_{\lambda\mu}=0$. This fact was initially pointed out by Reiner. We must also take care of the fact that hydrostatic presure vanishes when $e_{\lambda\mu}=0$ because $e=0$ if $e_{\lambda\mu}=0$.

§ 3. Hydrostatic Pressure and Maxwell Model

As it is well-known, characteristic properties of Maxwell model are represented by two assumptions that (1) the actual stress is equivalent to the elastic stress and also to the viscous stress and (2) the actual strain is the sum of the elastic strain and the viscous strain. In the theory of three-dimensional non-linear viscoelasticity,[2,3] the second assumption has been improved so that the actual strain rate is the sum of the elastic strain rate and the viscous strain rate but the first assumption has not been improved substantially.

Let the actual stress, the elastic stress and the viscous stress be denoted by $T^{\lambda\mu}$, $T_e^{\lambda\mu}$ and $T_v^{\lambda\mu}$ respectively, then the first condition is expressed by

$$T^{\lambda\mu}=T_e^{\lambda\mu}=T_v^{\lambda\mu} \qquad (3.1)$$

Moreover, let the actual strain rate, the elastic strain rate and the viscous strain rate be $f_{\lambda\mu}, f_{e\lambda\mu}$ and $f_{v\lambda\mu}$, respectively, then the second conditioned will be represented by

$$f_{\lambda\mu}=f_{e\lambda\mu}+f_{v\lambda\mu}\ . \qquad (3.2)$$

Similarly as above, let the actual strain, elastic strain and viscous strain be denoted by $e_{\lambda\mu}$, $e_{e\lambda\mu}$ and $e_{v\lambda\mu}$, respectively. Then, we can assume that

$$T_e^{\lambda\mu}=T_e^{\lambda\mu}(e_{e\lambda\mu})\ ,\quad T_e^{\lambda\mu}=0 \text{ when } e_{e\lambda\mu}=0 \qquad (3.3)$$

and

$$T_v^{\lambda\mu}=T_v^{\lambda\mu}(f_{v\lambda\mu})\ ,\quad T_v^{\lambda\mu}=0 \text{ when } f_v^{\lambda\mu}=0 \qquad (3.4)$$

It seems that Eq. (3.3) and Eq. (3.4) are surely natural and reasonable assumptions to be employed whenever we want to develop any theory of viscoelasticity. But as soon as we admit these assumptions we will encounter unpleasant results as we shall see just later.

As we have seen in § 2, hydrostatic pressure is such part of the isotropic components of stress tensor as remains when $f_{v\lambda\mu}=0$. But, if $f_{v\lambda\mu}=0$, we have from Eq. (3.4)

$$T_v^{\lambda\mu}=0$$

and from Eq. (3.1) also

$$T_e^{\lambda\mu}=0$$

and at the same time hydrostatic pressure will vanish because it belongs to the elastic stress.

From the above circumstances, we can see that hydrostatic pressure is not contained in Maxwell model and accordingly in Maxwell's formulas and this fact is natural result as far as we admit Eq. (3.1), Eq. (3.4) and the definition of hydrostatic pressure as mentioned above.

If we want to avoid this obstacle, we should adopt any other model different from the Maxwell model as mentioned above. For instance, we could employ such a model as parallel combination of a spring and a Maxwell element, but then we could no longer call that model a Maxwell model in the same sense of this paper and moreover we would face another obstacle.

Finally, we must notice that in Voigt model the circumstances are quite different from the above, there exist no obstacles, because now actual stress is the sum of elastic stress and viscous stress and elastic stress never vanishes even if viscous stress becomes zero.

§ 4. Conclusions

Hydrostatic pressure is such part of the isotropic components of the stress tensor as remains when components of the viscous strain rate tensor vanish. Whereas, as the condition that component of actual stress tensor is equivalent to that of the elastic stress tensor and also to that of the viscous stress tensor is assumed in Maxwell model and as components of the viscous stress tensor vanish when components of the viscous strain rate tensor becomes zero, we can conclude that the hydrostatic pressure can not be contained in the rheological equations of Maxwell model as far as we conserve the above conditions.

Rheological Equations of Generalized Maxwell Model and Voigt Model in Three-Dimensional, Non-Linear Deformation.

By Wataru SEGAWA

College of Humanities and Sciences, Nihon University, Tokyo

(Recieved October 24, 1960)

It is well known that the generalized Maxwell model and Voigt are very useful for description at the mechainical behaviours of the materials having the distribution of relaxation times or retardation times, as far as the deformation of the materials is one-dimensional and the strain and the strain rate are sufficiently small. In this paper, these two models have been extended so as to be applicable to three-dimensional and non-linear deformations of initially isotropic materials and two sets of rheological equations corresponding to each of such extended models have been obtained.

It has been also shown that, the condition of small deformation being introduced, each of the two sets are reduced to three-dimensional extensions of the corresponding classical equations, and moreover, the three-dimensionaly extended formulas, which are applied to simple elongation, are reduced to the corresponding classical (one-dimensional) equations for the case of simple elongation.

§1. Introduction

In the previous papers[1) 2)], we have derived the rheological equations of the Maxwell model and the Voigt model in the case of three-dimensional, non-linear deformation. Similar derivation was also done by Yamamoto[3)], in somewhat different formulation from our's.

In these treatment, one-dimensional, classical models have been extended so as to be applicable to three-dimensional, non-linear deformations. For instance, in the classical Maxwell model actual strain is the sum of elastic strain and viscous strain, whereas in our Maxwell model actual strain rate is the sum of elastic strain rate and viscous strain rate. Moreover, in order to represent nonlinearity, Hookeian spring and Newtonian dashpot have been replaced by non-Hookeian spring and non-Newtonian dashpot, respectively, and to be valid for three-dimensional deformation, various relations have been described by the components of their tensors.

As is well known, in the classical theory of viscoelasticity we considered the generalized Maxwell model and Voigt model having the distribution of relaxation times and retardation times, respectively, in order to represent the mechanical behaviours of materials and the former is the parallel combination of Maxwell elements and the latter is the series combination of Voigt elements.[4)]

In this paper, under the similar considerations of the previous papers, we will derive the rheological equations of the generalized models in the case of three-dimensional and nonlinear deformations of initially isotropic materials and moreover we will make clear how the above equations will be reduced to the corresponding classical formulas or the three-dimensional extensions of them.

§2. Rheological Equation of Generalized Maxwell Model

Let the quantities relating to p-th Maxwell element be denoted by subscript p.

The generalized Maxwell model in three-dimensional case will be specified by the condition

$$T^{\lambda\mu}=\sum_{p=1}^{n}T_p{}^{\lambda\mu} \tag{2.1}$$

where $T^{\lambda\mu}$ is the component of stress tensor (referred to the deformed state), and $T_p{}^{\lambda\mu}$ is the component of stress tensor in p-th Maxwell element.

Let the coordinates of a material particle in underformed state and deformed state (when elastic process alone took place in p-th Maxwell element) be denoted by x^i and $y_p{}^{*\lambda}$, respectively, in a rectangular coordinate system fixed in space. Then, strain rate-stress relation in p-th Maxwell element may be represented by

$$f_{\lambda\mu}=\frac{\partial y_p{}^{*\lambda}}{\partial x^i}\frac{\partial y_p{}^{*\mu}}{\partial x^j}\frac{d}{dt}\left\{\frac{\partial x^i}{\partial y_p{}^{*\alpha}}\frac{\partial x^j}{\partial y_p{}^{*\beta}}(A_p\delta_{\alpha\beta}+B_pT_p{}^{\alpha\beta}+C_pT_p{}^{\alpha\gamma}T_p{}^{\gamma\beta})\right\}+D_p\delta_{\lambda\mu}+E_pT_p{}^{\lambda\mu}+F_pT_p{}^{\lambda\nu}T_p{}^{\nu\mu} \qquad (2.2)^{1)}$$

where $f_{\lambda\mu}$ is the component of strain rate tensor and $A_p, B_p, C_p, D_p, E_p, F_p$ are the functions of stress invariants defined by

$$T_{p1}=T_p{}^{\lambda\lambda}, \qquad T_{p2}=\frac{1}{2}T_p{}^{\lambda\mu}T_p{}^{\lambda\mu},$$

$$T_{p3}=\frac{1}{3}T_p{}^{\lambda\nu}T_p{}^{\nu\mu}T_p{}^{\mu\lambda}. \tag{2.3}$$

In Eq. (2.2), we must notice that $\lambda, \mu, \cdots$, $i, j, \cdots$ etc. are so-called *dummy index*, but p is not so. This convention will be used throughout this article.

A component of strain tensor in p-th Maxwell element will be given by

$$e_{p\lambda\mu}=\frac{1}{2}(y^{*\lambda}_{p,i}y^{*\mu}_{p,i}-\delta_{\lambda\mu}) \tag{2.4}$$

where $y^{*\lambda}_{p,i}$ represents $\partial y_p{}^{*\lambda}/\partial x^i$ and $\delta_{\lambda\mu}$ is the Kronecker's delta. The strain stress relation is written as follows

$$e_{p\lambda\mu}=A_p\delta_{\lambda\mu}+B_pT_p{}^{\lambda\mu}+C_pT_p{}^{\lambda\nu}T_p{}^{\nu\mu} \tag{2.5}$$

which has appeared in Eq. (2.2).

By virtue of Eqs. (2.4) and (2.5), together with other conditions, we can decide $y^{*\lambda}_{p,i}$ (and accordingly $\partial x^i/\partial x_p{}^{*\lambda}$) ($\lambda, i=1, 2, 3$) as the functions of $T_p{}^{\lambda\mu}$($\lambda, \mu=1, 2, 3$), then Eq. (2.2) becomes the relation between $f_{\lambda\mu}$ and $T_p{}^{\lambda\mu}$. Thus, Eqs. (2.1) and (2.2) express the rheological equation of generalized Maxwell model for the material which is isotropic in the natural state.

When deformation is sufficiently small, we can use the relation

$$\frac{\partial y_p{}^{*\lambda}}{\partial x^i}\frac{\partial y_p{}^{*\mu}}{\partial x^j}=\delta_{\lambda i}\delta_{\mu j}\,,$$

$$\frac{\partial x^i}{\partial y_p{}^{*\alpha}}\frac{\partial x^j}{\partial y_p{}^{*\beta}}=\delta_{i\alpha}\delta_{j\beta}, \tag{2.6}$$

and the strain-stress relation and the strain rate-stress relation will become linear. Substituting these conditions into Eq. (2.2), we have

$$f_{\lambda\mu}=\frac{d}{dt}(A_p\delta_{\lambda\mu}+B_pT_p{}^{\lambda\mu})+D_p\delta_{\lambda\mu}+E_pT_p{}^{\lambda\mu} \tag{2.7}$$

where, denoting the shear modulus by μ_p and the coefficient of viscosity by η_p,

$$\left.\begin{aligned}A_p&=-\frac{1}{6\mu_p}T_{p1}, & B_p&=\frac{1}{2\mu_p}\\ D_p&=-\frac{1}{6\eta_p}T_{p1}, & E_p&=\frac{1}{2\eta_p}\end{aligned}\right\}. \tag{2.8}$$

if the material is incompressible and isotropic.

Eqs. (2.1) and (2.7), together with Eq. (2.8), are three-dimensional extension of the classical equation of generalized Maxwell model.

Let us apply Eqs. (2.1) and (2.7) to incompressible, simple elongation which is specified by

$$\left.\begin{aligned}&T^{11}\neq0, \quad \text{all others}=0\\ &T_p{}^{11}\neq0, \quad \text{all others}=0\\ &f_{\lambda\mu}=0 \text{ if } \lambda\neq\mu\\ &f_{22}=f_{33}=-\frac{1}{2}f_{11}\\ &T_{p1}=T_p{}^{11}\end{aligned}\right\} \tag{2.9}$$

Putting $T^{11}=T$, $T_p{}^{11}=T_p$, $f_{11}=f$, we have from Eq. (2.1)

$$T=\sum_{p-1}^{n}T_p \tag{2.10}$$

and from Eq. (2.7)

$$\left.\begin{aligned}&f=\frac{d}{dt}\left(-\frac{1}{6\mu_p}T_p+\frac{1}{2\mu_p}T_p\right)-\frac{1}{6\eta_p}T_p+\frac{1}{2\eta_p}T_p\\ &-\frac{1}{2}f=\frac{d}{dt}\left(-\frac{1}{6\mu_p}T_p\right)-\frac{1}{6\eta_p}T_p\end{aligned}\right\}, \tag{2.11}$$

accordingly,

$$f=\frac{1}{3\mu_p}\frac{dT_p}{dt}+\frac{1}{3\eta_p}T_p \tag{2.11}$$

Eq. (2.10) and (2.11) are equivalent to the classical equation of generalized Maxwell model.4)

§ 3. Rheological Equation of Generalized Voigt Model

Generalized Voigt model for three-dimensional deformations may be characterized by the condition

$$f_{\lambda\mu}=\sum f_{p\lambda\mu} \tag{3.1}$$

where $f_{p\lambda\mu}$ represents the component of strain rate tensor in the p-th Voigt element. (In this paragraph, we will represent the quantities relating to the p-th Voigt element by subscript p)

The rheological equation to the p-th element of Voigtian material which is isotropic in its natural state will be represented by

$$\begin{aligned} T^{\lambda\mu} &= L_p\delta_{\lambda\mu}+M_p e_{p\lambda\mu}+N_p e_{p\lambda\mu}e_{p\nu\mu} \\ &\quad +P_p\delta_{\lambda\mu}+Q_p f_{p\lambda\mu}+R_p f_{p\lambda\nu}f_{p\nu\mu} \qquad (3.2)^{2)\,3)} \end{aligned}$$

where $T^{\lambda\mu}$ is a component of stress tensor, $e_{p\lambda\mu}$ represents a component of strain tensor in p-th Voigt element, and L_p, M_p, N_p, P_p; Q_p, R_p are functions of the strain invariants and the strain rate invariants, respectively, defined by

$$\left.\begin{aligned} & e_{p1}=e_{p\lambda\lambda}, \quad e_{p2}=\frac{1}{2}e_{\lambda p\mu}e_{p\lambda\mu}, \\ & e_{p3}=\frac{1}{3}e_{p\lambda\nu}e_{p\nu\mu}e_{p\mu\lambda} \\ & f_{p1}=f_{p\lambda\lambda}, \quad f_{p2}=\frac{1}{2}f_{p\lambda\mu}f_{p\lambda\mu} \\ & f_{p3}=\frac{1}{3}f_{p\lambda\nu}f_{p\nu\mu}f_{p\mu\lambda} \end{aligned}\right\} \qquad (3.3)$$

If the material is incompressible, L_p will be reduced to an undetermined coefficient φ, and f_{p1} will become zero.

Strain component in the p-th Voigt element may be defined by

$$e_{p\lambda\mu}=\frac{1}{2}(y^{*\lambda}_{p,i}y^{*\mu}_{p,i}-\delta_{\lambda\mu}) \qquad (3.4)$$

where $y^{*\lambda}_{p,i}$ represents $\partial y_p{}^{*\lambda}/\partial x^i$ and x^i and $y_p{}^{*\lambda}$ express the coordinates of a material particle of undeformed and deformed states in the p-th Voigt element, respectively. Moreover, strain components and strain-rate components are related to each other as follows:

$$e_{p\lambda\mu}=y^{*\lambda}_{p,i}y^{*\mu}_{p,j}\int\frac{\partial x^i}{\partial y_p{}^{*\alpha}}\frac{\partial x^j}{\partial y_p{}^{*\beta}}f_{p\alpha\beta}dt \qquad (3.5)$$

or

$$f_{p\lambda\mu}=y^{*\lambda}_{p,i}y^{*\mu}_{p,j}\frac{d}{dt}\left(\frac{\partial x^i}{\partial y_p{}^{*\alpha}}\frac{\partial x^j}{\partial y_p{}^{*\beta}}e_{p\alpha\beta}\right). \qquad (3.5')^{1)}$$

Then, we can express $e_{p\lambda\mu}(\lambda, \mu=1, 2, 3)$ as the function of $f_{p\lambda\mu}(\lambda, \mu=1, 2, 3)$ by virtue of Eqs. (3.4) and (3.5). Thus, Eq. (3.1), Eq. (3.2), together with Eqs. (3.4) and (3.5), constitute the rheological equation of the generalized Voigt model for the material which is isotropic in natural state.

When the deformation is sufficiently small, Eq, (3.2) will become linear, and using the relation

$$y^{*\lambda}_{p,i}y^{*\mu}_{p,j}=\delta_{\lambda i}\delta_{\mu j}, \quad \frac{\partial x^i}{\partial y_p{}^{*\alpha}}\frac{\partial x^j}{\partial y_p{}^{*\beta}}=\delta_{i\alpha}\delta_{j\beta} \qquad (3.6)$$

Eq. (3.5) and Eq. (3.5′) will be reduced to

$$e_{p\lambda\mu}=\int f_{p\lambda\mu}dt \quad \text{and} \quad f_{p\lambda\mu}=\frac{d}{dt}e_{p\lambda\mu} \qquad (3.7)$$

respectively. We must notice that Eq. (3.7) is valid as far as we concern with small deformation, on the other hand in large deformation strain rate is not given mere by the time derivative of strain but by Eq. (3.5′). Thus, Eq. (3.2) will be reduced to

$$T^{\lambda\mu}=L_p\delta_{\lambda\mu}+M_p e_{p\lambda\mu}+P_p\delta_{\lambda\mu}+Q_p f_{p\lambda\mu} \qquad (3.8)$$

where, denoting the shear modulus by μ_p and the coefficient of viscosity by η_p

$$M_p=2\mu_p, \quad Q_p=2\eta_p$$

and L_p and P_p are linear functions of e_{p1} and f_{p1}, respectively. Moreover, if the material is incompressible, Eq. (3.8) will be reduced to

$$T^{\lambda\mu}=\varphi\delta_{\lambda\mu}+2\mu_p e_{p\lambda\mu}+2\eta_p f_{p\lambda\mu} \qquad (3.9)$$

where φ is an undetermined coefficient. Eq. (3.1) and (3.9) express the three-dimensional extension of the classical rheological equation of generalized Voigt model.

In the case of incompressible materials, simple elongation is specified by

$$\left.\begin{aligned} & T^{11}\neq 0, \text{ all others}=0 \\ & f_{\lambda\mu}=0 \text{ if } \lambda\neq\mu, \ f_{22}=f_{33}=-\frac{1}{2}f_{11} \\ & f_{p\lambda\mu}=0 \text{ if } \lambda\neq\mu, \ f_{p22}=f_{p33}=-\frac{1}{2}f_{p11} \\ & e_{p\lambda\mu}=0 \text{ if } \lambda\neq\mu, \ e_{p22}=e_{p33}=-\frac{1}{2}e_{p11} \end{aligned}\right\} \qquad (3.10)$$

Putting $T^{11}=T$, $f_{11}=f$, $f_{p11}=f_p$ and $e_{p11}=e_p$ we have from Eq. (3.1)

$$f=\sum_p f_p \qquad (3.11)$$

and from Eq. (3.9)

$$\left.\begin{aligned} & T=\varphi+2\mu_p e_p+2\eta_p f_p \\ & 0=\varphi+2\mu_p\left(-\frac{1}{2}e_p\right)+2\eta_p\left(-\frac{1}{2}f_p\right) \end{aligned}\right\}$$

or

$$T=3\mu_p l_p+3\eta_p f_p \qquad (3.12)$$

Eqs. (3.11) and (3.12) represent the classical equation of generalized Voigt model in the case of simple elongation.[4]

§ 4. Discussions

In the precedings, we have derived two sets of rheological equations for the generalized Maxwell model and Voigt model in the case of three-dimensional, non-linear deformations, and it has been shown that, the conditions of small deformation being introduced, the derived equations are reduced to three dimensional extensions of the corresponding classical equations, which, in turn, being applied to simple elongation, are reduced to the corresponding classical equations. We can easily show that the three-dimensionally extended formulas are also reduced to the corresponding classical equations in the case of simple shear, the conditions of simple shear being introduced.

As we have seen, any Hookian spring and any Newtonian dashpot have been thoroughly replaced by non-Nookian spring and non-Newtonian dashpot, respectively, and stress-strain-strain rate relations in the most general type have been effectively utilized.

Eq. (2.1) and (2.2), together witn Eq. (2.4), (2.5), can serve for solving actual problems of general deformation of Maxwellian material which is isotropic in natural state, in principle. But, these equations are very complicated and such calculations will be much involved, because of non-linearity of the equations. The same is true in the case of Eq. (3.1), (3.2), (3.4) and (3.5). More detailed discussions relating to these problems and others will be done later.

The Velocity Distribution at the Interface between Two Liquids

By Setsuo OKUDA

Department of Physics, Okayama University, Okayama

(Received October 31, 1960)

By carrying out detailed experiments in a water flume of dimensions 180 cm×50 cm×15 cm we have observed, by the use of a suitable colouring material, the velocity distribution near the interface between two superposed liquids having different densities, the lighter liquid flowing over the heavier one confined in a hollow. It has thus been found that if there is any difference, however small, between the densities of the two liquids, the velocity of the upper liquid decreases fairly rapidly near the interface, as if it were a solid plane, while the lower liquid is almost at rest in the hollow.

Attempts have then been made to explain the observed flow pattern theoretically. First, a rather simple approximate calculation has been performed by assuming that the two liquids are in direct contact with each other, but no satisfactory explanation of the observed flow pattern has been obtained.

We have next carried out an improved calculation by assuming that there is formed a thin intermediate zone between the two liquids and it has been found that the calculated flow pattern is, in this case, in fairly good agreement with the observed one.

§ 1. Introduction

In natural flows at rivers, lakes and the sea or in artificial flows in chemical engineering process, it is frequently observed that a lighter liquid flows over a heavier one in a concave hollow and that there exists an interface or a thin contacting zone with sharp density gradient between those two liquids. The investigation of such a phenomenon, especially the study of the velocity distribution in the contacting zone, is not only physically interesting for the problem of boundary layer between two liquids, but also practically useful for the technical planning of water supply or the treatment of chemical substance. The purpose of the present study is to observe, by carrying out experiments in a water flume, the velocity distribution in the contacting zone between two liquids having different densities, one of which flows over the other confined in a hollow, and to explain the observed results by theoretical analysis.

§ 2. Experiments

The water flume used in the present experiments is shown in Plate 1.

It consists of two glass side-plates (length being 180 cm and height 50 cm) placed in parallel at a distance of 15 cm and two steel walls and steel bottom. For the scale measurement grid lines with spacing of 10 cm are drawn on the semi-transparent paper pasted on the backside glass plate. For convenience in treatment and application of the obtained results to natural flow, brine was used for heavier liquid and its density was controlled by the concentration of salt, while tap water was used for lighter liquid.

The densities of the liquids were measured by a precise hydrometer (scale interval being 1.000~1.020 gr/cm^3) and it was found that the density difference $\Delta\rho$ between the two liquids did not exceed 0.02 gr/cm^3 which is the maximum value of density difference found in natural water flows under normal conditions.

The thickness of the flowing liquid layer was changed by controlling the positions of the water surface S and the mouths of inlet I and exit E. The lighter liquid was made to circulate by a motor pump M along the course of I→E→C (cock)→M→I and the flow speed was controlled by turning the cock C and regulating the voltage for the motor pump M.

Prior to the present experiments a few physical experiments have been carried out

on stratified water flow.

G. I. Taylor1) observed two-layer flow (tap water flowing over brine in a hollow) in a small water flume (50 cm×6 cm×0.6 cm) in order to explain qualitatively the wind distribution under stabilized condition and G. H. Keulegan2) investigated quantitatively the stability of interface and the mixing of two liquids in various water flumes. In his experiments tap water was made to flow over sugar water.

However, the exact velocity distribution in the contacting zone between two liquids was not determined in their experiments.

In order to determine precisely the velocity distribution in the thin layer, a newly devised "Water-blue Method"3) was applied to the present experiment. When small particles of water-blue (a kind of aniline dye-stuff) of diameters of 0.1∼0.3 mm are plunged into water, they fall down vertically and are dissolved in water and, as shown in Plate 2, there appear blue vertical lines along their paths.

If water flows horizontally, these vertical blue lines shift as time goes on, so that the vertical distribution of the horizontal velocity can be determined by recording the positions of these lines by means of photography or cinematography. It was observed that the flow in the central vertical plane containing flow direction is completely two-dimensional, because the plane is the center of symmetry and the velocity component perpendicular to it vanishes.

In order to determine the density distribution in the contacting zone in motion, small glass spheres4) of various densities, which had been measured precisely beforehand, were put into the zone and their equilibrium positions were observed.

The position at which discontinuous change of density occurs is indicated by a partial bending of the straight line drawn diagonally on the backside wall, as shown in Plate 2, which may be caused by discontinuous change of refractive index5). If ferric chloride is dissolved in brine and potassium ferrocyanide in tap water, prussian blue becomes visible in the mixing zone between two liquids and by observing such a coloured layer it is readily found that the flow in the zone is laminar or turbulent.

For the sake of comparison of the observed results with slow-motion theory, the flow speed was made so slow and the contacting zone was made so stable in most experiments that the coloured layer was very thin and could hardly be recognized in photographs. Lest a small natural convection should occur in the water flume due to the temperature gradient on the side-wall, the temperature of air in the laboratory was kept nearly constant and experiment was not carried out until the temperature of water had become nearly equal to the temperature of air. For convenience in photographing or observation three photo flood lamps (500 W×3) were used to illuminate the wall from behind, but only in short duration lest they should overheat the wall.

Some typical behaviours of the stratified flow as observed by the above-mentioned method are shown in Plates 3, 4, and 5. In each of these plates, the plate with mark (A) shows the general feature of the stratified flow as revealed by pouring the blue ink into the upper liquid at supply mouth, while the plates with mark (B) show the velocity distribution at the central part of the water flume which are visualized by water-blue lines. It is to be noted that the flow in the upper layer is laminar in Plate 3, whereas it is turbulent in Plate 4.

Plate 5 shows the feature of the flow in the case of a homogeneous liquid without density difference.

From these plates it will be seen that when there exists any density difference between two liquids, each liquid flows as if there were a solid plane in the interface, namely, the upper liquid flows with the parabolic velocity distribution in the case of laminar flow or with the flattened one in the case of turbulent flow, while the lower liquid is confined in the hollow and is almost at rest. In the case of a homogeneous liquid without density difference, however, the moving upper layer induces the motion of the lower liquid, and the horizontal velocity decreases continuously.

In the following sections, some analytical calculations are tried in order to explain the remarkable diminution of velocity in the contacting zone between two liquids with density difference.

§ 3. Calculation of the Horizontal Flow in Two Layers, neglecting Vertical Flow

A considerable amount of studies has been carried out so far on two-layer flows stratified vertically. Especially, the velocity distribution in a half jet with infinite layer thickness and infinite horizontal extent has been calculated by G. H. Keulegan[6], R. C. Lock[7] and O. E. Potter[8] for the case of laminar flow, and by S. I. Pai[9] for the case of turbulent flow. But their results that the velocity in the interface is nearly equal to the mean value of the upper and lower velocities are inconsistent with the prompt vanishing of velocity in the contacting zone as observed in the present experiments on a finite flume.

In the branch of estuarine hydrography, on the other hand, many experimental studies[10] have been carried out on the velocity distribution in two-layer flow which consists of upper fresh river water and lower sea water and has finite vertical thickness and infinite horizontal extent. But, their results too cannot be applied to the present experiment for a finite flume.

A. Thom and C. J. Apelt[11] calculated the flow pattern when the horizontally moving liquid with the parabolic velocity distribution flows over the same liquid contained in rectangular hollow whose height is twice as large as its width. The general feature of the calculated flow pattern is very similar to that of the observed one in homogeneous liquid as shown in Plate 5, but as a matter of course their results cannot be applied to the stratified flow with density difference. The stable interface between two liquids with density difference coincides nearly with the ceiling plane of the hollow and the lower liquid is confined and circulates in the hollow.

K. Hidaka[12] calculated the liquid flow in a rectangular hollow subject to the boundary condition that constant tangential stress is acting along the ceiling plane of the hollow. Also, M. Kawaguti[13] calculated a similar flow subject to the boundary condition that there is a constant velocity along the ceiling plane of the hollow. But they did not consider the flow over the ceiling plane. Although both of these authors carried out their rather troublesome calculations by solving the Navier-Stokes equations of motion numerically, yet it will be shown below that a simple calculation can give an approximate flow pattern at the central part of the water flume where the vertical component of velocity is negligibly small.

Hidaka shows that when the liquid circulates in a horizontally long rectangle, the vertical component of velocity is negligible except in the regions near the vertical edgewalls.

This situation does not change even when a horizontal flow contacts with the liquid in the rectangular hollow at its ceiling, and in fact, observation of the motion of the fine materials in the water shows that the vertical flow is negligible in the central region of the long flume.

Thus, a simple calculation for two-layer flow is tried to investigate approximately the flow pattern in the central region of the flume.

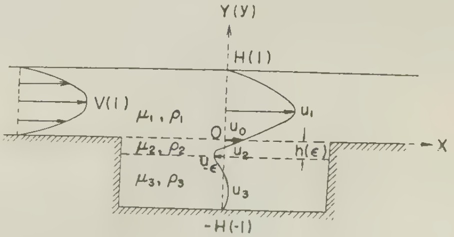

Fig. 1. Two-layer flow.

As shown in Fig. 1, we take the x-axis along the ceiling of the rectangular hollow in the direction of horizontal flow and the y-axis vertically upwards.

Then, if we neglect the vertical component of velocity, the equation of stationary horizontal motion becomes

$$\mu\frac{\partial^2 u}{\partial y^2}=\frac{\partial p}{\partial x}\,, \tag{1}$$

where μ is the coefficient of viscosity, u the horizontal velocity, and p the pressure.

The boundary conditions to be satisfied by the horizontal flow are

$$u_1=0 \qquad \text{at } y=1 \quad \text{(at the fixed surface)},$$

$$\left.\begin{aligned} &u_1=u_2 \\ &\mu_1\frac{\partial u_1}{\partial y}=\mu_2\frac{\partial u_2}{\partial y} \end{aligned}\right\} \qquad \text{at } y=0 \quad \text{(at the interface)},$$

$$u_2=0 \qquad \text{at } y=-1 \quad \text{(at the bottom)},$$

the suffixes 1 and 2 indicating the values in the upper flow and the lower one respectively.

The total flow rate Q_1 through the upper layer is calculated by the use of the initial parabolic velocity distribution $U_{01}=4y(1-y)$ with the maximum value of unity at a section sufficiently upstream of the hollow. Thus we have

$$Q_1=\int_0^1 u_1 dy=\int_0^1 4y(1-y)dy=2/3\,,$$

while the total flow rate Q_2 through the lower layer should vanish, since the lower heavier liquid is confined and circulates in the hollow. Thus,

$$Q_2=\int_0^{-1} u_2 dy=0\,.$$

The solutions of Eq. (1) satisfying the above conditions are given by

$$\left.\begin{aligned} &u_1=\{-(4r+1)y^2+4ry+1\}/(1+r)\,, \\ &u_2=(3y^2+4y+1)/(1+r)\,, \end{aligned}\right\} \tag{2}$$

where $r\equiv\mu_2/\mu_1$ is the ratio of the coefficients of viscosity of the two fluids. From these solutions the pressure gradients in the upper and lower fluids are calculated to be

$$\frac{\partial p_1}{\partial x}=-\frac{8\mu_2+2\mu_1}{1+r}<0\,,$$

$$\frac{\partial p_2}{\partial x}=\frac{6\mu_2}{1+r}>0\,,$$

and the interface inclination γ necessary for balancing with the difference of the pressure gradients in the two layers is given by

$$\gamma=\left(\frac{\partial p_2}{\partial x}-\frac{\partial p_1}{\partial x}\right)\Big/ g\Delta\rho$$

$$=(14\mu_2+2\mu_1)/\{(1+r)g\Delta\rho\}\,, \tag{3}$$

where g is the acceleration of gravity and $\Delta\rho=\rho_2-\rho_1$ is the density difference.

The velocity at the interface, u_0, which indicates the scale of motion in the lower layer, is derived from Eq. (2) as:

$$u_0=(u_1)_{y=0}=1/(1+r)\,. \tag{4}$$

Thus, it will be seen that the larger the viscosity μ_2 of the lower liquid as well as the value of r are, the smaller are the value of u_0 as well as the circulating velocity in the hollow.

The velocity distribution as given by Eq. (2) is very similar to that obtained by Hidaka in the central region of the flume, but it does not coincide with the result observed in the present experiments.

In fact, a slight difference of viscosities between the upper and lower liquids (as measured by the Ostwald viscosimeter) gives the value of $r\fallingdotseq 1$ so that we have from Eq. (4) $u_0\fallingdotseq 0.5$, which conflicts with the prompt vanishing of u_1 near the interface as observed in the experiments.

§ 4. Shear Flow Jumping over the Hollow; Effect of Vertical Walls upon the Flow

In the preceding section the effect of vertical walls upon the flow has been considered only as an indirect condition that the lower liquid is confined in the hollow, which gives rise to $Q_2=0$, and the vertical flow near the vertical walls has not been taken into account in the calculation.

We shall now investigate theoretically the direct effects of the vertical walls upon the

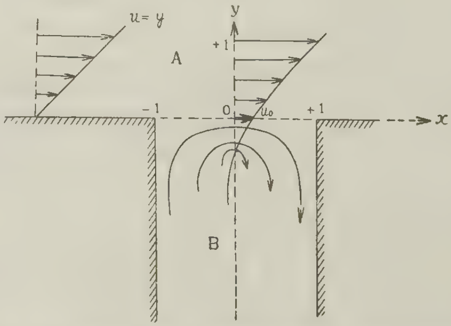

Fig. 2. Shear flow jumping over the hollow.

flow as well as upon the general features of the flow jumping over a narrow and deep hollow.

In order to simplify the calculation and especially to investigate the flow pattern near the interface in detail, we shall study the shear flow jumping over a semi-infinite vertical hollow.

As shown in Fig. 2, the horizontal interface between the two liquids coincides with the ceiling plane of the hollow, and with the origin 0 at the middle point of interface of length 2 we take the x-axis along the direction of the horizontal flow and the y-axis vertically upwards. We call the region of the upper lighter liquid over the interface and the horizontal walls "Region A" and that of the lower heavier liquid in the hollow "Region B", namely:

Region A: $y \geqq 0$,

Region B: $y < 0$, $-1 \leqq x \leqq 1$.

If, in the case of a stationary slow motion of fluid, we neglect inertia terms in the equations of motion, a stream function which satisfies the equation of continuity is a solution of the following biharmonic equation:

$$\Delta\Delta\psi = 0 , \tag{5}$$

where, as usual, Δ stands for the Laplacian operator $\partial^2/\partial x^2 + \partial^2/\partial y^2$.

In Region A, ψ consists of the term $y^2/2$ as originated from the shear flow with velocity distribution $u = y$ and a term ψ_A as originated from the effects of the lower liquid in Region B, while in Region B the flow originates only from the tangential viscous drag exerted by the flowing upper liquid in Region A. Thus,

$$\text{in Region A:} \qquad \psi = (1/2)y^2 + \psi_A , \tag{6}$$

$$\text{in Region B:} \qquad \psi = \psi_B . \tag{7}$$

The boundary conditions to be satisfied by the solution of Eq. (5) are as follows. In Region A the effect of the lower liquid upon the flow is very small at a great distance from the interface, so that

$$\psi_A \to 0 \qquad \text{as } |x|,\ y \to \infty . \tag{8}$$

In Region B, on the other hand, the effect of the upper liquid upon the flow at an infinite distance from the interface vanishes and the liquid sticks to both the vertical walls. Thus,

$$\psi_B \to 0 \qquad \text{as } y \to -\infty , \tag{9}$$

$$\psi_B = \partial\psi_B/\partial x = 0 \qquad \text{at } x = \pm 1 . \tag{10}$$

A particular streamline coincides with the interface line itself, and the horizontal velocities as well as the tangential viscous stresses at both sides of the interface are continuous and the liquid sticks to the horizontal walls. Thus we have

$$\psi_A = \psi_B = 0 \qquad \text{at } y = 0 , \tag{11}$$

$$\frac{\partial\psi_A}{\partial y} = \frac{\partial\psi_B}{\partial y} = \left\{\begin{matrix} 0 & |x| > 1 \\ f(x) & |x| \leqq 1 \end{matrix}\right\} \text{at } y = 0 , \tag{12}$$

$$\mu_A\left(\frac{\partial^2\psi_A}{\partial y^2} + 1\right) = \mu_B\frac{\partial^2\psi_B}{\partial y^2} \qquad \text{at } y = 0 , \tag{13}$$

where μ_A and μ_B are the coefficients of viscosity of the liquids in Region A and Region B respectively, and $f(x)$ is an unknown function which expresses the velocity distribution at the interface.

A solution of Eq. (5) can be obtained by assuming ψ in the form:

$$\psi = e^{ikx}Y(y) ,$$

where $Y(y)$ is a function of y alone. Inserting this into Eq. (5) and solving a resulting ordinary differential equation for $Y(y)$, we get

$$Y(y) = K_1e^{ky} + K_2e^{-ky} + K_3ye^{ky} + K_4ye^{-ky} ,$$

where K_1, K_2, K_3 and K_4 are constants to be determined by the conditions described in the above.

Thus, in Region A the conditions (8) and (11) require that

$$K_1 = K_2 = K_3 = 0 ,$$

so that the function $Y(y)$ becomes

$$Y(y) = Bye^{-ky}$$

and therefore

$$\psi = Bye^{-ky}e^{ikx} ,$$

where B, like K_4, is a constant.

This solution can be generalized by assuming B to be a function of k and then taking all values for k.

Thus, taking into account that the flow pattern is symmetric with respect to x, the appropriate expression for ψ_A in Region A can be put in the form:

$$\psi_A = y\int_0^\infty B(k)e^{\ ky}\cos kx\,dk , \tag{14}$$

and the function $B(k)$ is determined by the boundary condition (12) as:

$$B(k) = \frac{2}{\pi}\int_0^\infty f(\xi)\cos k\xi\,d\xi . \tag{15}$$

In like manner the, appropriate general solution ψ_B of Eq. (5) for Region B can be obtained, which satisfies the conditions (9) and (10), and is symmetric with respect to x. It can be expressed by the sum of two infinite series as:

$$\psi_B=\sum_{m=1}^{\infty} A_m(\psi_m+\psi_m^*)\ , \qquad (16)$$

where A_m's are constant and

$$\psi_m=y\, e^{p_m y}\cos p_m x\ ,$$

$$\psi_m^*=\int_0^\infty c_m(x\sinh kx-\tanh k\cosh kx)\sin ky\, dk\ ,$$

$$p_m=\frac{\pi}{2}(2m-1)\ ,$$

$$c_m=4(-1)^{m+1}kp_m^2/\pi\{(p_m^2+k^2)^2(\sinh k + k\,\mathrm{sech}\, k)\}\ .$$

$m=1, 2, 3, \cdots\cdots$(positive integers) .

From (16) and (12) we get the relation $f(x)$ and A_m's in the form:

$$f(x)=\sum_{m=1}^{\infty} A_m G_m(x)\ , \qquad |x|\leqq 1 \qquad (17)$$

where

$$G_m(x)=\cos p_m x + \int_0^\infty kc_m(x\sinh kx-\tanh k\cosh kx)dk\ ,$$

and this is a completely definite function of x and k.

Also, the relation between the function $B(k)$ and A_m's is obtained by substituting (14) and (16) into (13) as follows:

$$1-2\int_0^\infty kB(k)\cos kxdk = r\pi\sum_{m=1}^{\infty}(2m-1)A_m\cos p_m x\ , \qquad (18)$$

where $r\equiv\mu_B/\mu_A$ is, like r in (2) in § 3, the ratio of the coefficients of viscosity of the liquids in the upper and lower layers.

In order to determine the feature of the flow, it is necessary to get, from the above three relations (15), (17) and (18), definite functional forms of $B(k)$ and $f(x)$ as well as numerical values of A_m's.

First, taking account of the symmetry of flow pattern with respect to x, we expand the horizontal velocity distribution $f(x)$ along the interface into a Fourier cosine series. Thus,

$$\left.\begin{aligned} f(x) &= \sum_{m=1}^{\infty} D_m\cos p_m x\ , && |x|\leqq 1\ ,\\ &=0 && |x|>1\ . \end{aligned}\right\} \qquad (19)$$

Putting this into (15) and carrying out integrations, we get

$$B(k)=\sum_{m=1}^{\infty}\{2D_m p_m(-1)^{m-1}/\pi(p_m^2-k^2)\}\ . \qquad (20)$$

Then the integral on the left-hand side of Eq. (18), which is denoted simply by $F(x)$, can be evaluated as:

$$F(x)\equiv\int_0^\infty kB(k)\cos kxdk=\sum_{m=1}^{\infty} D_m H_m(x)\ , \qquad (21)$$

where

$$H_m(x)= \frac{(-1)^{m-1}}{\pi}p_m\{C_i(p_m^+)\cos(p_m^+)+C_i(p_m^-)\cos(p_m^-) + S_i(p_m^+)\sin(p_m^+)+S_i(p_m^-)\sin(p_m^-)\}\ ,$$

with

$$p_m=\frac{\pi}{2}(2m-1)\ ,\ p_m^+=p_m+p_m x\ ,\ p_m^-=p_m-p_m x\ ,$$

$$C_i(\eta)\equiv-\int_\eta^\infty\frac{\cos u}{u}du\ ,$$

$$S_i(\eta)\equiv\int_0^\eta\frac{\sin u}{u}du\ .$$

$H_m(x)$'s are completely known functions containing the functions $C_i(\eta)$ and $S_i(\eta)$ whose values can be obtained by the use of suitable numerical tables.

Using (21) and (19), Eqs. (18) and (17) become respectively

$$2r\sum_{m=1}^{\infty} p_m A_m\cos p_m x=1-2\sum_{m=1}^{\infty} D_m H_m(x)\ , \qquad (22)$$

$$\sum_{m=1}^{\infty} D_m\cos p_m x=\sum_{m=1}^{\infty} A_m G_m(x)\ . \qquad (23)$$

From these equations approximate values of the first eight constants A_1, A_2, A_3, A_4, D_1, D_2, D_3 and D_4 have been obtained by neglecting terms with suffixes $m\geqq 5$ and using numerical values of $\cos p_m x$, $H_m(x)$ and $G_m(x)$ at four fixed points $x=0$, 0.25, 0.5 and 0.75. Since the ratio r of the coefficients of viscosity of the two liquids is nealy equal to unity in the present experiments, we have put $r=1$ in Eq. (22). Thus, we have

$$\begin{aligned} A_1&=0.2573, & A_2&=-0.0330,\\ A_3&=0.0099, & A_4&=-0.0024,\\ D_1&=0.1875, & D_2&=-0.0160,\\ D_3&=0.0038, & D_4&=-0.0008. \end{aligned}$$

These values show that each series in Eqs. (22) and (23) converges fairly rapidly and that the neglect of the terms with suffixes $m\geqq 5$ does not bring about an error exceeding 1%.

Therefore it may be expected that the general feature of the flow pattern can be obtained with sufficient accuracy by using the above numerical values of the constants.

With the use of the above numerical values of D_1, D_2, D_3 and D_4, the horizontal velocity distribution at the interface $u_{(0)}=f(x)$ has been calculated by Eq. (19). The result is shown in Fig. 3. It will be seen that the interfacial velocity changes rather slowly in the central part whose length is about one third of the total length of the interface and that it decreases rapidly near the vertical walls.

In order to investigate how the interfacial velocity is affected by the value of the ratio $r=\mu_B/\mu_A$, the velocity at the origin has been calculated for various values of r. The result is shown in Fig. 4. It is found that the increase of r, namely the increase of the coefficient of viscosity of the lower liquid brings about the decrease of flow velocity in the lower liquid as in § 3.

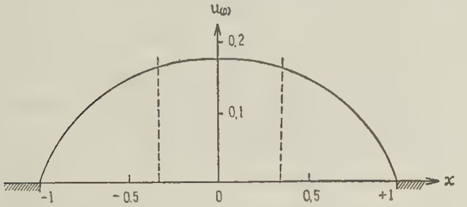

Fig. 3. Velocity distribution along the interface.

Next, the velocity distribution near the interface has been compared with the observed one.

The horizontal velocity u is derived from the stream function as:

$$u=\partial\psi/\partial y\ .$$

Thus, by using (14) we obtain the horizontal velocity in Region A as:

$$u_A=y+\int_0^\infty(1-yk)B(k)e^{-ky}\cos kxdk\ , \qquad (24)$$

while, by (16), the horizontal velocity in Region B becomes

$$u_B=\sum_{m=1}^{\infty}A_m(u_m+u_m^*)\ , \qquad (25)$$

with

$$u_m=(1+yp_m)e^{p_m y}\cos p_m x\ ,$$

$$u_m^*=\frac{4}{\pi}(-1)^{m+1}\int_0^\infty\frac{k^2p_m^2\cos ky(x\sinh kx-\tanh k\cosh kx)}{(p_m^2+k^2)^2(\sinh k+k\operatorname{sech}k)}dk\ .$$

The velocity distribution calculated by these formulae at four fixed points $x=0, 0.5, 1$ and 2 is shown in Fig. 5. The definite integrals involved have been evaluated by the Simpson rule with an accuracy of 0.1%. From this figure it will be seen that even in the central section ($x=0$), where the horizontal velocity is maximum, the flow of the lower layer vanishes at the depths nearly twice as large as the width of the hollow and this result suggests that the flow in a rectangular

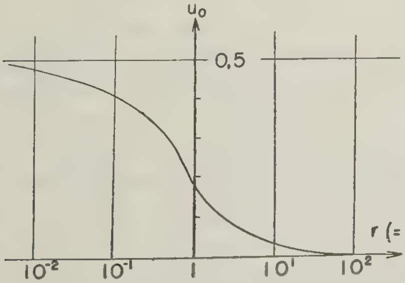

Fig. 4. Relation between the ratio of the coefficients of viscosity of the two liquids and the interfacial velocity.

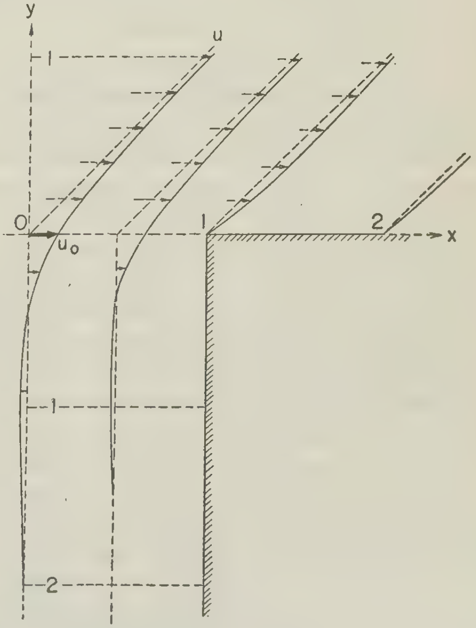

Fig. 5. Distribution of horizontal velocity near the interface.

hollow, whose height is greater than twice of its width, is very similar to the flow in the semi-infinite vertical hollow.

Also, the calculation by M. Kawaguti for the flow in a rectangular hollow with large value of the ratio of height to width gives a similar flow pattern in the central section to that obtained by the present calculation.

According to the present calculation, however, there exists in the central section a horizontally moving layer with considerable thickness in the lower liquid, and this result does not coincide with the observed fact that the horizontal velocity near the interface vanishes rapidly.

§ 5. Horizontal Flow with Intermediate Zone; Three-Layer Flow

In the preceding two sections we have calculated the velocity distribution in two superposed liquids under the assumption that the lower heavier liquid is confined in the hollow and the upper liquid flows over it and that they contact with each other directly at the ceiling of the hollow, but no satisfactory explanation has been obtained for the observed fact that the horizontal velocity vanishes rather rapidly. In the present section, therefore, an attempt will be made to carry out improved calculations, assuming the existence of an intermediate zone between the two liquids.

It is generally observed that when a lighter liquid such as tap water is piled on a heavier liquid such as brine, a thin zone with intermediate density is formed up between these two liquids owing to inevitable mixing even at very slow piling.

In the present experiment, the arrangement of two superposed liquids was obtained practically by pouring tap water very slowly over a filter paper spread on a veneer-sheet which was initially floating on the surface of brine filled the hollow to its ceiling. As the thickness of the upper water layer increased, the veneer-sheet rose up very slowly from its initial position. At the very initial stage of piling, the poured fresh water flowed out of the edge of the filter paper in the form of a very thin film, with a rather considerable speed in spite of very slow pouring of the fresh water. Then, mixing occurred along the interface between brine and fresh water, and a thin intermediate zone was formed up. Not only at the initial stage of arrangement, but also in the course of experiment, such a mixing zone grew up along the initial interface owing to (molecular or turbulent) diffusion and shear flow.

A part of the liquid in the mixing zone, which did not flow into the mouth of exit but impinged upon the vertical wall of the hollow, moved downwards vertically along the wall. Owing to its small density, however, it could not go down to the bottom of the hollow, but rather flowed back horizontally at a small depth from the ceiling, as shown in Fig. 6. Thus, a thin intermediate liquid layer with intermediate density was formed, which circulates between the upper and lower liquids.

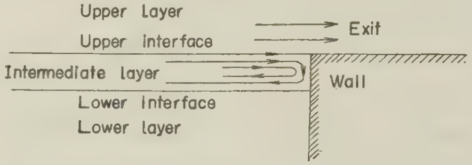

Fig. 6. Growth of intermediate layer.

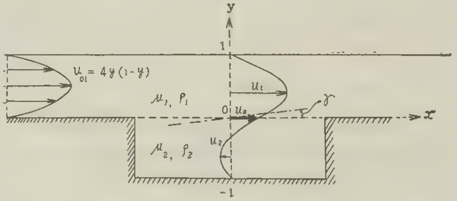

Fig. 7. Three-layer flow.

It has been observed that in a finite time-duration (a few hours) for observation, the thickness of such an intermediate zone is very small in comparison with that of the upper or lower layer. It is likely, however, that the existence of such a thin layer affects the general flow pattern remarkably.

We now calculate the flow pattern approximately, neglecting, for the sake of simplicity as in § 3, the vertical motion in the central major part of the flume which is very long in the horizontal direction as compared with the vertical one. With the coordinate-origin O at the center of the ceiling of the hollow, we take the X-axis along the ceiling in the direction of horizontal flow and the Y-axis vertically upwards, as shown in Fig. 7.

The equation of stationary horizontal motion is then given by Eq. (1), namely:

$$\mu\frac{\partial^2 U}{\partial Y^2}=\frac{\partial p}{\partial X},$$

where μ is the coefficient of viscosity, p the pressure and U the horizontal velocity.

As a simple model for calculation, the three-layer flow is assumed as shown in the figure, which consists of the horizontal flow in the upper layer with thickness H, the circulating flow in the intermediate zone with small thickness h and the circulating flow confined in the hollow with thickness $(H-h)$.

In order to distinguish physical quantities in each layer, suffixes 1, 2 and 3 have been used for the upper, intermediate and lower layers, respectively. For convenience of numerical calculation, the maximum velocity V in the far upstream of the hollow has been taken as the standard scale of the horizontal velocity, while the thickness of the upper liquid layer, H, as the standard scale of the vertical distance.

Then, introducing non-dimensional horizontal velocity u and non-dimensional distance y defined as:

$$u=U/V, \qquad y=Y/H,$$

the equations of motion become

$$\frac{\partial^2 u_i}{\partial y^2}=\frac{H^2}{\mu_i V}\cdot\frac{\partial p_i}{\partial X}, \qquad (i=1,2,3). \tag{26}$$

The non-dimensional thicknesses of the three layers become respectively

$$\begin{array}{ll} 1 & \text{(upper layer)},\\ \varepsilon=h/H(\ll 1) & \text{(intermediate layer)},\\ 1-\varepsilon & \text{(lower layer)}. \end{array}$$

If we assume that the pressure gradients $\partial p_i/\partial X$ $(i=1,2,3)$ are all constant, Eq. (26) can be integrated easily, obtaining

$$u_i=a_i y^2+b_i y+c_i \qquad (i=1,2,3), \tag{27}$$

where

$$a_i=\frac{H^2}{2\mu_i V}\frac{\partial p_i}{\partial x}.$$

The nine constants a_i, b_i, c_i $(i=1,2,3)$ in (27) can be determined by solving simultaneous linear algebraic equations as obtained by substituting (27) into the following six boundary conditions and three flow-rate conditions:

(i) Boundary conditions:

$$\left.\begin{array}{ll} u_1=0 & \text{at } y=1,\\ u_1=u_2,\ \mu_1\partial u_1/\partial y=\mu_2\partial u_2/\partial y & \text{at } y=0,\\ u_2=u_3,\ \mu_2\partial u_2/\partial y=\mu_3\partial u_3/\partial y & \text{at } y=-\varepsilon,\\ u_3=0 & \text{at } y=-1; \end{array}\right\} \tag{28}$$

(ii) Flow-rate conditions:

$$\left.\begin{array}{ll} \int_0^1 u_1 dy=2/3 & \text{(upper layer)},\\ \int_{-\varepsilon}^0 u_2 dy=0 & \text{(intermediate layer)},\\ \int_{-1}^{-\varepsilon} u_3 dy=0 & \text{(lower layer)}. \end{array}\right\} \tag{28}$$

In the first place, we have solved approximately the said simultaneous linear algebraic equations, assuming that the thickness of the intermediate zone is very small so that $\varepsilon\ll 1$. Since, in the present experiment, the coefficients of viscosity of the liquids in the three layers are nearly equal to each other, we have assumed, for simplicity, that $\mu_1=\mu_2=\mu_3$. The results obtained are

$$\left.\begin{array}{l} a_1=-4+4\varepsilon,\\ b_1=b_2=4-5.3\varepsilon,\\ c_1=c_2=1.3\varepsilon,\\ a_2=(2/\varepsilon)-1.3,\\ a_3=-2\varepsilon-2.6\varepsilon^2,\\ b_3=-2.7\varepsilon-4.8\varepsilon^2,\\ c_3=-0.7\varepsilon-2.2\varepsilon^2, \end{array}\right\} \tag{29}$$

Using these values we have calculated approximately the horizontal velocity u_0 at the upper interface $y=0$ as well as the similar quantity $u_{-\varepsilon}$ at the lower interface $y=-\varepsilon$, thus obtaining

$$\left.\begin{array}{l} u_0=1.3\varepsilon,\\ u_{-\varepsilon}=-0.7\varepsilon. \end{array}\right\} \tag{30}$$

From these results it will be seen that the thinner the thickness of the intermediate layer is, the smaller are the velocities in the intermediate and lower layers.

Next, we have also calculated exact values of the nine constants a_i, b_i, c_i $(i=1,2,3)$ by solving, by the use of a digital computer, the above-mentioned simultaneous linear algebraic equations for various values of ε such as 0.1, 0.03 and 0.01, and it has been found that relative errors of the preceding approximate values of a_i, b_i and c_i do not exceed 10%, 3% and 1% for $\varepsilon=0.1$, 0.03 and 0.01 respectively.

The velocity distributions as calculated by using the exact values of a_i, b_i and c_i corresponding to $\varepsilon=0.1$, 0.03 and 0.01 are shown in Fig. 8. In this figure, the observed velocity distribution is also shown for comparison by a dotted curve.

From Fig. 8 it will readily be seen that the calculated velocity distributions are in fairly good agreement with the results of observation and that the existence of a thin intermediate zone between two superposed liquid layers with different densities rather prevents the motion in the lower layer of heavier liquid confined in the hollow.

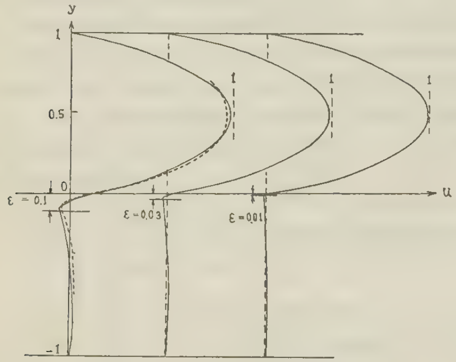

Fig. 8. Calculated velocity distributions in the three-layer flow with various thicknesses of the intermediate layer. The dotted curve shows the observed velocity distribution.

It is worth noticing here that even when the thickness of the intermediate layer is fairly small, the velocity distribution in the three-layer flow is remarkably different from that in the two-layer flow without intermediate layer which has been discussed in §3.

In case when ε is vanishingly small, the value of the constant a_2 as given in (29), namely:

$$a_2 = \frac{H^2}{2\mu_2 V}\frac{\partial p_2}{\partial X} = \frac{2}{\varepsilon} - 1.3$$

becomes large, and therefore the inclinations of the upper and lower interfaces should become very steep in order to balance with the large pressure gradients $\partial p_i/\partial X$. The existence of a thin intermediate layer becomes then difficult and neglect of the vertical velocity component as done in the present calculation becomes inadequate.

Next, in order to investigate the effect of the value of the ratio $r=\mu_3/\mu_1$, of the coefficient of viscosity, μ_3, of the lower liquid to that μ_1, of the upper liquid upon the flow in the lower liquid layer, we have calculated the horizontal velocity u_0 at the upper interface $y=0$ for various values of r, assuming that the coefficient of viscosity, μ_2, of the mixed liquid in the intermediate layer with thickness $\varepsilon=0.1$ is equal to the algebraic mean of μ_1 and μ_3, i.e. $\mu_2=(1/2)(\mu_1+\mu_3)$.

The result of calculation is shown in Fig. 9, in which the interfacial velocity as calculated by Eq. (4) in §3 as well as that derived from Fig. 4 in §4, both for the two-layer flow, are also shown for comparison. Here, the velocity $u_{0.5}$ at $y=0.5$ has been taken as the standard scale of velocity, which is equal to the maximum velocity in the upper layer in the flows treated in §3 and §5.

From this figure it will be seen that the interfacial velocity is much smaller in the case of the three-layer flow than that in the case of the two-layer flow for all values of the ratio $r=\mu_3/\mu_1$.

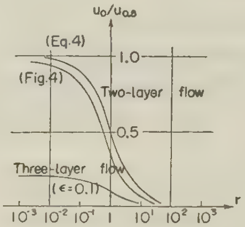

Fig. 9. Effect of the ratio of the coefficients of viscosity of the upper and lower liquids upon interfacial velocity.

§6. Stability of Intermediate Layer

In the preceding section we have given a fairly satisfactory theoretical explanation to the observed velocity distribution near the interface between two superposed liquids having different densities by assuming three-layer flow with a thin intermediate layer.

But we have not yet verified theoretically or experimentally the stable existence of such an intermediate layer. In the present section we shall discuss analytically the stability of the intermediate layer and explain experimentally the effect of the said layer upon the velocity distribution in the superposed liquids.

A few theoretical studies[14] have been made so far on the stability of horizontal flow with vertical density gradient. L. F. Richardson has investigated the atmospheric turbulence by the energy method, and G. I. Taylor and S. Goldstein have studied independently, by the use of the method of small disturbances, the stability of a horizontal shear flow with density stratification. All these authors have shown that the horizontal flow with density stratification is stable when the so-called "Richardson number" Θ defined as:

$$\Theta=-\frac{g}{\rho}\frac{d\rho}{dY}\bigg/\left(\frac{dU}{dY}\right)^2 \tag{31}$$

exceeds a certain critical value, where ρ is the density of the fluid, U the horizontal velocity, g the acceleration of gravity, the Y-axis being taken vertically upwards.

Also, H. Schlichting[15] has studied theoretically the stability of boundary-layer flow near a horizontal solid plane with vertical density gradient by the method of small disturbances, obtaining the result that the flow is stable for all values of Reynolds number if

$$\Theta>1/25\ , \tag{31$'$}$$

and he has shown that this theoretical result is in good agreement with the result of experiment by H. Reichardt who investigated the stability of air flow in a wind tunnel with large temperature gradient.

In our experiment, the lower heavier liquid is almost at rest in the hollow, as mentioned already, and therefore the flow near the upper interface is quite similar to the boundary-layer flow on a solid plane. Thus, we may use the above critical value of $\Theta=1/25$ as the criterion for stability of the flow.

The velocity gradient at $y=0$, where the flow is most liable to be unstable, is given by (29), as:

$$\left(\frac{du_1}{dy}\right)_{y=0}=b_1=b_2=4-5.3\varepsilon\doteqdot4\ ,$$

and therefore we have

$$\frac{dU}{dY}\doteqdot\frac{4V}{H}\ ,$$

for small value of ε.

Also, since the intermediate layer is sufficiently thin, we may put approximately

$$-\frac{d\rho}{dY}=\frac{\Delta\rho}{h}\ ,$$

where $\Delta\rho$ is the difference between the densities of the liquids in the upper and lower layers and h is the thickness of the intermediate layer. In practice, however, there occur sharp density gradients along the upper and lower interfaces, so that the value of $-d\rho/dY$ near the interfaces is much larger than the above mean value and the flow there is more stable than expected by the estimation.

Substituting the above values of dU/dY and $-d\rho/dY$ into Eq. (31), we obtain

$$\Theta\doteqdot\frac{g}{\rho}\frac{\Delta\rho}{h}\bigg/\left(\frac{4V}{H}\right)^2=\frac{g\Delta\rho H^2}{16V^2\rho h}\ . \tag{32}$$

In the present experiment $\rho=1$ gr/cm³, $H=10$ cm, $h=1$ cm and $V=2$ cm/sec approximately. Thus, using these values and adopting the critical value 1/25 for Θ, we obtain, from (32),

$$\Delta\rho\doteqdot2.5\times10^{-5}\quad \text{gr/cm}^3\ .$$

This result shows that only a slight difference in the densities of the upper and lower liquids suffices to stabilize the flow in the intermediate zone.

Although, as can been seen from (32), the flow in the intermediate layer becomes more stable as its thickness becomes thinner, yet the pressure gradient $\partial p_i/\partial X$ becomes then very large and the inclinations of the upper and lower interfaces become very steep. We shall next estimate numerically the slopes of the interfaces.

We write the density differences $\rho_2-\rho_1$ and $\rho_3-\rho_2$ as $\Delta\rho_{12}$ and $\Delta\rho_{23}$ respectively, and we denote the inclination of the upper interface by γ_{12} and that of the lower interface by γ_{23}. Then it is found that if there hold the following relations, the equilibrium of pressure in each layer can be maintained:

$$\Delta\rho_{12}g\gamma_{12}=\frac{\partial p_2}{\partial X}-\frac{\partial p_1}{\partial X}\ ,$$

$$\Delta\rho_{23}g\gamma_{23}=\frac{\partial p_3}{\partial X}-\frac{\partial p_2}{\partial X}\ .$$

If, in these relations, we substitute the expressions for the pressure gradients from (27), namely:

$$\frac{\partial p_i}{\partial X}=\frac{2Va_i\mu_i}{H^2}\ ,$$

we get

$$\left.\begin{aligned}\gamma_{12}&=\frac{2V}{g\Delta\rho_{12}H^2}(a_2\mu_2-a_1\mu_1)\ ,\\ \gamma_{23}&=\frac{2V}{g\Delta\rho_{23}H^2}(a_3\mu_3-a_2\mu_2)\ .\end{aligned}\right\} \tag{33}$$

In case when the three coefficients of viscosity μ_1, μ_2 and μ_3 are nearly equal to each other, as in the present experiment, a_2 is much greater than either of $|a_1|$ and $|a_3|$ for very small values of ε, as can be seen from (29), and therefore

$$\gamma_{12}>0\ ,\qquad \gamma_{23}<0\ .$$

Thus, it will be seen that the thickness of the intermediate layer increases towards downstream.

If we assume that the density of the liquid in the intermediate layer is equal to the algebraic mean of the densities of the upper and lower liquids, so that

$$\varDelta\rho_{12}=\varDelta\rho_{23}=\frac{1}{2}(\rho_3-\rho_1)\equiv\frac{1}{2}\varDelta\rho\ ,$$

and if, for very small ε, we neglect a_1 and a_3 in comparison with a_2, we have approximately

$$\gamma_{12}=-\gamma_{23}=\frac{8V\mu}{g\varDelta\rho H^2\varepsilon}\ . \tag{33'}$$

Under normal conditions in the present experiment, the coefficient of viscosity of water was $\mu=0.01$ poise (c. g. s.), the maximum velocity in the upper layer $V=2$ cm/sec, the density difference between the upper and lower liquids $\varDelta\rho=0.02$ gr/cm^3, the thickness of the upper layer $H=10$ cm, and the thickness of the intermediate layer $h=1$ cm ($\varepsilon=0.1$). Substituting these values into (33′), we get

$$\gamma_{12}=|\gamma_{23}|\doteqdot 8\times10^{-4}\ ,$$

and then the difference in thicknesses, $\varDelta h$, at both ends of the intermediate layer with length of 200 cm is calculated as:

$$\varDelta h=200\times2\times8\times10^{-4}=0.32\text{ cm}\ ,$$

which is considerably large compared with the mean thickness $h=1$ cm, but since the slopes of the interfaces are gentle, the neglect of the vertical velocity component may be allowed.

If, however, the thickness h of the intermediate layer would decrease, for example, to a value of 0.1 cm, then the slopes γ_{12} and γ_{32} would take a large value of 8×10^{-3} and the value of $\varDelta h$ would become 3.2 cm which is much larger than the mean thickness of the layer, and consequently such a very thin intermediate layer cannot exist in the flume.

Lastly, summarizing the above results we may say that as the thickness of the intermediate layer becomes thinner, the flow in the layer becomes more stable, but the slopes of both the upper and lower interfaces become more steep. The limiting thickness of the layer which can exist between the upper and lower liquids depends upon the horizontal velocity V, the density difference $\varDelta\rho$ between the upper and lower liquids and the thickness H of the upper layer. As can be inferred from (33′), even a very thin intermediate layer can exist in case when the horizontal velocity V is small and either or both of the density difference $\varDelta\rho$ and the thickness H of the upper layer are large.

Next, in order to verify experimentally the stable existence of a thin intermediate layer and its effect upon the velocity distribution, some experiments of the three-layer flow have been carried out in the water flume.

Coloured brine of density $\rho_2=1.01$ was poured very slowly, to the thickness of 1 cm, on the heavier brine of density $\rho_3=1.02$ confined in the hollow, and then tap water of density $\rho_1=1.00$ was poured gently on the coloured brine over the ceiling plane of the hollow.

The fresh water in the upper layer was moved horizontally by a motor pump as explained in § 2.

In the first several hours of flowing in the upper layer, the coloured brine remained in the stable state in the intermediate layer, and the inclinations of the upper and lower interfaces were observed to be $|\gamma_{12}|\doteqdot|\gamma_{23}|\doteqdot 10^{-3}$, in fairly good accordance with the theoretically estimated value of 8×10^{-4} given above.

The stable existence of the coloured brine in the intermediate layer and the velocity distribution in the layer are shown in Plate 6 (A) and (B). It will be seen that the velocity distribution as revealed by water-blue lines is very similar to the theoretical curve shown in Fig. 8 for the case of the intermediate layer with thickness of 1 cm ($\varepsilon=0.1$), and this result seems to justify the present analysis on the basis of the three-layer flow.

Further, in order to observe the flow pattern with a very thin intermediate layer, the coloured brine in the layer was sucked up by a small siphon very slowly so as not to disturb the flow. As the volume of the coloured brine decreased, the thickness of the layer became thinner and the slopes of the upper and lower interfaces became steeper, and ultimately the coloured brine became confined in a rather long horizontal triangular region as shown in Plate 7.

In such a state of flow, the upper and lower liquids were in direct contact with each other at the upstream side of the hollow and the two-layer flow occurred there temporarily, which however could not be maintained owing to the turbulent mixing of the upper and lower liquids at irregularly vibrating interface near the vertical wall.

In § 5 we have carried out the theoretical analysis under the condition that the liquid in the intermediate zone is confined and is circulating in the zone. If, however, a part of the liquid in the intermediate layer flows out towards the exit, a remarkable change occurs in the flow pattern. Such a flow could be realized by lowering slightly the horizontal wall surface at the exit side. The velocity distribution in this case is shown in Plate 8. It will be seen that this velocity distribution resembles to that in the case of the two-layer flow treated in § 3 and § 4. It is to be remarked here, however, that in this case too, a new intermediate zone grows up, after a short time-duration, along the interface between the old intermediate layer and the lower liquid and the flow pattern comes soon back to that in the case of the three-layer flow.

§ 7. Summary

The principal results obtained in the present work may be summarized as follows.

(1) Carrying out detailed experiments in a water flume of dimensions 180 cm × 50 cm × 15 cm we have observed, by the use of a suitable colouring material, the velocity distribution near the interface between two superposed liquids having different densities, the lighter liquid (such as tap water) flowing over the heavier one (such as brine) confined in a hollow. It has been found that if there is any difference, however small, between the densities of the two liquids, the velocity of the upper liquid decreases fairly rapidly near the interface, as if it were a solid plane, while the lower liquid is almost at rest in the hollow.

(2) Attempts have been made to explain the observed flow pattern theoretically. In the first place, a rather simple approximate calculation has been carried out by assuming that the two liquids are in direct contact with each other. However, no satisfactory explanation of the observed flow pattern has been obtained, namely, in such a two-layer flow the velocity near the interface is not so small compared with the velocity in the upper layer.

(3) We have next carried out an improved calculation by assuming that there is formed a thin intermediate zone between the two liquids owing to inevitable mixing of the liquids, and it has been found that the calculated flow pattern is, in the present case of the three-layer flow, in fairly good accordance with the observed one.

(4) The effect of the ratio of viscosities of the liquids in the upper and lower layers upon the flow pattern has also been discussed, and it has been found that the larger the viscosity of the lower liquid in the hollow is, the smaller is the velocity near the interface and consequently the weaker is the motion in the hollow.

(5) The stability of thin intermediate layer has been discussed and it has been shown that the thin intermediate layer can exist in stable state, provided that its thickness is not too small.

(6) Further, it has been observed that artificial removal of the intermediate layer makes the two-layer flow appear temporarily, but such a flow cannot be maintained for a long time owing to the growth of a new intermediate zone by inevitable mixing of the liquids at the interface.

In conclusion, it may be remarked that the phenomenon that a lighter liquid flowing over a hollow is prevented by a thin intermediate layer from contacting directly with a heavier liquid which is confined and is nearly at rest in the hollow, is frequently observed in natural circumstances, and such a phenomenon seems to be a cause of the existence of dead water in a deep hollow in storage dam or in estuarine reservoir, where, in the former, cold water originated from snow melting, and, in the latter, sea water flowed in at the time of artificial blocking of estuarine mouth are conserved for a rather surprisingly long period.

Acknowledgements

The author wishes to express his cordial thanks to Professor Keiji Yamashita and Mr. Shigeru Matsubara of Okayama University for their kind guidance in the course of the present work. He is also indebted to Professors S. Tomotika and Kō Tamada of Kyoto

University for their invaluable advices and encouragement.

Annealing of Radiation Damage on Lifetime in Silicon

By Kenji MATSUURA and Yoshio INUISHI
Faculty of Engineering, Osaka University

(Received December 14, 1960)

The annealing of carrier lifetime τ in γ-ray irradiated n type silicon crystals was observed. The lifetime at room temperature was obtained by measuring the decay of photo-injected carrier by microwave absorption method (10 GC) without using any electrode[1].

40 ($\Omega\cdot$cm) Sb-doped, pulled silicon which shows intense infrared absorption (9 μ) and 20 ($\Omega\cdot$cm) floating-zoned n-type silicon containing little oxygen were irradiated with Co^{60} γ-ray at room temperature.

Surfaces were etched with CP4 before measuring lifetime. Since little difference in lifetime was found between etched and non-etched crystals after irradiation, it might be concluded that bulk effects play the important part in the present experiment. Fig. 1 shows the effect of annealing temperature on τ following γ irradiation. According to Shockley-Read theory[2], $1/\tau - 1/\tau_0$ is proportional only to recombination center density provided that the Fermi level does not change appreciably and that the capture cross sections for holes and electrons are kept constant during the annealing cycle. τ_0 and τ are the lifetimes measured at room temperature before irradiation and after each annealing intervals, respectively.

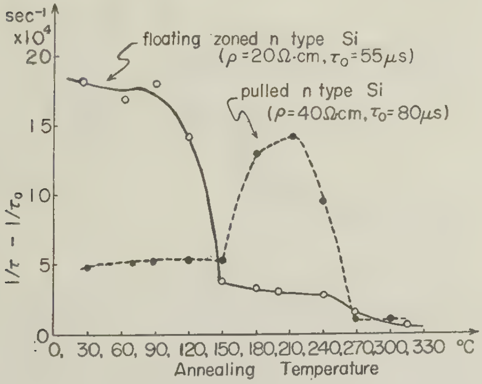

Fig. 1. Isochronal annealing of two different kind n type Si. (Annealing time of these crystals is ten minutes at each temperature.)

An Sb-doped, pulled Si crystal shows different dependence on annealing temperature from floating-zoned crystal, having a peak of $1/\tau - 1/\tau_0$ at about 200°C which is not observed with the latter. Probably, the oxygen in silicon will be mainly related to the mechanism of this behaviour. An isothermal percentage annealing curve for pulled Si at 240°C shown in Fig. 2 also has a peak but those for floating-zoned Si do not show such a peak. From these curves, the activation energy of the annealing process in floating-zoned Si is calculated as 1.2 eV. which is in good agreement with the value reported by Bemski and Augustyniak[3]. These annealing curves, however, represent neither first order process alone describable with an exponential time dependency nor second order process.

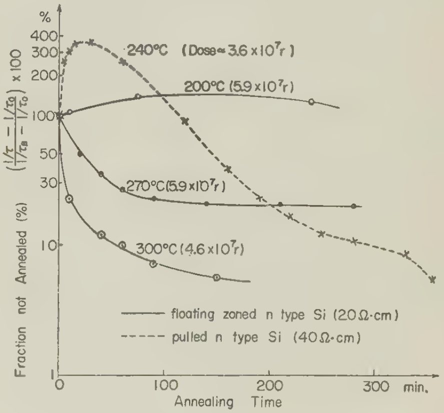

Fig. 2. Isothermal annealing curves of a pulled n type Si and floating zoned n type Si. (τ_B is the lifetime just after γ irradiation.)

Experiments are being prepared to clarify the mechanism of interaction between radiation-induced defect and oxygen or various other imperfections.

The Fundamental Absorption of Lithium Fluoride and Sodium Fluoride

Ryumyo Onaka, Atsuo Fukuda and
Arisato Ejiri

Institute for Optical Research, Tokyo University of Education, Shinjuku-ku, Tokyo

(Received December 15, 1960)

The fundamental absorption of alkali halides has been measured by many authors. Eby, Teegarden and Dutton[1] have recently investigated them extensively in the vacuum ultraviolet region both at room temperature and at liquid nitrogen temperatures. Since the alkali halide samples measured by them were of thin films evaporated on lithium fluoride plates, the measurement of the fundamental absorption of lithium fluoride itself was not undertaken.

Thin films of lithium fluoride were prepared by evaporation on thin film substrates in the present study. It was found that celluloid is the best material as the substrate. Substrate films of about 100 A thick were easily prepared by dripping a drop of one percent amylacetate solution of celluloid onto pure water, and by picking up with a frame made of brass wire. The celluloid films gave the transmission of about 30 to 50 percent at 900 A.

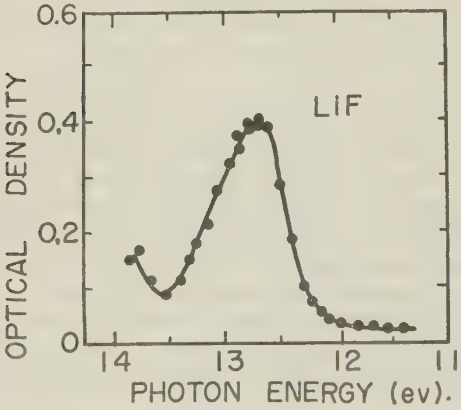

Fig. 1. The fundamental absorption spectrum of lithium fluoride.

The thickness of a lithium fluoride film evaporated on the substrates was so controlled as to give the optical density of about 0.5 to 1.0. No annealing of the sample was tried because the material of the substrate was organic.

A small vacuum spectrophotometer with a 20 cm concave grating was used in measurement of the transmittance. The slit width used corresponded to about 7 A in wavelength. With a hydrogen discharge tube as the light source, the transmittance of lithium fluoride films was measured at wavelengths down to 900 A. The correction for the background intensity was carefully made, since its amount is almost of the same order as the signal below 1000 A.

Transmissions of two portions of the prepared film, on one of which lithium fluoride was evaporated, were measured, and from them the optical density of the lithium fluoride film was deduced, for the absorption of the substrates was almost the same. No correction was applied to the difference of reflection. The measurement was made only at room temperature.

The transmittance of a lithium fluoride film measured is shown in Fig. 1 as a function of the photon energy. A strong absorption band was found with its peak at 12.7 ± 0.1 ev, and a depression at 13.5 ± 0.1 ev on the higher energy side. These values of the peak and the depression agree very well with those in the reflection spectrum recently reported by Kato *et al*[2]. Remarkable asymmetry is observed in the absorption band shape, which seems to imply that the band consists of two or more components. A similar asymmetry of shape of the first fundamental band is seen in the spectrum of sodium fluoride obtained by Eby *et al*[1].

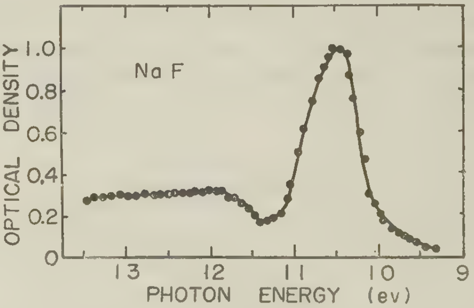

Fig. 2. The fundamental absorption spectrum of sodium fluoride.

The fundamental absorption of sodium fluoride was also measured by the same method described above. (Eby *et al* measured it at wavelengths above 1100 A). The wavelength range of the present measurement was extended down to 900 A, and the second absorption peak was investigated. As shown in Fig. 2, it was found that the second absorption band is broad, similar to that observed in sodium chloride and sodium bromide.

The Inverse Solution of the TFD Equation*

By Kwai UMEDA, Yasuo TOMISHIMA
and Chikao KAWABATA

Department of Physics, Okayama University

(Received November 8, 1960)

The series expansion of the inverse solution of the TF equation has recently been calculated by Gold[1]. We have carried out in turn the similar calculation for the TFD equation

$$\frac{d^2\psi}{dx^2}=x\left[\beta+\left(\frac{\psi}{x}\right)^{1/2}\right]^3 \qquad (1)$$

with the initial conditions

$$\psi(0)=1 \quad\text{and}\quad -\psi'(0)=B, \qquad (1a)$$

the value of B being dependent on the boundary condition.

For smaller values of x, $\psi(x)$ can be expanded into a semiconvergent power series of the form

$$\psi(x)=1+\sum_{n=2}^{\infty}a_n x^{n/2} \qquad (2)$$

a_n's being listed by several investigators[2] as functions of a_2 only.

As for the inverse solution it is convenient to take not the intrinsic one $x=x(\psi)$ but the alternative one $x=x(\Psi)$ where $\Psi=1-\psi$, since we are concerned in the shaded region ($x\approx0$ and $\psi\approx1$ or $\Psi\approx0$) in Fig. 1. The inverse of (1):

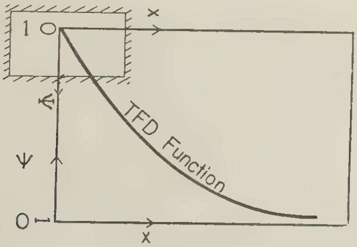

Fig. 1.

$$\frac{d^2x}{d\Psi^2}=x\left(\frac{dx}{d\Psi}\right)^3\left[\beta+\left(\frac{1-\Psi}{x}\right)^{1/2}\right]^3 \qquad (3)$$

allows in the neighborhood of $\Psi=0$ the series expansion of $x(\Psi)$ of the form

$$x(\Psi)=\sum_{n=2}^{\infty}c_n\Psi^{n/2}, \qquad (4)$$

c_n's being given in Table I as functions of c_2 only. The β-free part in c_n reproduces b_{n-1} given by Gold[1] for the TF case exactly, as it must be. The a_n's and the c_n's are connected parametrically by B via the relation

$$c_2=\left(\frac{dx}{d\Psi}\right)_{\Psi=0}=-1\Big/\left(\frac{d\psi}{dx}\right)_{x=0}=-1/a_2=1/B. \qquad (5)$$

Table I. c_n's as functions of c_2 only.

$$c_3=c_2^{1/2}\left[\frac{4}{3}c_2^2\right]$$

$$c_4=\left(\frac{8}{3}c_2^4\right)+\left(\frac{3}{2}c_2^3\right)\beta,$$

$$c_5=c_2^{1/2}\left[\left(\frac{56}{9}c_2^5-\frac{2}{5}c_2^2\right)+\left(7c_2^4\right)\beta+\left(\frac{4}{5}c_2^3\right)\beta^2\right],$$

$$c_6=\left(\frac{1,280}{81}c_2^7-\frac{9}{5}c_2^4\right)+\left(\frac{80}{3}c_2^6-\frac{1}{2}c_2^3\right)\beta \\ +\left(\frac{263}{30}c_2^5\right)\beta^2+\left(\frac{1}{6}c_2^4\right)\beta^3,$$

$$c_7=c_2^{1/2}\left[\left(\frac{1,144}{27}c_2^8-\frac{34}{5}c_2^5+\frac{3}{70}c_2^2\right)\right. \\ +\left(\frac{286}{3}c_2^7-\frac{349}{70}c_2^4\right)\beta+\left(\frac{2,189}{40}c_2^6-\frac{6}{35}c_2^3\right)\beta^2 \\ \left.+\left(\frac{32}{5}c_2^5\right)\beta^3\right],$$

$$c_8=\left(\frac{28,672}{243}c_2^{10}-\frac{656}{27}c_2^7+\frac{58}{105}c_2^4\right) \\ +\left(\frac{8,960}{27}c_2^9-\frac{421}{14}c_2^6\right)\beta+\left(\frac{7,462}{27}c_2^8-\frac{983}{168}c_2^5\right)\beta^2 \\ +\left(\frac{4,991}{72}c_2^7\right)\beta^3+\left(\frac{57}{20}c_2^6\right)\beta^4,$$

$$c_9=c_2^{1/2}\left[\left(\frac{739,024}{2,187}c_2^{11}-\frac{2,288}{27}c_2^8+\frac{16,718}{4,725}c_2^5+\frac{1}{252}c_2^2\right)\right. \\ +\left(\frac{92,378}{81}c_2^{10}-\frac{56,485}{378}c_2^7+\frac{151}{120}c_2^4\right)\beta \\ +\left(\frac{405,977}{324}c_2^9-\frac{1,523,929}{25,200}c_2^6-\frac{1}{42}c_2^3\right)\beta^2 \\ +\left(\frac{1,308,307}{2,592}c_2^8-\frac{1,156}{315}c_2^5\right)\beta^3 \\ \left.+\left(\frac{11,869}{200}c_2^7\right)\beta^4+\left(\frac{11}{15}c_2^6\right)\beta^5\right].$$

Table II. c_n's for free A-atom
($Z=18$, $\beta=0.030835$, $B=1.635403$).

n	c_n	β-free part	β-part	$(\beta)/(\beta\text{-free})$
2	0.611470	0.611470		
3	0.389832	0.389832		
4	0.383369	0.372794	0.010575	0.02837
5	0.322702	0.298970	0.023732	0.07938
6	0.293607	0.253433	0.040174	0.15852
7	0.264282	0.205509	0.058773	0.28599
8	0.241408	0.162868	0.078540	0.48223
9	0.223037	0.124016	0.099021	0.79845

In order to see the effect of exchange on the c_n's, we have evaluated them for free neutral Argon atom[3], as shown in Table II. It is noteworthy that the series (4) converges very slowly and the exchange (β-dependent) part predominates more and more with the increasing sequential order n.

Spin Wave Resonance in Cu-Ni Alloy Films

By Hiroshi Nosé
Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received December 10, 1960)

The studies on the spin wave resonance in Cu-Ni alloy films were carried out at 9300 Mc/sec. These films were prepared by the evaporation of alloyed materials on the glass substrates maintained at room temperature, following the procedure established in the case of pure Ni films[1].

The rate of evaporation in the present work was considerably rapid such as about 500∼1000 Å/sec in order to prevent the films from imperfect alloying. The film thicknesses measured by the multiple beam interferometer were about 2500 Å. The colorimetric analysis on the prepared films showed that the weight contents of Cu had increased by a factor of two. The electron diffraction patterns of these films by the reflection method, however, made clear the facts that the line widths were similar to that of pure Ni films and moreover the lattice constants were nearly consistent with the data of the X-ray diffraction measured on a bulk specimen[2], as shown in Fig. 1. These results were hardly affected by annealing at 300°C for one hour. Therefore, it may be admitted to believe that the present films have a nearly perfect structure.

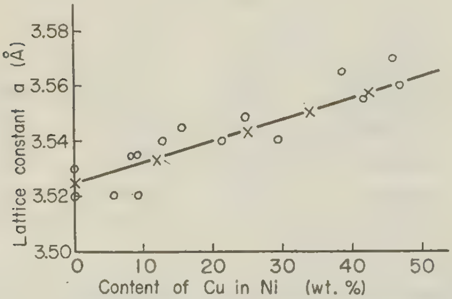

Fig. 1. Concentration dependence of lattice constants of Cu-Ni alloy films; ○: present value by E. D., ×: Coles' value by X-ray as bulk[2].

The exchange coupling constant A can be determined from the term $2A/M_s(p\pi/L)^2$ of spin wave resonance, where M_s is the saturation magnetization, L the film thickness and p the mode number. The values of A in these alloy films are shown in Fig. 2, where the value for pure Ni is somewhat different from that of reference 1 because of the uncertainty of assignments of p. They decreased rapidly in proportion to the concentration of Cu. For reference, the Curie temperature T_c measured for a bulk specimen by Marian[3] are plotted on this figure. It seems that the variation of A with concentration behaves in the similar way to that of T_c.

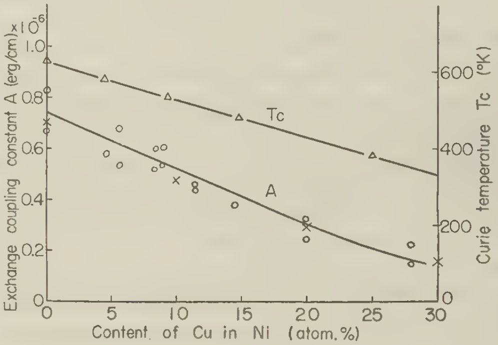

Fig. 2. Concentration dependence of exchange coupling constants of Cu-Ni alloy films; ○: present value, ×: value estimated from measurements by Kondorskij, et al.[4], △: T_c by Marian[3].

We can estimate the values of A in a bulk specimen from the coefficient of $T^{3/2}$ law for the temperature dependence of saturation moment measured by Kondorskij, et al.[4] and compare them with the present values. They are in good agreement. However, it is surprising to note that the observation of spin wave resonance in 28% Cu-Ni alloy at room temperature corresponds to the observation at the temperature as high as about 80% of its Curie temperature.

The author wishes to express his thanks to Prof. R. Kimura for his continued encouragement and to Mr. M. Ichikuni for his colorimetric analysis.

Nuclear Magnetic Resonance Study of NaCl Crystal Containing Ca Impurities

By Junkichi ITOH, Mitsuo SATOH*

Department of Physics, Faculty of Science, Osaka University, Osaka

and Akio HIRAKI

Faculty of Engineering, Osaka University, Osaka

(Received December 9, 1960)

Reif[1] first made nuclear magnetic resonance studies of the diffusion of positive-ion-vacancies in AgBr containing Cd impurities. We have made an extensive study on NaCl crystals containing various kinds of divalent impurities. In this note, we shall report only the results of our measurement of the spin lattice relaxation time T_1 of Na nucleus in crystals containing Ca impurity.

Fig. 1 shows the temperature dependence of T_1.

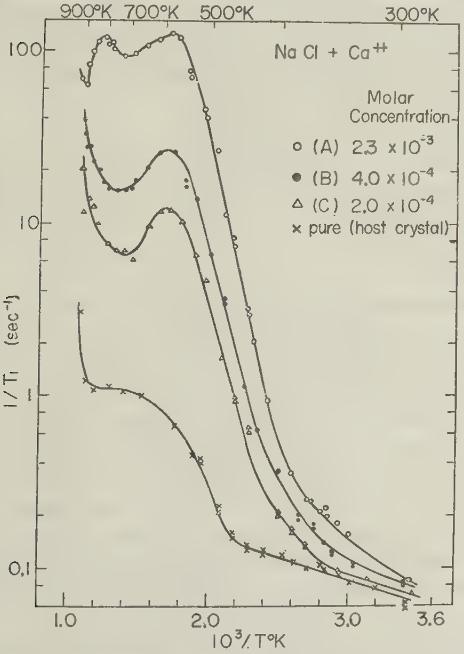

Fig. 1. Spin lattice relaxation rate $1/T_1$ of Na in NaCl+Ca^{++} versus inverse absolute temperature

Samples A, B and C are those containing Ca impurity with concentrations shown in the figure. The contribution of imperfections to $1/T_1$ may be considered as the difference of the curve A, B or C and that of "pure", which will be denoted as $1/T_1°$.

Now these crystals containing Ca impurity will have various types of imperfections; isolated Ca^{++} impurity ions, isolated positive ion vacancies with a concentration equal to that of isolated Ca^{++} ions, the complexes between Ca^{++} and the vacancy, aggregate or precipitate of Ca^{++} (probably accompanying positive ion vacancies), and at high temperatures, thermal vacancies. These various kinds of imperfections may contribute differently to $1/T_1°$.

Above 400°K, $1/T_1°$ first increases exponentially with $1/T$. The line A, B and C in Fig. 1 are all parallel, and the value of $1/T_1°$ is roughly proportional to the concentration of the impurity. This means that $T_1°$ is determined by the motion of isolated positive ion vacancies, and the activation energy for the jump of vacancy is obtained as 0.75 eV[2]. Thus it might be suggested that there is no appreciable number of complexes even at~400°K[3]. At about 580°K, the correlation frequency ν_c of the jump of the vacancy becomes equal to $2\nu_0$ (ν_0: nuclear Zeeman frequency) and a maximum in $1/T_1°$ occurs.

If only the vacancy diffusion contributes to $1/T_1°$ at still higher temperatures, $1/T_1°$ must decrease monotonously above 600°K. Actually, however, there appears a second maximum at about 810°K in A. Also an indication of the tail of the second maximum appears in B and C. This second maximum may be due to the diffusion of Ca^{++} ions. The correlation frequency of the diffusion of Ca^{++} via vacancies which contributes to $T_1°$ is of the order of $Cz\nu_c$, where C is the concentration of Ca^{++} ions and z the number of the nearest neighbor positive ion sites. The maximum of $1/T_1°$ due to this origin will occur at the temperature where $Cz\nu_c \sim 2\nu_0$, and the height of this maximum will be about the same as that due to vacancy diffusion, for the effective charge of the vacancy is $-e$, while that of Ca^{++} is $+e$. In A, this is just the case for the maximum at 810°K, but in B and C the expected maximum lies at a much higher temperature, being masked by the effect to be described next.

Above 900°K, $1/T_1°$ increases sharply with temperature. This may be due to thermal vacancies; the main contribution may come from the negative ion vacancies, which may produce much larger electric quadrupole energy in the surrounding Na nuclei and also moves much more slowly than the positive ion vacancies[4].

Temperature Dependence of the Line Width of Ferrimagnetic Resonance in Polycrystalline Nickel Cadmium Ferrite

By Susumu TAKEMOTO

Department of Physics, Faculty of Literature and Science, Shimane University, Matsue

(Received December 16, 1960)

Ferrimagnetic resonance experiments were carried out on polycrystalline nickel cadmium ferrite ($Ni_{0.7}Cd_{0.3}Fe_2O_4$) in the temperature range from −180°C to 100°C at 9500 MC and 24000 MC in order to invesigate the temperature dependence of the line width and the g-value. The writer used a standard electron spin resonance equipment at 9500 MC because of the high fidelity in measurements. But it was modified such that the scanning field was broadened to about 2000 oersted. The sample cavity was of cylindrical H_{111} mode and was kept in a temperature controlled Dewar vessel at low temperature measurements, liquid oxygen being used as low temperature agent. In order to reduce the frequency shift which might be caused by the resonance absorption, it was necessary to make the sample diameter less than 0.30 mm. The samples used in the present experiment were selected, by a microscope, out of scores of spherical samples which were obtained by the Bond sphere grinder. It was found that the resonance condition was greatly affected by a slight deviation of sample shape from sphericity. The absorption curves were almost Lorentzian over the measured region. The derivatives of the absorption curves at various temperatures are shown in Fig. 1, where ΔH_m means the width between the points of maximum slope of the absorption curve. The resonance field was found to strikingly drop as the temperature was lowered. As shown in Fig. 2, the full line width ΔH is affected to a great extent by both the temperature and the frequency. The line width increases at lower temperatures in a similar manner to Healy's result[1] on nickel ferrite and to Tannenwald's result[2] on manganese ferrite. The curves, (a) and (b), were obtained using the conventional resonance apparatus and the curve (c) using the ESR equipment described above. The g-value varies from 2.13 at −180°C to 2.03 at 100°C, gradually increasing with decreasing temperature and the internal field[3] takes values from 300 oersted to 200 oersted in the same temperature range. The writer could not find any subsidiary peaks of the absorption curves in the range of dc magnetic field swept by the scanning field. The line broadening due to the electron migration between ferrous iron and ferric iron seems to be negligiblly small because of the low electrical conductivity[4] of the present ferrite sample. The writer wishes to thank Proffesor I. Takahashi of Kyoto University for many helpful and stimulating discussions and the Central Laboratory of Tôyô Rayon Company for co-operation in part of the present experiments.

Electrical Resistivity of Ferromagnetic Chromium Dioxide

By Buichi KUBOTA and Eiichi HIROTA

Research Department, Wireless Division,
Matsushita Electric Industrial
Co., Ltd. Osaka, Japan

(Received December 9, 1960)

The electrical resistivity of CrO_2 has been studied with the powder specimen, which was prepared in the same way as that described in the previous paper1),2). The measurement of electrical resistivity was carried out by the modified Brentano's method3). Since the electrical resistivity of powder varies with a packing factor, the factor was kept to be about 60% throughout this experiment.

In Table I, the electrical resistivities of CrO_2 prepared under various conditions are tabulated with other properties of CrO_2. It is seen that the resistivity of CrO_2 is in the order of $10^{-1}\Omega$-cm at room temperature and does not seem to be related directly to the ratio, *O/Cr*. The temperature dependence of the electrical resistivity is shown in Fig. 1. It is of interest to note that the resistivity exhibits a peak near the Curie temperature of CrO_2, 116°C, and, except this anomaly, decreases with increasing temperature in the range between −150°C and 350°C. The thermal hysteresis and the absolute value of resistivity are somewhat uncertain due to the powder form of the specimen. Activation energies have also been obtained from this measurement except near the Curie temperature, and the results are about 0.1 to 0.3 ev in the range between 200°C and 350°C, and 0.005 ev between −100°C and the room temperature. To understand the conduction mechanism of CrO_2, the Seebeck effect has been studied. The results are also shown in Table I. It is seen that the thermoelectric power of various oxides is negative.

In view of the above results a probable conclusion to be drawn is that the *N*-type conduction of CrO_2 may be attributed to the interstitial Cr ions of the oxides4), and the peak of resistivity near the Curie temperature may be due to a magnetic interaction between the bulk magnetization and a

Measurements on Collision Frequencies of Electrons in Neon Gas

By Taro DODO

Hitachi Central Research Laboratory,
Kokubunji, Tokyo

(Received December 12, 1960)

The collision frequency of electrons in an arc discharge in neon gas has been measured by the cyclotron resonance method[1]. The microwave of frequency 9.6 Gc/s was propagated along a square wave guide in TE_{01} mode. The discharge tube was mounted across the wave guide inclined 30 degrees to the H-plane. The values of V.S.W.R. due to the reflection from the discharge tube were found to be less than 1.2 in any case. The attenuation of microwave power transmitted through the discharge tube has been measured as a function of the static magnetic field applied perpendicular to both the axis of the wave guide and the E-vector of the microwave.

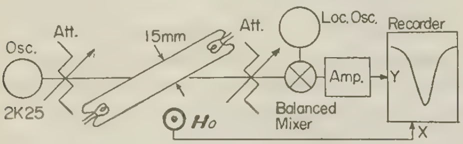

Fig. 1. Abbreviated schematic of experimental apparatus.

The collision frequencies obtained for the various gas pressures from the half-widths of the attenuation spectra are shown in Fig. 2. The electron density in these measurements was $0.3\sim1\times10^{11}/\text{cm}^3$. The collision frequency for momentum transfer of electrons in neon gas obtained from our measurement is

$$\nu_m=7.3\times10^8 p\,, \quad p\text{: gas pressure in mm Hg.} \tag{1}$$

This value is in agreement with the fact that the collision probability P_c[2] (in cm–mm Hg) for the electron of energy 3 eV in neon atoms is 7. The collision frequencies for 0.5 and 1 mm Hg neon gases are larger than the values given by (1). This result could be originated if the electron temperature in these low pressure gaseous discharges is higher than that of high pressure discharge. To confirm this speculation, we have performed a probe measurement[3]. The results indicate that the electron temperatures at 2 mm Hg and 4 mm Hg are 4.1×10^4°K and 3.1×10^4°K, respectively. The collision probability P_c for the 4 eV electron is 8.3[2].

The measurement has been made at higher electron concentration; $n_e\simeq5\times10^{11}/\text{cm}^3$. In this experiment, the discharge tube was mounted across the wave guide parallel to the H-plane and to the static magnetic field. The collision frequencies in this measurement are the same as for the case of low electron density. Therefore, we can conclude that the collisions between charged particles, e–i and e–e, are negligible in these gaseous discharges of low degree of ionization as compared with the electron-neutral atom collision.

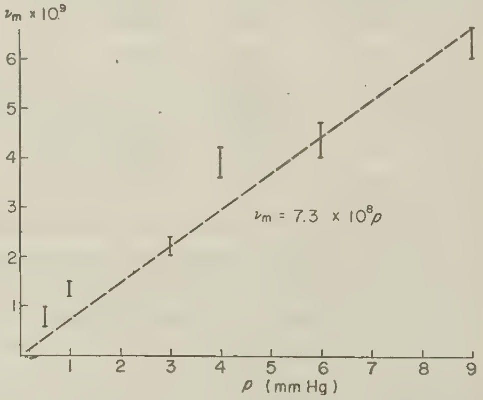

Fig. 2. Electron collision frequencies in neon gas as a function of gas pressure.

The author expresses his thanks to Dr. B. Tadano for his continual encouragements and to Mr. K. Sakai for his assistance in this experiment. He is also obliged to Mr. T. Kuroda of Tohoku University for his assistance and discussions and to Messrs. M. Yamamoto and H. Takano for their preparation of discharge tubes.

Observations of Dislocation Network in Neutron-Irradiated LiF Crystal

By Kazuko Kubo and Yoshio Katano

Japan Atomic Energy Research Institute
Tokai-mura, Ibaraki-ken, Japan

(Received November 11, 1960)

Optical-microscopic observations have been made with phase-contrast attachment for LiF crystal which was irradiated with neutrons of about 2×10^{17} nvt in the JRR-1 reactor and annealed at successively higher temperature from 400°C up to 800°C.

Microscopic observations of the same object have been made by several authors[1-4], who have reported that the square cavities, with the faces parallel to (100) and colored by the interference of light, were found densely near cracks and sub-boundaries while often isolatedly in sub-grains. Besides these facts, we have observed the followings:

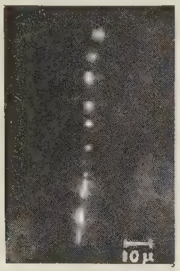

Photo. 1. Square cavities precipitated on a dislocation line.

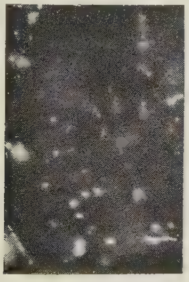

Photo. 2. Isolated dislocation lines, a closed loop and a four-fold node are seen at the lower middle part and a corner respectively.

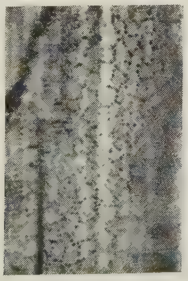

Photo. 3. Polygonal dislocation network.

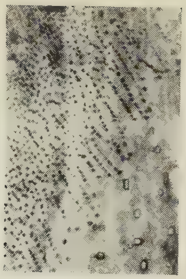

Photo. 4. Parallel dislocation lines found at the terminal part of a network.

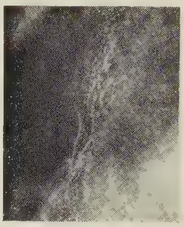

Photo. 5. Dislocation lines on a sub-boundary.

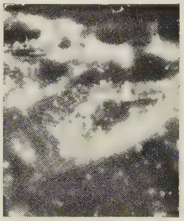

Photo. 6. Cobwebby arrangement of dislocation lines near crack.

(1) Closely formed cavities decorate sub-boundaries and make them visible but few cavities are observed in the region within about 30 μ from the outer surfaces or sub-boundaries of the crystal.

(2) There are isolated dislocation lines, as well as isolated cavities, in sub-grains, which are visually observable by being decorated with light-scatterers. It is almost certain that the most of decorating light-scatterers grow to square cavities with increasing annealing time and temperature (Photo. 1) but there still remains a little uncertainty that some of the quite small light-scatterers might be metallic Li colloids precipitated during thermal annealing but not the nuclei of square cavities which are coagulation of vacancies. It is difficult to find the regularity in distribution of the dislocation lines. The density of the lines is different from one sub-grain to another sub-grain. Those are 30~40 μ in average length and have various shapes, that is, an isolated line, group of lines with nodes, nearly straight line, helical line and closed loop (Photo 2).

(3) Dislocation network exists near the spot with

very dense concentration of the cavities. The decorations of the network appear to be same as described in (2). We show the first picture of the dislocation network in neutron-irradiated LiF crystal. The network consists of either irregular polygons or long parallel lines (Photo 3 and 4).

(4) Dense arrangements of dislocation lines become observable on sub-boundaries and near cracks when the crystal is annealed at about 700°C for a short time (Photo. 5 and 6).

It is certain that tremendous Frenkel pairs are produced by fast neutrons and fission fragments resulted from (n, α) reaction of Li^6 by thermal neutrons during in-reactor irradiation. It is believed that interstitial F-atoms, forming F_2-gas, escape from the crystal and interstitial Li-atoms precipitate to colloids and vacancies coagulate to the square cavities during thermal annealing. The existence of F_2-gas and clloidal Li metal in the crystal lattice, which has been ascertained by nuclear magnetic resonances[5], partly supports this idea. The dislocation lines appear to play an important role which might give F_2-gas some means of escape from the crystal lattice or might offer interstitial Li-atoms and the vacancies the opportunity and the location of coagulation. The microscopic observations in the present note is a part of the studies on the annealing behavior of the neutron-irradiated LiF crystal, which are in progress and the details will be reported soon.

Spectrum of the Electron Cyclotron Resonance in a Plasma

By Taro DODO

Hitachi Central Research Laboratory, Kokubunji, Tokyo

(Received December 15, 1960)

When the electromagnetic wave is propagated through a plasma in the direction perpendicular to the static magnetic field, a cyclotron resonance peak should occur at the angular frequency ω:

$$\omega=(\omega_c{}^2+\omega_p{}^2+\nu_m{}^2)^{1/2}\,, \qquad (1)^{1)}$$

where $\omega_c/2\pi$, $\omega_p/2\pi$, and ν_m are the gyration frequency $eH/2\pi mc$, the plasma frequency $(ne^2/m\pi)^{1/2}$, and the collision frequency for momentum transfer, respectively. We have carried out a measurement on microwave attenuation and verified the relation (1).

The experimental apparatus is the same as the preceeding article.[5] The attenuation spectrum for a constant discharge current is obtained by changing the magnetic field strength and fixing the frequency $\omega/2\pi$ of microwave at 9.6 Gc/s throughout this experiment. The discharge tube is a fluorescent lamp, and it contains 3.5 mm Hg argon and mercury vapour at room temperature. According to the theoretical result (1), the magnetic field strength at which the resonance peak occurs should depend on the electron density $\omega_p{}^2$. In order to confirm this prediction, the attenuation measurements were carried out for various electron densities. The electron density is controlled by the discharge current. Although the magnetic field strength at which the gyration frequency $\omega_c/2\pi$ becomes 9600 Mc/s is 3429 gauss, for a high density plasma the attenuation peak occurs at 2000 gauss or less. The magnetic field strength at which the attenuation peak occurs is shown as a function of the discharge current in Fig. 1.

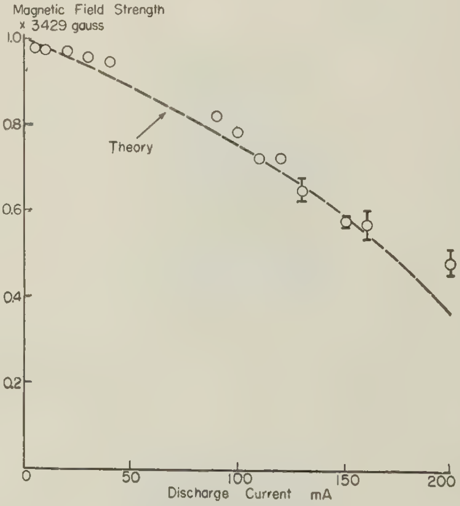

Fig. 1. Field strength at the resonance peak as a function of the discharge current.

From the peak height of the cyclotron resonance spectrum, we can obtain the electron density. From the peak heights of the resonance spectra at the discharge currents of 5, 10, and 20 mA, we find that the electron density is proportional to the discharge current and is $5\times10^{10}/cm^3$ for the discharge current of 10mA*. The plasma frequency $\omega_p/2\pi$ for the electron density $5\times10^{10}/\mathrm{cm}^3$ is 2×10^9 c/s. From this numerical relation and the proportionality of ω_p^2 to the discharge current I, we obtain the relation between $(\omega_p/\omega)^2$ and I for our experiment:

$$(\omega_p/\omega)^2=4.4\times10^{-3}\ I\ (I \text{ in mA}). \qquad (2)$$

When we put the theoretical relation (1) into the form

$$\omega_c/\omega=[1-(\omega_p/\omega)^2-(\nu_m/\omega)^2]^{1/2}\ , \qquad (1)'$$

we can see more easily the relation between the theoretical result and our experimental result. The relation (1)′ tells us that the magnetic field strength, at which the cyclotron resonance peak occurs, decreases as the electron density increases**. The theoretical curve which is obtained by substituting (2) into (1)′ is shown in Fig. 1 by a dotted line***. The theoretical prediction is in good agreement with our experimental result.

Recently, S. Tanaka[3] has carried out the measurement on cyclotron resonance absorption in neon gas and he has also verified the relation (1) in the range of low electron density: $(\omega_p/\omega)^2\sim0.1$ to 0.3. K. Kato[4] has also verified the relation (1) by the measurement on cyclotron radiation from a mercury discharge tube.

Finally, we shall make another remark on the shape of resonance spectrum. Examples of spectra for low and high current discharges are shown in Fig. 2. The half-widths of the spectra for high current discharges (90 mA, 160 mA) are very broad. One may suppose that the width becomes broad because the collisions between charged partcles become frequent. But this is not true and the broadening of spectrum width comes from the inhomogeneity of the electron density in space. By the Lorentz force, the discharge current is pushed to one side of the wall of the tube and the electron density becomes high at this side and low at the other side. As can be seen from (1)′, when the electron density is n_1 in the region 1 in the discharge tube and is n_2 in the region 2, the field strength, at which the resonance peak occurs, is H_1 and H_2 in respective regions. In this way the spectrum is a superpose of many spectra which have peaks at different field strength, and its width becomes broader. When we used an arrangement which insures a uniform distribution of electron density, (for example having the discharge current parallel to the static magnetic field,) the width of spectrum for high current discharge became as narrow as that for low current discharge.

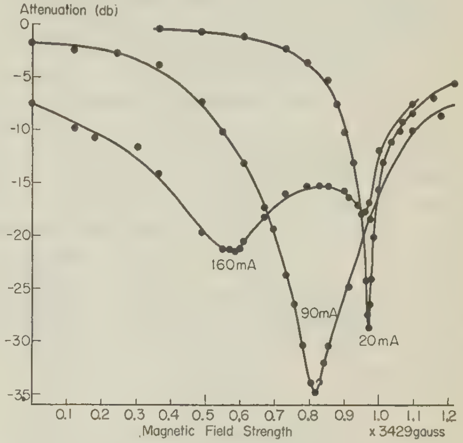

Fig. 2. Attenuation spectra for the discharge currents of 20, 90, and 160 mA. The shape of of spectra for 5, and 10 mA is similar to that of 20 mA.

The author is deeply obliged to Mr. T. Kuroda for his assistance and discussions.

* J. Nakamura had carried out the measurements on electron density in a discharge tube similar to ours using the double probe method[2]. He found that the electron density was proportional to the discharge current and was $4\times10^{11}/\mathrm{cm}^3$ for the discharge current of 50 mA.

** Note that the microwave frequency $\omega/2\pi$ is fixed throughout this experiment.

*** From the half-width of the resonance spectrum for the discharge current of 20 mA, we obtained the numerical value of 1.8×10^9 c/s for ν_m.

On the Inelasticity in High-Energy Nuclear Interactions

By Shigeo MATSUMOTO and Shoji MIKAMO
Institute of Polytechnics, Osaka City University

(Received December 5, 1960)

The inelasticity, K, in a nucleon-nucleon collision is defined as the ratio of all the energy of created particles to the available kinetic energy of the nucleons before collision in the center-of-mass system. Let $\langle n_\pm \rangle$ be the average number of charged mesons produced, $\langle E \rangle$ its average total energy in the center-of-mass system. Then the average value of $K, \langle K \rangle$, is expressed by the formula

$$\langle K \rangle = \frac{1.5 \langle n_\pm \rangle \langle E \rangle}{2(\langle \gamma_c \rangle - 1)Mc^2} ,$$

where $\langle \gamma_c \rangle$ is the Lorentz factor of nucleon (in the center-of-mass system) having the average primary energy and M is the nucleon mass. In order to estimate $\langle K \rangle$, we will first try to obtain $\langle n_\pm \rangle$.

A stack of Ilford G5 emulsions (108 sheets of 9″×6″, 600μ thick) was flown at an altitude of 29 km during six hours from Kobe. In this stack, 54 nuclear interactions induced by singly charged particles and 12 by neutral particles* were detected by the tracing-back method. This method consists of tracing star-producing flat tracks back along their passage through successive emulsion strips and finding primary interactions1). The above singly charged particles are mostly the primary cosmic ray protons incident upon the top of atmosphere, but some of them are the protons produced in the atmosphere and the emulsion stack. The effect of the latter protons may be subtracted by the following assumptions: both interactions of these protons and neutral particles are equal in number (12 interactions) and have the same distribution in the number, n_s, of shower particles (particles with blob density less than 1.5 times plateau blob density). Another thing to be considered is a bias against low multiplicity events which is due to the tracing-back method. This bias has been corrected by the probable assumption that the detection probability in this method is proportional to n_s. In this way, the average value of $n_s, \langle n_s \rangle$, was found to be 4.5. We will subtract one track to obtain $\langle n_\pm \rangle$. In the above process, the contamination of π-mesons among singly charged particles which induce nuclear interactions has been neglected. This neglect does not lead to serious error, because the contamination of π-mesons could be estimated to be of the order of 4%. For the primary protons incident upon the stack without undergoing nuclear interactions in the atmosphere, the average kinetic energy can be obtained by the energy spectrum of the primary cosmic ray protons with a sharp geomagnetic cutoff at a kinetic energy of 10 GeV. The value obtained was 26 GeV. Thus, the value of $\langle n_\pm \rangle$ at an average energy of 26 GeV was found to be 3.5. The same method was applied for the interactions with less than 6 heavily ionizing prongs, N_h. In this case, the value of $\langle n_\pm \rangle$ was estimated to be 2.8.

It was found, in this laboratory, that the value of $\langle E \rangle$ in nucleon-nucleon collisions around 40 GeV is 0.44 GeV2). It has to be borne in mind that the events analysed in reference 2 are confined to the relatively large multiplicity showers. We will take the above value of $\langle E \rangle$ to calculate $\langle K \rangle$, because it is known that, for primary energies around several tens GeV, the change of $\langle E \rangle$ with primary energy is small2),3). From the above value of $\langle E \rangle, \langle \gamma_t \rangle = 3.9$, and $\langle n_\pm \rangle = 2.8$, the value of $\langle K \rangle$ was estimated to be 0.34 for the interactions with $N_h \leqslant 5$.

This value is slightly smaller than those of 6.2 GeV4),5) and 8.7 GeV6). If the value of $\langle E \rangle$ for events with low n_s is comparatively large, $\langle K \rangle$ will increase. However, it seems that a considerably large value of $\langle E \rangle$ is less plausible by the following facts. Kalbach et al4). made an analysis of proton-proton collisions using protons of energy 6.2 GeV from the Bevatron. Their observation indicates that the value of $\langle E \rangle$ does not change appreciably as the prong number increases. Analysing the cosmic ray showers, Kaneko and Okazaki3) suggested that the value of $\langle E \rangle$ in each nucleon-nucleon collision does not depend on the inelasticity. This suggestion is also supported by the data observed in reference 2. Thus we reach the conclusion that $\langle K \rangle$ does not change greatly with increasing energy at least up to several tens GeV.

The authors wish to express their sincere thanks to Prof. Y. Watase for his interest and encouragement. Thanks are due to Dr. S. Kaneko for suggesting to obtain the inelasticity. They are also indebted to Mr. O. Kusumoto for his criticisms.

Enhancement of Photoconductivity upon Cadmium Sulphide Single Crystals

By Saburo KITAMURA, Takao KUBO
and Toshio YAMASHITA

Central Research Laboratory, Matsushita Electric Industrial Co., Osaka

(Received November 30, 1960)

It has been generally accepted that the infrared quenching upon CdS or CdSe crystals was associated with the recombination of electrons and holes made free from traps by irradiation of infrared rays[1,2]. In the case of CdS single crystal, it was reported[1,2] that the photocurrent produced by irradiation with visible rays was reduced by irradiation with infrared rays of 900 mμ or 1400 mμ. But, when a high voltage (of about 2000 volts/cm) was applied to CdS crystal, it was found that the photocurrent was enhanced by irradiation of infrared rays of 900 mμ or 1400 mμ.

Pure CdS crystals used in the present experiment were prepared by the sublimation method[3] in argon gas. The average size of the crystal was 8×6×0.04 mm. A schematic diagram of the experimented arrangement is shown in Fig. 1. Electrodes were formed by indium evaporated on opposite surfaces of a specimen. A specimen to be measured was mounted on a fused quartz plate and was then put in a hard glass tube with quartz windows in which nitrogen gas was flowing.

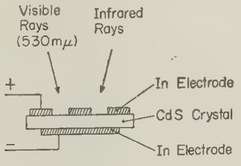

Fig. 1. Schematic diagram of specimen.

Quenching and enhancement of photocurrent by irradiation with infrared rays superposed on visible rays are shown in Fig. 2. When D. C. 750 volts/cm was applied to the crystal, two quenching maxima were observed at 900 mμ and 1400 mμ. On the other hand, when D. C. 1250 volts/cm was applied to the crystal, the quenching value* decreased, most apparent decrease being at 900 mμ and 1400 mμ. When D. C. 2000 volts/cm was applied to the crystal, the enhancement of photocurrent appeared at 900 mμ and 1400 mμ. By irradiation with infrared rays of 900 mμ or 1400 mμ only, there was no photocurrent to be measured. When the electrode on the plane of incidence was negative, the enhancement of photocurrent appeared above 3000 volts/cm of applied voltage.

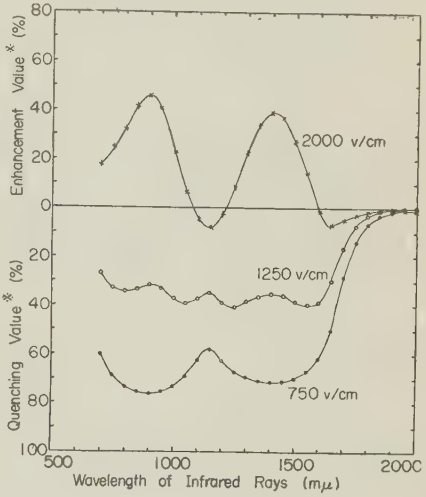

Fig. 2. Quenching and enhancement of photocurrent by irradiation of infrared rays superposed on visible rays.

The above phenomena cannot be understood by the previous interpretation[1,2] that free holes available for recombination are produced by irradiation of infrared rays. Experiments are now being carried on in order to investigate the mechanism of infrared enhancement. The author wishes to thanks Assistant Professor K. Fukuda at Kyoto University for his valuable advice.

* Quenching value is indicated as $\{1-I_{p+s}/(I_p+I_s)\}\times 100(\%)$, where I_{p+s} is the photocurrent produced by the irradiation of infrared rays superpose on visible rays, I_p is the photocurrent produced by irradiation of visible rays and I_s is the photocurrent produced by irradiation of infrared rays. In the present experiments, I_s was nearly zero. When the quenching value is negative, the word infrared enhancement is used.

A New Phase of an Intermetallic Compound Mn$_{3.4}$Ge and its Magnetism

By Tetuo OHOYAMA,
Department of Physics, Faculty of Science, Tokyo Metropolitan University
Kō YASUKŌCHI and Kazuo KANEMATSU
Department of Physics, College of Science and Engineering, Nihon University, Tokyo

(Received December 10, 1960)

According to Zwicker, et al.[1], an intermetallic compound of manganese with germanium, Mn$_{3.25}$Ge, has a hexagonal close packed structure, in which an ordered, D0$_{19}$ (Ni$_3$Sn) type of structure is induced by annealing the specimen at 750°C for 2 days. The ordered structure, however, was not established in our specimen similarly treated, and a phase transformation into a tetragonal one was found at a lower temperature.

The specimen for this study had a composition of Mn$_{3.4}$Ge (22.7 at. % Ge) and was prepared as follows: Powders of electrolytic manganese (99.9%) and germanium (seven-nine purity) were mixed in the proportion, and the mixture was charged in an alumina crucible, sealed in an evacuated silica tube, and melted by an electric furnace at 1150°C.

Table I. The X-ray diagram of Mn$_{3.4}$Ge, annealed at 430°C (Cu Kα radiation).

obs.			*hkl*	calc.	
2θ (degrees)	*d* (Å)	I/I_0		*d* (Å)	I/I_0
41.8	2.16	100	111	2.16	100
47.8	1.90	30	200	1.90	34
50.4	1.81	15	002	1.81	14
69.8	1.35	17	220	1.35	10
72.0	1.31	20	202	1.31	18
84.9	1.14	25	311	1.14	22
88.7	1.10	8	113	1.10	10
91.0	1.08	8	222	1.08	10
			400	0.951	2
			004	0.904	2
124.5	0.87	10	331	0.870	8
129.8	0.85	20	313	0.852	18
			420	0.850	9

After examined by an X-ray diffractometer to have the same (h.c.p.) structure as Mn$_{3.25}$Ge reported previously[2], the specimen was annealed at 430°C for 9 days and quenched into cold water, with the intention of investigating the effects of heat treatment on the magnetic property and on the atomic arrangement as well. Then, a structure change was brought about, rather than a modification of the original one as has been first expected.

As seen from the X-ray diagram which was obtained by the diffractometer and given in Table I, the specimen thus annealed consisted of a single phase with a face centered tetragonal structure.* No superlattice lines were found and the lattice parameters were determined to be $a=3.80_3$ Å, $c=3.61_8$ Å, and $c/a=0.951$.

As to the magnetic property, the new phase exhibits an anomalous behavior, and has a fairly stronger magnetism than the hexagonal one. Fig. 1 shows the values of the saturation magnetization as a function of temperature, which were determined under a field of 9 kilo-oersteds from the force exerted on the specimen in an inhomogeneous field. The saturation magnetization is nearly constant at low temperatures and extrapolated to be 11 cgs emu/g at 0°K, while, on heating above the room temperature, increases gradually towards its maximum value 17 cgs emu/g at 700°K. Then it falls off quite rapidly and the Debye photograph taken for this specimen after cooled to the room temperature gives only the h.c.p. pattern. Accordingly, the falling off of the thermo-magnetic curve is not due to the magnetic transition of the tetragonal phase, but may be associated with the phase transformation into the hexagonal one, which is paramagnetic at these temperatures. Apart from this point, the magnetic behavior of the tetragonal phase is somewhat similar to that of Néel's P type[3] of ferrimagnetism, but it should be postponed to make that classification until further investigations will be carried out.

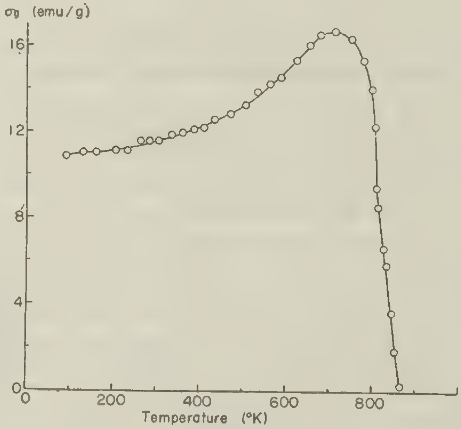

Fig. 1. Temperature dependence of the saturation magnetization of tetragonal Mn$_{3.4}$Ge.

Thus it may be concluded that the hexagonal phase reported by Zwicker, et al. is stable only at higher temperatures, but the transformation from it to the tetragonal one, which is more stable at lower temperatures, takes place so sluggishly that the latter seems to be realized only after a long time annealing.

---

* A f.c.t. structure is equivalent to a b.c.t. structure with $a'=a/\sqrt{2}$. The former is prefered here in relationship to L6$_0$ (Ti$_3$Cu) type of structure, to which D0$_{19}$ type of structure would be transformed.

More detailed examinations of the transformation, as well as as of the anomalous magnetic behavior of the tetragonal phase, are now in progress, and will be reported on later, together with the findings on other compounds of the Mn–Ge system.

Gamma Rays from Inelastic Scattering of Neutrons by Fe, Cu, Zn, Ge and Se

By Kazuaki NISHIMURA

Nuclear Physics Laboratory, Division of Physics, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken

(Received October 8, 1960)

Gamma rays following inelastic scattering of neutrons by Fe, Cu, Zn, Ge and Se, have been measured with 3.11~4.72 MeV neutrons using a ring geometry arrangement. The excitation functions for the following gamma rays were observed: 0.844, 1.23*, 1.80*, 2.11* and 2.56* MeV in Fe^{56}, 0.665, 0.965 and 1.33 MeV in Cu^{63}, 0.760 and 1.11 MeV in Cu^{65}, 0.810*, 0.995 and 1.81 MeV in $Zn^{64,66,68}$, 0.590 MeV in $Ge^{74,76}$, 0.830 MeV in Ge^{72}, 1.01 MeV in Ge^{76}, 0.560 MeV in Se^{76}, and 0.660 MeV in $Se^{76,78,80}$, respectively. The asterisk indicates the transitions from the higher excited to the 1st excited states. An aspect of de-excitation of higher energy levels was also discussed by analyzing the ratio of probabilities of de-excitation through or not through the 1st excited state as a function of the incident neutron energy.

§1. Introduction

A nucleus, that is raised to an excited state by the inelastic scattering of neutrons, will decay to its ground state with the emission of gamma radiation. It is an important problem to observe the de-excitation gamma rays as well as the inelastically scattered neutrons. These two observations, complementary in nature, present useful informations to clarify the nuclear structure and the mechanism of nuclear reactions.

Measurements of the de-excitation gamma rays following inelastic scattering of fast neutrons have been made by many authors,[1),2),3),4),5)] and yielded valuable data on the structure of nuclear levels, especially in those cases where excitation of the levels is not attainable by beta decay or Coulomb excitation. The excitation functions of gamma rays near the threshold have also been measured by several authors[6),7),8)] for the lowlying levels in various nuclides, and the results have been compared with the theory of Hauser and Feshbach[9)] based on the statistical model.

On the other hand, only a few measurements have been made on the production of gamma rays at neutron energies higher than 3 MeV, well above the threshold for the low-lying levels in medium-weight nuclides. With increase of the incident neutron energy, more levels in the residual nucleus are excited and analysis of data becomes difficult due to the increase of contributions from the higher levels. Some informations about higher levels of the residual nucleus may, however, be obtained by these measurements, since the character of nuclear levels is reflected in the gamma-ray spectra or their excitation functions.

This paper reports the results of measurements on the gamma-ray production in five elements (iron, copper, zinc, germanium and selenium) excited by neutrons of 3.11~4.72 MeV. The gamma-ray spectra observed are illustrated at a neutron energy of 4.04±.10 MeV. Most of these gamma-rays are fitted to known level scheme in relevant nuclide. The absolute production cross sections of gamma rays measured at the neutron energy of 4.04 MeV. are also tabulated.

An analysis on the ratio of transition probabilities from the higher to the 1st and the ground state was also made in iron and zinc, by combining the data of the present work with those obtained with time-of-flight technique[10)].

§2. Experimental Arrangements

The de-excitation gamma rays following neutron inelastic scattering were studied with the ring-geometry arrangements as shown in Fig. 1. Ring scatterers of iron, copper, zinc and carbon had an inner and outer diameter of 9.0 cm and 11.0 cm and a thickness of

5.0 cm. Germanium oxide and selenium were enclosed in aluminum containers, having the same dimensions with a wall thickness of 0.5 mm.

Neutrons were produced by the $D^2(d, n)He^3$ reaction. Deuteron beam of 0.5 μA was focused on a gas target at a distance of 1.7 m from a steering magnet, which was located at 2 m from a 90° beam-analyzing magnet. Measurements were done in a large room, the dimension of which was 25 m by 14 m, and 10 m in height, and which had a pit 2.5 m deep covered with gratings. The target was positioned 1.06 m above the gratings. The neutron background due to the scattering from the wall and floor were found to be negligible.

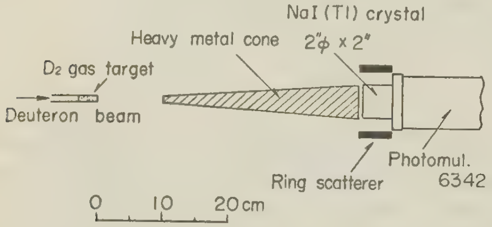

Fig. 1. Experimental arrangement for observing gamma rays from the inelastic scattering of neutrons. The scattering sample has ring geometry.

The gas target was of a cylindrical shape, 3 cm in length and 1 cm in diameter, and had an entrance window covered with a nickel foil of 1.27×10^{-3} mm thickness. The bottom was sealed with a platinum foil of 0.05 mm thickness. The pressure of deuterium gas was 40 cm Hg. The energy loss of the deuterium ions in passing through the nickel foil and the deuterium gas was calculated by use of published data[11].

The scattering ring was placed 45 cm distant from the target with its axis in the direction of the deuteron beam. Owing to its finite dimensions, it received the neutrons emitted in a range of 4.5°~8.5° with respect to the deuteron beam. The average angle between the neutrons incident on the scatterer and the de-excitation gamma rays which entered the detector, was about 100°.

The spread in the energy of the neutrons incident to the sample, which resulted from the spread in the energy of the deuterons in the target and the divergence in the angle of emission of neutrons, was estimated to be less than ±100 keV.

The spread was also checked experimentally by observing the 2.95 MeV resonance in the neutron total cross section of carbon. Both results agreed fairly well with each other.

The gamma rays from the scattering sample were detected with a $2''\phi \times 2''$ NaI(TI) crystal, mounted on a RCA 6342 photomultiplier. Pulses from the scintillation counter was fed into an RCL 256-channel pulse height analyzer through a preamplifier.

A cone of heavy metal, 30 cm in length, was placed between the scintillation counter and the neutron source. The heavy metal cone was made from wolfram, copper and nickel, and had a density of 17 gm/cm^3. It shielded the scintillation crystal against the neutrons and gamma rays from the neutron source effectively.

Neutron flux was monitored using a BF_3 long counter, placed 3.6 m distant from the target in a direction of 60° to the deuteron beam.

§ 3. Experimental Procedures

Day[3] has reported that there are two methods of calculation of inelastic scattering cross sections; one is to neglect completely the effects of all neutron scattering, assuming that the neutron flux is constant throughout the scatterer, and the other is to calculate rigorously taking multiple scattering of neutrons into account. But according to him the root-mean-square difference was only 3.5% between the results mentioned above. We take, therefore, the simple method in which the effects of multiple scattering just cancel out the neutron attenuation.

One can generally determine the gamma-ray intensity by measuring number of counts in a photo-peak. If neutrons enter the scattering ring parallel to its axis, the number of counts C produced in the gamma-ray detector is given approximately by Eq. (1):

$$C = nN\int_V\int_\Omega\left(\frac{d\sigma}{d\Omega}\right)\eta dV\,d\Omega \qquad (1)$$

Here n denotes the number of incident neutrons per cm^2, N the number of nuclei per cm^3 of the scatterer, Ω the solid angle subtended by the scintillator at an elementary colume dV of the scatterer, and V the volume of the scatterer, respectively. $d\sigma/d\Omega$ represents the differential cross section for the gamma-ray production by the neutron inelastic scattering and η the photo-peak efficiency of the NaI detector.

Assuming that the angular distribution of gamma-ray yield does not change greatly in the range of observation, Eq. (1) can be simplified as follows:

$$C=nN\left(\overline{\frac{d\sigma}{d\Omega}}\right)\mathcal{E}V \qquad (2)$$

where $\mathcal{E}\equiv(\overline{\eta\Omega})$ is called the effective photo-peak efficiency, which is determined experimentally by a method to be mentioned later.

The neutron flux n incident to the scatterer was calculated from published data[12)] on the differential cross section of $D^2(d,n)He^3$ reaction.

Then, the differential cross section at $\theta=100°$, $(d\sigma/d\Omega)_{100°}$ can be obtained by measuring the photo-peak yield C and the effective photo-peak efficiency $\mathcal{E}$.

Some of the neutrons, which are scattered at the sample, enter the NaI crystal. These neutrons cause inelastic scattering or neutron capture in the sodium iodide, and result in producing gamma rays which contribute to the background. These scattered neutrons can be closely reproduced by replacing the scattering sample with a carbon scatterer, which does not give an inelastic scattering of neutrons below $E_n=4.43$ MeV, although the energy spectra of scattered neutrons are slightly different in the two cases. The gamma-ray yield C is, therefore, obtained by taking the difference between the measurement with the scattering sample and that with a carbon scatterer.

The pulse-height distribution of the background for neutron energies from 3.11 to 4.72 MeV are shown in Fig. 2 (a) and 2 (b), which are mainly attributed to gamma rays caused by the neutron inelastic scattering in the

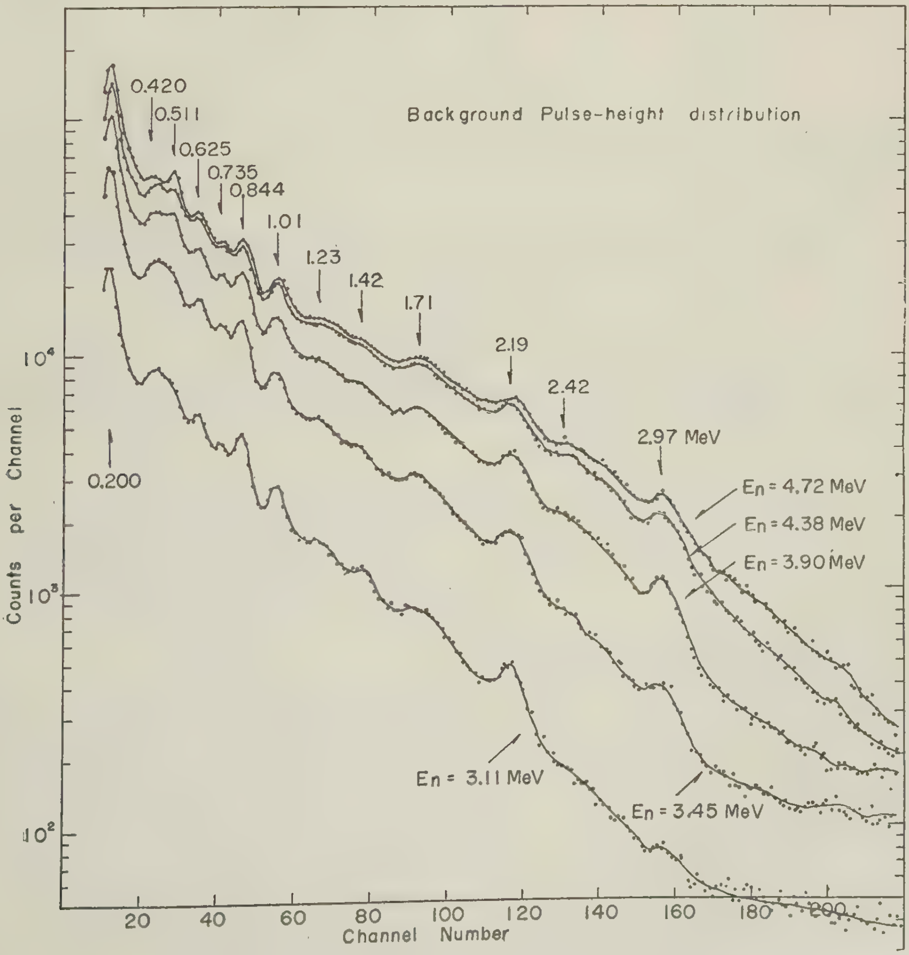

Fig. 2(a).

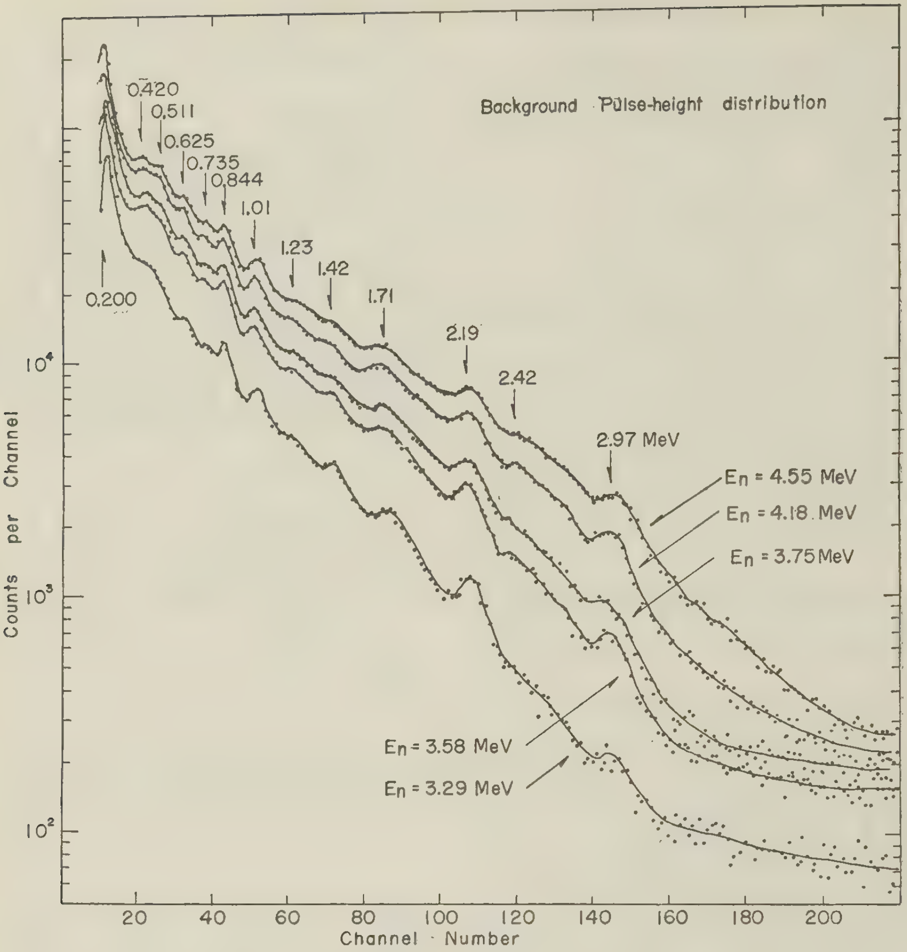

Fig. 2(b).

Fig. 2(a) and 2(b). The pulse-height distribution of the background, which were measured with a carbon ring scatterer. The energies of the incident neutrons are in the range of 3.11∼4.72 MeV. Most of gamma-rays, which are indicated by arrows, arise from inelastic scattering in the NaI(TI) crystal, as listed in Table I.

sodium iodide crystal. Table I gives the energies and de-excitation scheme of these gamma rays at a neutron energy of 4.04±.10 MeV.

The effective photo-peak efficiency $\mathcal{E}$ have to be known as a function of gamma-ray energy E_γ. It depends on the shape of the gamma-ray source and scintillation crystal, and on their relative position. Sodium bicarbonate was irradiated in the JAERI water-boiler reactor (JRR–1) and its absolute activity was measured by a 4π beta counter. Then, this sodium bicarbonate was put in place of the scatterer and the efficiency was determined for the Na^{24} gamma rays of 1.37 and 2.75 MeV, with a result of $(1.04\pm0.04)\times10^{-2}$ and $(4.46\pm0.12)\times10^{-3}$, respectively.

According to Day[3] and Freeman et al.,[8] $\mathcal{E}$ can be expressed by a simple power of E_γ in a range between 0.5 and 2.8 MeV, that is

$$\mathcal{E}=AE_\gamma^{-B} \tag{3}$$

From the efficiency measured for Na^{24} gamma rays, $A=1.55\times10^{-2}$ and $B=1.21$ was obtained.*

The errors in the absolute cross section are originated mainly in the determination of the gamma-ray yield C and the neutron flux n, involved in the published data[12] of $D^2(d, n)He^3$ reaction, is about 7%. The statistical accuracy of gamma-ray counting was 1% or better.

---

* According to Freeman et al.,[8] $A=6.14\times10^{-3}\pm5\%$ and $B=1.09\pm2\%$.

Table I. Background gamma rays which were determined with a carbon ring scatterer in the arrangement shown in Fig. 1. In the second column the de-excitation scheme of the nuclide emitting the gamma ray is given. A comparison with energies given by other authors is listed in the third column.

The errors due to background subtraction were negligible for large or isolated photo-peaks. But the determination of area under a weak or unresolved photo-peak caused appreciable error; sometimes it amounted to 20%. The correction for absorption of gamma rays in the sample was made by assuming that all gamma rays passed through an average thickness of 5 mm in the sample. The standard error in the effective photo-peak efficiency $\mathcal{E}$, which was within 3.5% as mentioned above, was originated from the statistical accuracy in the absolute beta-counting.

Taking account of these errors, standard errors in the absolute measurement were estimated as follows:

Table II. The energies of gamma rays produced by the inelastic scattering of (4.04±.10)-MeV neutrons, and the differential cross sections for the production of relevant gamma-rays at $\theta=100°$. The cross section values in parentheses have rather large errors (~±30%), since the yields are small compared with other gamma rays. De-excitation schemes are also shown in the fifth column, those in parentheses represent tentative, but most probable assignments. [ ] represents the average energy in the superposition of more than two gamma rays. References are cited in the text.

§ 4. Results

The spectra of gamma rays from iron, copper, zinc, germanium, and selenium excited by the inelastic scattering of (4.04±.10) MeV neutrons are shown in Figs. 3, 5, 7, 9 and 11, respectively. The background spectra as determined with the carbon ring are also shown in these figures with the crossed points.

The differential cross sections for the production of these gamma rays are presented in Table II, together with the scheme of de-excitation. In Table II, the isotropic cross sections of nuclides specified with mass number are calculated taking account of the isotopic abundance. Those described by chemical symbol only, are calculated using the number of nuclei per nuit volume of the natural element.

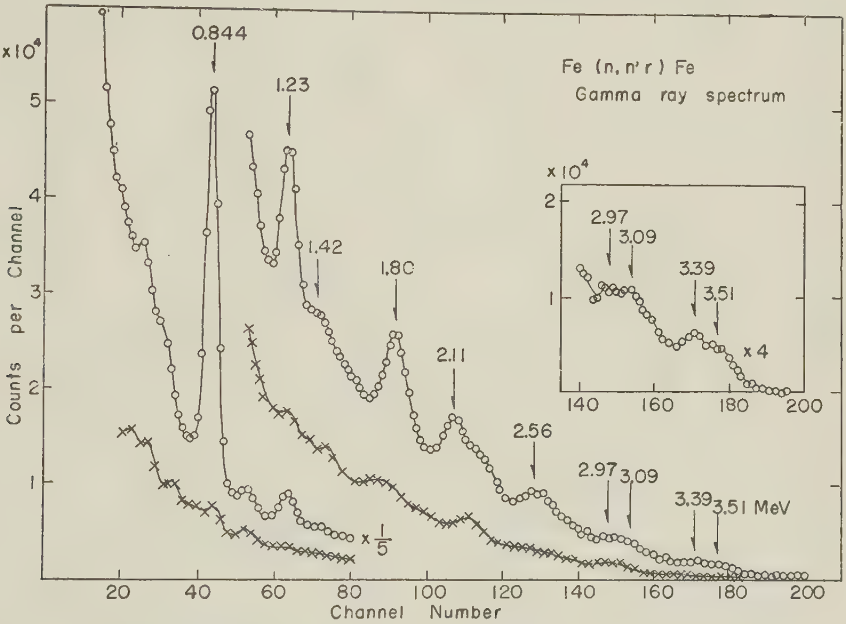

Fig. 3. The spectrum of gamma rays following the inelastic scattering of (4.04±.10)-MeV neutrons in iron. The background spectrum determined with the carbon ring scatterer is illustrated with crossed points. There are subtracted in the inserted figure.

The differential cross sections for gamma-ray production by the neutron inelastic scattering, which were measured in the range of incident neutron energies 3.11∼4.72 MeV, are shown in Figs. 4, 6, 8, 10 and 12. The cross-section values in parentheses in Table II have rather large errors (∼±30%), since the yields are small compared with other gamma rays. Measurements of the excitation functions for these weak gamma rays, therefore, was not performed.

(1) Iron

The gamma rays from low-lying levels in iron are clearly fitted to the known level scheme[13]. The peak around 2.56 MeV in Fig. 3 seems to be composed of three peaks at 2.56, 2.58 and 2.66 MeV; i.e. a peak due to the

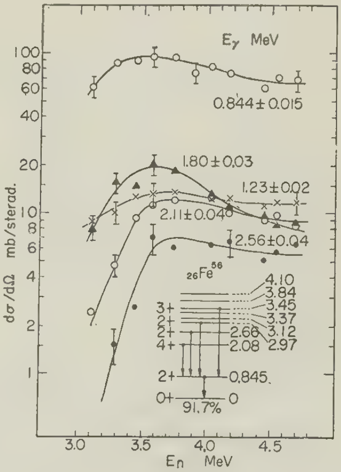

Fig. 4. Excitation curves for gamma-ray production by the neutron inelastic scattering Fe(n, $n'\gamma$) Fe. Those gamma rays which corresponded to the arrows in the inserted level scheme, were investigated.

transition from the 7th (3.45 MeV) to the 1st level (0.844 MeV), one-quantum escape peak of the gamma rays from the 5th (3.12 MeV) to the ground level, and a peak due to the transition from the 3rd (2.66 MeV) to the ground level, respectively.

The excitation curves for iron gamma rays are shown in Fig. 4, together with the known level scheme. The 2.11-MeV gamma ray is considered not to be due to a cross-over transition (2.08 MeV to the ground level) but cascade one (2.97 to 0.844 MeV), since the excitation curve rises steeply above 3.0 MeV.

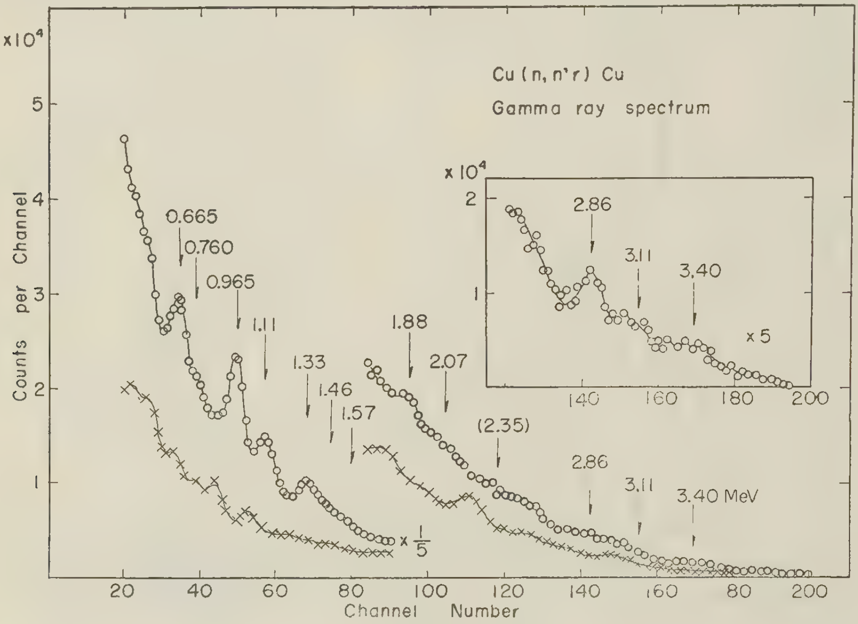

Fig. 5. The spectrum of gamma rays from Cu$(n, n'\gamma)$Cu reaction.

(2) Copper

The gamma-ray spectra of the present measurements are in good agreement with those by Day[3] and Pasechnik et al.[4] as shown in Fig. 5. Furthermore, gamma rays of 2.86, 3.11 and 3.40 MeV were found in our measurement.

The excitation curves of five gamma rays are shown in Fig. 6. Those gamma rays corresponding to the direct transition from the 1st, 2nd and 3rd to the ground state, are predominant. This mode of de-excitation is different from those of even-even nuclei such as iron, zinc, germanium and selenium.

(3) Zinc

The first excited states of zinc isotopes are known to be 0.99 MeV (Zn^{64}), 1.04 MeV (Zn^{66}) and 1.07 MeV (Zn^{68}), respectively[14),15),16)]. The observed photo-peak has an energy of 0.995 ±.015 MeV, which result from the superposition of gamma rays of these energies.

There is almost the same amount of cross-over transition (1.81 MeV) as the cascade one (0.81 MeV). This mode of de-excitation is different from that of iron.

Recently, gamma-ray spectra from the Zn$(n, n'\gamma)$Zn reaction were observed for $E_n=1.0 \sim 3.3$ MeV by Van Patter et al..[17)] The pre-

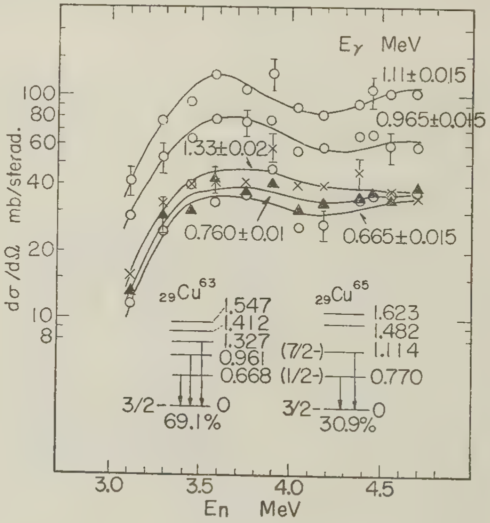

Fig. 6. Excitation curves for Cu$(n, n'\gamma)$Cu reaction.

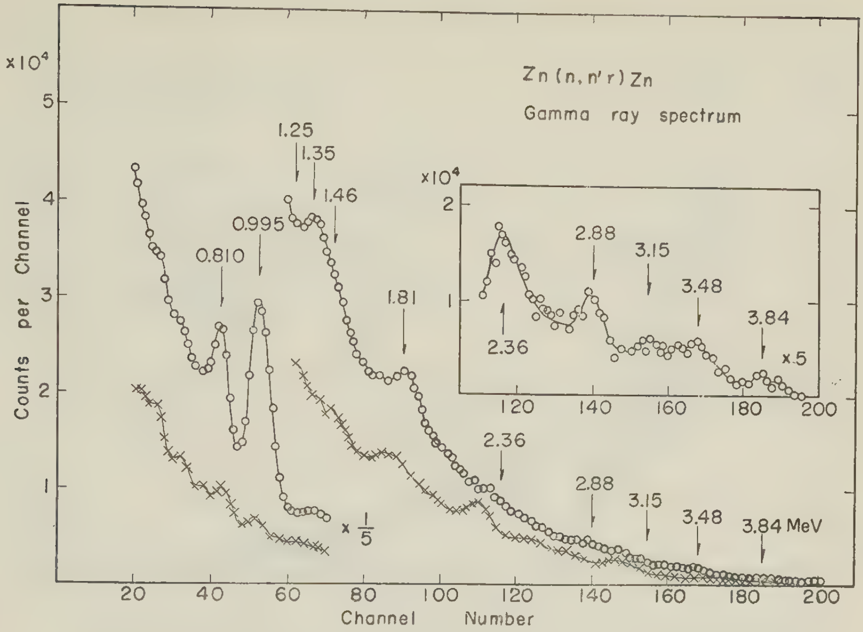

Fig. 7. The spectrum of gamma rays from $Zn(n, n'\gamma)Zn$ reaction.

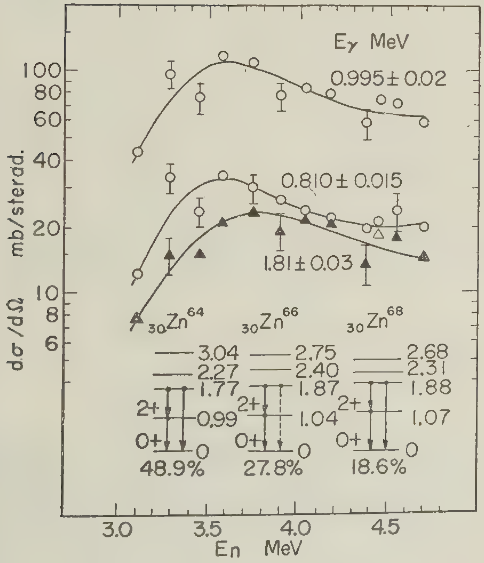

Fig. 8. Excitation curves for $Zn(n, n'\gamma)$ Zn reaction.

sent results will be connected to their excitation function.

(4) Germanium

A detailed pulse-height distribution from 1.0 MeV to 2.0 MeV is shown in the insert of Fig. 9. The transitions from the 1st (1.04 MeV) to the ground state in Ge^{70} and from the 4th (1.73 MeV) to the 1st (0.69 MeV) in Ge^{72} are probably observed as a single peak at 1.01±.02 MeV. Some of gamma rays observed are fitted to known level scheme[15),16)].

The excitation curves for gamma rays of energies 0.59, 0.83 and 1.01 MeV are shown in Fig. 10, and these excitation curves show rather flat variation in the energy range observed.

(5) Selenium

The 0.660 MeV peak is remarkably larger than those of any others. The 0.56-MeV gamma ray is narrowly resolved from the 0.660-MeV gamma ray by the subtraction of background.

The detailed pulse-height spectra are shown in Fig. 11 (a). If one takes the 1st level of Se^{82} as 0.670 MeV[18)] and estimates the energy of its 2nd excited state by the systematics of level scheme for even-even nuclide, the value obtained becomes 1.57 MeV. Then, the gamma ray of 1.57±.03 MeV will be the transition from the 2nd to the ground state of Se^{82}. Furthermore, the 0.900 MeV gamma ray will be the transition from the 2nd (1.57 MeV) to the 1st (0.670 MeV) state of Se^{82}.

Fig. 12 shows the excitation curves for gamma rays of 0.56 and 0.66 MeV. The fact that there is many transitions of rather small intensities in the de-excitation of selenium following the neutron inelastic scattering, agrees with the results of a recent time-of-

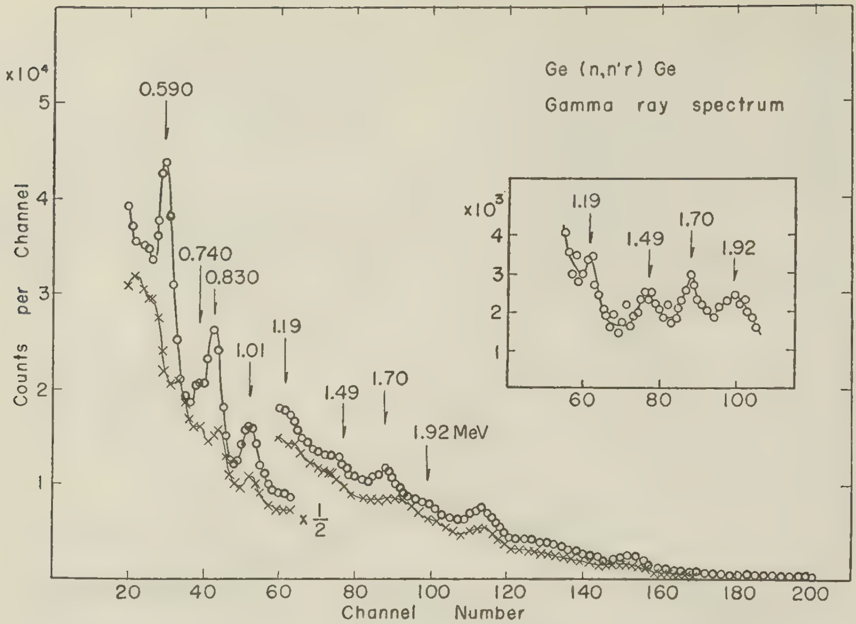

Fig. 9. The spectrum of gamma rays from Ge(n, $n'\gamma$)Ge reaction.

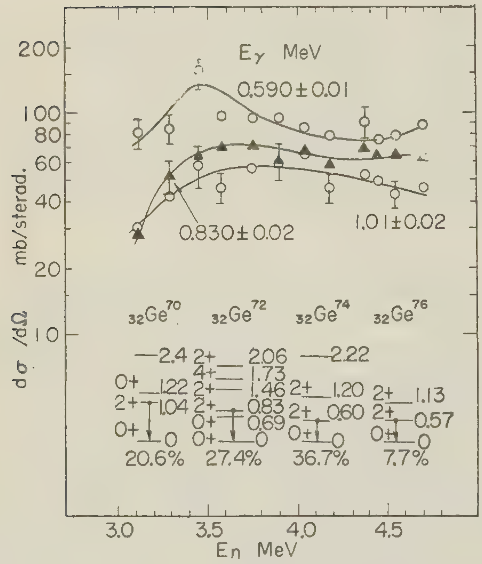

Fig. 10. Excitation curves for Ge(n, $n'\gamma$)Ge reaction.

flight experiment[10].

§ 5. Discussions

In the present measurements of gamma-ray yield from low-lying levels excited by the inelastic scattering of neutrons, we find an amount of cascade transitions from the higher excited states. We can obtain some information about the de-exciting property of higher excited states by combining the present data with the results of time-of-flight measurement of neutron inelastic scattering and the relevant non-elastic scattering cross sections.

For this purpose, we examine the probability that higher states ($E_{i\geq 3}$) excited by the neutron inelastic scattering are de-excited to the ground state by cascading through or not through the 1st excited state. These probabilities are represented by T_1 and T_0, respectively, and expressed by definition as follows:

$$\left.\begin{aligned} T_1 &= \sum_{i=3}^{k} \sigma_i^{n'}(E_n,\, E_i)\, p_1(E_i) \\ T_0 &= \sum_{i=3}^{k} \sigma_i^{n'}(E_n,\, E_i)\, p_0(E_i) \end{aligned}\right\} \qquad (4)$$

where the index i indicates the i-th excited state, k is the index of the highest state excited by the inelastic scattering, $p_1(E_i)$ or $p_0(E_i)$ the probability of transition from the i-th excited state to the ground state by cascading through or not through the 1st excited state, respectively (see Fig. 13) and $\sigma_i^{n'}$ the neutron inelastic scattering cross section leading to the i-th state. In the above equation, the 2nd excited state is excluded from the summation for simplifying the discussion. T_1 and T_0 can be determined experimentally by the following equations as follows:

$$\left.\begin{aligned} T_1 &= \sigma_1^{\gamma} - (\sigma_1^{n'} + \alpha\sigma_2^{n'}),\ \alpha = a/(1+a) \\ T_1 + T_0 &= \sum_{i=3}^{k} \sigma_i^{n'} \simeq \sigma_{\mathrm{non}} - (\sigma_1^{n'} + \sigma_2^{n'}) \end{aligned}\right\} \qquad (5)$$

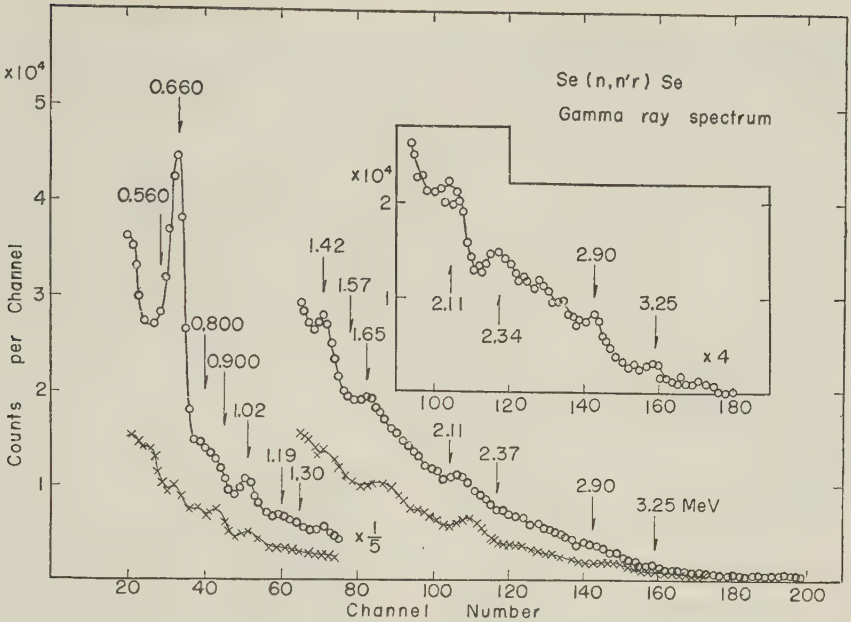

Fig. 11. The spectrum of gamma rays from Se(n, $n'\gamma$)Se reaction.

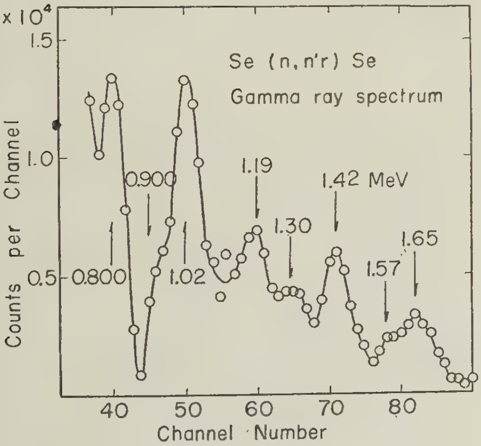

Fig. 11(a). The spectrum of gamma rays from Se(n, $n'\gamma$)Se reaction, especially in the range from 0.80 to 1.65 MeV. The background is subtracted.

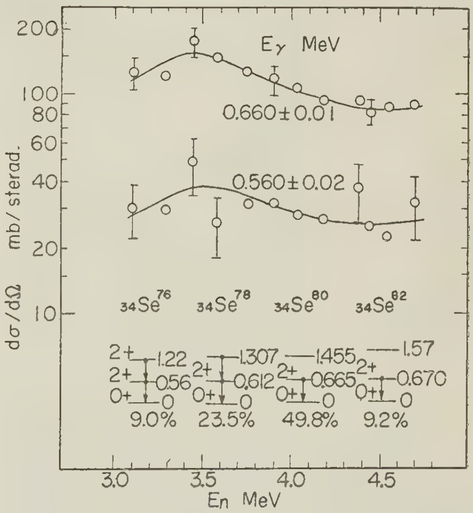

Fig. 12. Excitation curves for Se(n, $n'\gamma$)Se reaction.

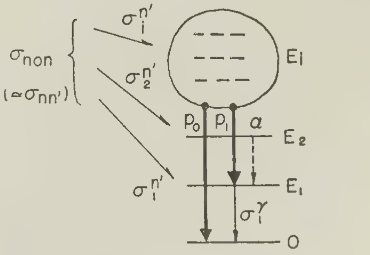

Fig. 13. Notations, which are used in Eq. (6).

Here, σ_1^{γ} is the gamma-ray production cross section which de-excites from the 1st to the ground state, as observed in the present experiment; $\sigma_1^{n'}$ and $\sigma_2^{n'}$ the inelastic neutron cross sections which leave the target nucleus in the 1st and 2nd state, as reported in the time-of-flight experiment[10]. σ_{non} is the non-elastic cross section as given in reference (19). a is the cascade-to-cross-over ratio of the 2nd excited state. $a=(2\text{nd}\rightarrow 1\text{st})/(2\text{nd}\rightarrow \text{ground})$. This quantity is introduced to take account of the cascade transition from the 2nd excited state through the 1st excited state.

Then, the probability ratio R is given as follows:

$$R=\frac{T_1}{T_0}=\frac{\sigma_1{}^{\gamma}-(\sigma_1{}^{n'}+\alpha\sigma_2{}^{n'})}{\sigma_{\text{non}}-\sigma_1{}^{\gamma}-(1-\alpha)\sigma_2{}^{n'}} \qquad (6)$$

The notations used in Eq. (6) are illustrated in Fig. 13.

The results of the calculations of the probability ratio R vs. neutron energy E_n are shown in Fig. 14, where the angular distributions for the emission of gamma rays and neutrons are assumed to be isotropic, the branching ratio for the cascade transition from the 2nd excited state in iron is assumed to be one[13], i.e. $\alpha=1$, and for zinc an isotopic average of reported values[14] is used, i.e. $\alpha=0.55$.

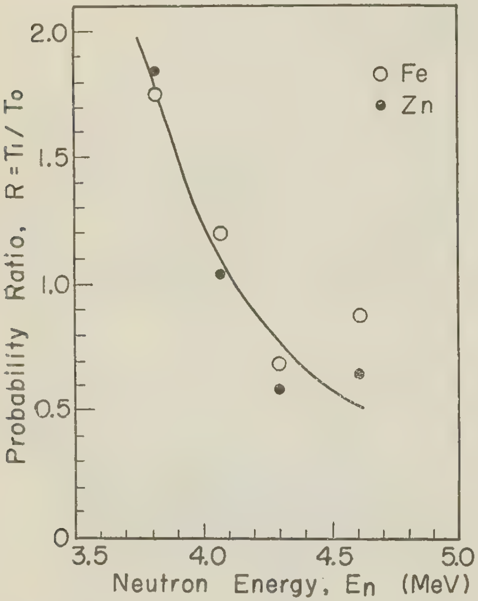

Fig. 14. The results of probability ratio R in Eq. (6).

Fig. 14 shows that the probability ratio R decreases as the incident neutron energy increases. This fact suggests that higher excited states are in general more difficult to be de-excited through the 1st excited state than lower excited states. This property of higher excited states in iron will be explained to some extent by the β-decay data[15] which show that branching ratio to the 1st excited state decreases gradually with increase of the excitation energy.

Acknowledgements

The author would like to express his sincere thanks to Dr. T. Momota for his valuable advice and interest. The author is greatly indebted to Dr. K. Tsukada and Mr. S. Kikuchi for their helpful cooperation throughout this work. Theoretical discussions with Drs. A. Sugie, K. Harada and T. Terasawa are gratefully acknowledged. Thanks are also due to Messrs. T. Kobayashi, Y. Sato and members of the fast-neutron group for operation and maintenance of the Van de Graaf accelerator.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 3, MARCH, 1961

Angular Distributions and Excitation Functions of the Be^9 (d, p) Be^{10} Ground-State Reaction

By Toshiyuki ISHIMATSU, Naoyuki TAKANO, Yûki HACHIYA and Takao NAKASHIMA

Department of Physics, Kyusyu University, Hukuoka, Japan.

(Received November 11, 1960)

Angular distributions and excitation functions of the Be^9 (d, p) Be^{10} ground-state reaction were studied in the energy range of deuteron from 1.7 to 3.0 MeV. Six angular distributions were measured at the deuteron energies of 1.74, 1.97, 2.24, 2.51, 2.73 and 3.03 MeV. Each angular distribution has a forward peak characteristic of the deuteron stripping process for $l_n=1$. The yields in the backward directions, however, are predominant at the lower energies. The excitation curve taken at the laboratory angle of 30°, where the forward peak occurs in the angular distribution, shows a monotone and rather fast rise with deuteron energy. On the other hand, the excitation function of the total cross section of this reaction shows a comparatively slow variation and has a broad peak at about 2.1 MeV of deuteron energy.

§ 1. Introduction

A number of investigations on the Be^9 (d, p) Be^{10} reaction have previously been made in the energy range of deuteron up to about 10 MeV, and there are many informations on the angular distributions of the proton groups from this reaction[1]. At the deuteron energies from 100 keV to 20 MeV, the angular distributions of protons from the Be^9 (d, p) Be^{10} ground-state reaction have been measured at small intervals of deuteron energy and the results show somewhat regular variation of the angular distribution with deuteron energy[2)3)4)]. At the deuteron energies below 800 keV, the differential cross section of this reaction increases smoothly and rapidly with emission angle of protons to the direction of incident deuteron beam. At about 900 keV of deuteron energy, a peak appears at a forward angle and it becomes more and more eminent as deuteron energy increases. At about 2 MeV, however, the proton yield in the backward direction is still predominant. At the deuteron energies of 3.6 and 3.9 MeV, the angular distributions are those of stripping type though they have a relatively high second maximum at about 100°, and the forward peak at the deuteron energy of 3.6 MeV is fitted fairly well by the stripping curve for $l_n=1$ evaluated with Butler's formula using the nuclear radius of 4.5×10^{-13}cm[5)6)]. At the deuteron energies from 8 to 12 MeV, the angular distributions show a more distinct stripping feature having a weaker second peak compared with those at lower deuteron energies, and were well explained by Butler's stripping theory for $l_n=1$ using the nuclear radius of about 5×10^{-13} cm[7)8)9)10)].

The excitation function of the $Be^9(d, p)Be^{10}$ ground-state reaction at the laboratory angle of 90° has been measured by Canavan[2)], using a proportional counter and aluminium absorbers over the energy range of deuteron from 0.55 to 2.95 MeV. The result shows broad maxima in the excitation curve at about 0.9, 1.3 and 2.1 MeV of bombarding deuteron energy, and the last one is thought to be indicative of overlapping resonances due to the compound states at about 17.5-MeV excitation in B^{11} nucleus.

We tried to investigate the variation of the angular distribution of protons from the $Be^9(d, p)Be^{10}$ ground-state reaction with deuteron energy, and investigate the excitation functions of the forward peak in the angular distribution and of the total cross section, over the energy range of deuteron from 1.7 to 3.0 MeV. It was hoped that these informations, together with the previouslv obtained results, would give a clue to understand the mechanism of (d, p) reaction at lower deuteron energies.

§ 2. Experimental Methods

Details of the apparatus used in this experiment are to be reported elsewhere[11)], so here they will be described briefly. The magnetically analyzed deuteron beam emerging from the Van de Graaff accelerator of Kyusyu University passed through a slit of 1 mm in width which served to get error signals for the stabilizer of accelerating voltage and another slit of 4 mm in diameter, and then entered into a scattering chamber and struck a beryllium target mounted at the center of the chamber. These two slits were distant each other about 26 cm and the plane of the target made 45° to the beam direction. The inner diameter of the chamber was 23 cm, and the target was metalic beryllium of 0.27 mg/cm² in thickness evaporated in vacuum on the silver foil of 2.2 mg/cm² in thickness. Charged particles emitted from the target came out of the chamber through the windows made on the side wall of the chamber at intervals of 15°. The windows consisted of openings of 6 mm in diameter covered with aluminium foils of 20 microns in thickness.

A CsI(Tl) crystal of 1 mm in thickness which was mounted on a DuMont 6291 photomultiplier tube was placed close to one of the windows and it stopped all of the charged particles outgoing through this window. Output pulses from the photomultiplier were amplified and then analyzed by a 20-channel differential pulse-height analyzer. A typical pulse-height spectrum obtained by this arrangement is shown in Fig. 1.

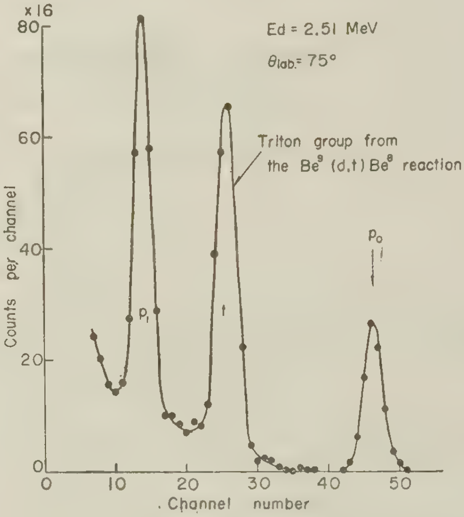

Fig. 1. Pulse-height spectrum of charged particles from the deuteron bombardment of beryllium, obtained at the deuteron energy of 2.51 MeV and at the laboratory angle of 75°.

Another scintillation counter similar to that mentioned above was mounted on the window at 22.5° to the direction of deuteron beam and used as a monitor counter. Output pulses from this counter were discriminated in such a way that only pulses corresponding to the ground-state protons from the $Be^9(d, p)Be^{10}$ reaction were registered.

The deuteron beam was collected in a Faraday cup, 3 cm in diameter and 5 cm in depth, and integrated by a current integrator similar to that designed by Higinbotham and Rankowitz[12)]. To insure accurate measurements of the beam current, the secondary electrons emitted from the cup wall were suppressed by the magnetic field produced by two pieces of Ferite mounted just outside of the cup. The excitation curve was taken at the laboratory angle of 30° where the forward peak occurs in the angular distribution. At that time the Faraday cup was placed as close to the target as possible in order to avoid the effect of deuteron scattering in the backing material of the target, i.e. the distance between the forward edge of the cup and the center of the target was chosen to be 5 cm.

The peaks corresponding to the ground-state protons from the $Be^9(d, p)Be^{10}$ reaction in pulse-height spectra, obtained at different angles and at a certain deuteron energy were integrated to get the areas under them, which give the measures of the intensities of this group at different angles. The angular distribution in the laboratory system at that deuteron energy was obtained by normalizing these areas to a fixed number of monitor counts, and it was transformed to the center-of-mass system.

Experimental points at 0° in the angular distributions were taken, preventing the direct deuteron beam to reach the detector by means of silver absorbers of suitable thickness inserted in front of the window made in 0° direction, and allowing protons of higher energy to enter the scintillation crystal.

To obtain the excitation function, the pulse-height spectra were taken at a fixed counter angle of 30° at different deuteron energies in the same manner as for the angular distribution measurements. Areas under the peaks corresponding to the ground-state proton group in these pulse-height spectra were normalized to a fixed value of integrated beam current, to obtain the excitation function at the laboratory angle of 30°.

Each of the angular distributions at different deuteron energies obtained in this experiment was integrated over the whole solid angles to obtain the total yield of the ground-state protons from the $Be^9(d, p)Be^{10}$ reaction. Six values of the total yield at different deuteron energies derived in this way were normalized with each other using the measured excitation curve at the laboratory angle of 30°. Thus, the excitation function of the total cross section of the reaction concerned was obtained.

§ 3. Results and Discussions

Figs. 2 and 3 show the angular distributions of the ground-state protons from the $Be^9(d, p)$-Be^{10} reaction at different deuteron energies. Deuteron energies indicated in these figures are the mean values in the target material, measured in the laboratory system. The statistical uncertainty of each experimental point is less than 3%. Fig. 4 shows the excitation function of the $Be^9(d, p)Be^{10}$ ground-state reaction at the laboratory angle of 30°. Errors indicated in the figure include uncertanties ascribed to the counting statistics and beam current integration. The relative uncertainty in the beam-current integration was estimated to be less than 1% from the distribution of ratios of integrated beam currents to the corresponding monitor counts in every runs at a certain deuteron energy. Fig. 5 shows the excitation function of total cross section of the $Be^9(d, p)Be^{10}$ ground-state reaction, derived from the angular distributions shown in Figs. 2 and 3, and the 30°-excitation

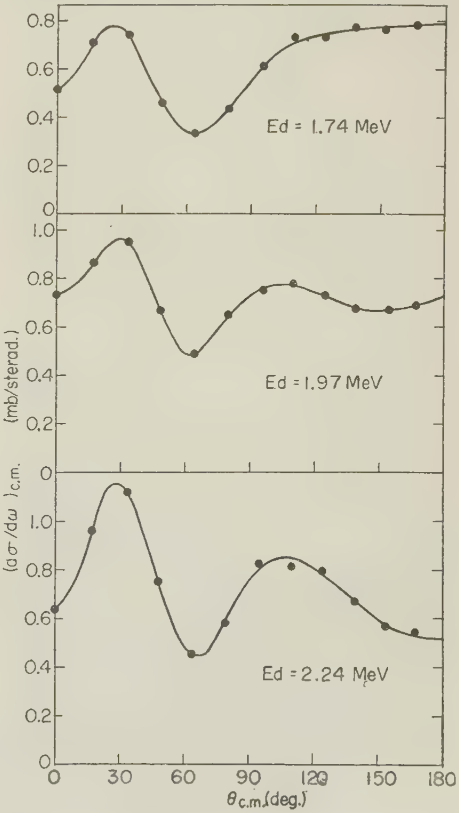

Fig. 2. Angular distributions of the protons from the $Be^9(d, p)Be^{10}$ ground-state reaction at the deuteron energies of 1.74, 1.98 and 2.24 MeV.

function give in Fig. 4.

The scales on the ordinates of these figures were determined with the peak areas and corresponding values of integrated beam current, which were obtained when the 30°-excitation function was measured, and the geometry of the experimental arrangement. They are estimated to have inaccuracy of ±20%, mainly due to the uncertainty in the determination of the target thickness. The target thickness was determined by weighing the backing foil by means of a chemical balance before and after the vacuum evaporation of the beryllium metal.

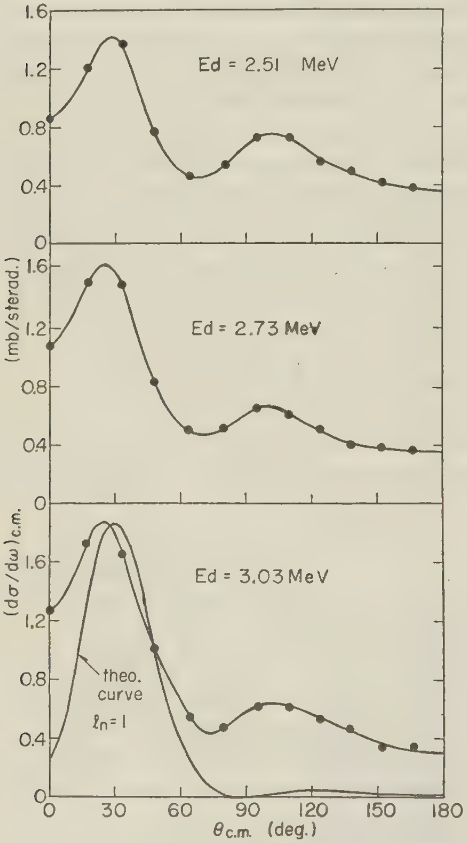

Fig. 3. Angular distributions of the protons from the $Be^9(d, p)Be^{10}$ ground-state reaction at the deuteron energies of 2.51, 2.73 and 3.03 MeV.

Canavan[2)] has measured angular distributions of protons from the same reaction by means of photographic plates at six deuteron energies from 1.0 to 2.2 MeV. He has also studied the excitation function at the laboratory angle of 90° from 0.55 to 2.95 MeV using a proportional counter and aluminum absorbers. His result on the angular distribution at 1.75-MeV agrees well with ours at 1.74 MeV and his result at 2.0 MeV agrees reasonably with ours at 1.98 MeV. In Fig. 5, the points derived from Canavan's results are also shown, where his point at 1.75 MeV is normalized to our 1.74-MeV point.

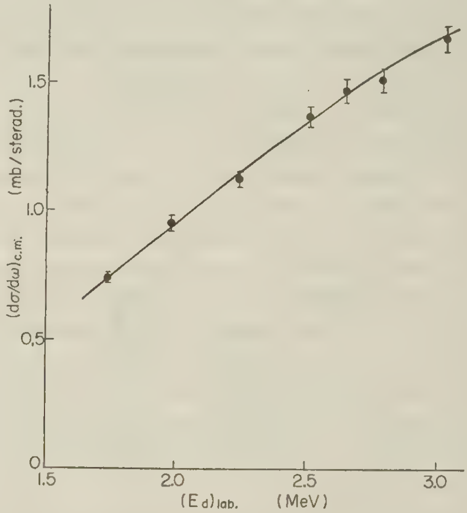

Fig. 4. Excitation function of the $Be^9(d, p)Be^{10}$ ground-state reaction at the laboratory angle of 30°.

It is clearly seen from the results on angular distributions that the forward peak in the angular distribution becomes more and more eminent with increasing deuteron energy and finally the angular distribution approaches to that characteristic of the deuteron-stripping process of Butler type. In Fig. 3, a theoretical angular distribution for $l_n=1$ and $E_d=3.0$ MeV, evaluated by a formula derived by Bhatia *et al.*[13)] on the basis of the deuteron stripping, is also shown. Nuclear radius of 7.0×10^{-13} cm was used in the evaluation. Agreement between the experimental and theoretical angular distributions is not so well and the value of nuclear radius used here is rather large. At such a low deuteron energy, however, in addition to the contribution of the compound-nucleus process to the (d, p) reaction, there may be a considerable amount of contributions of Coulomb and nuclear interaction effects discussed by Tobocman and Kalos[14)], and it is expected that the experimental angular distributions deviate from the theoretical ones derived from a simple theory of the deuteron stripping.

As shown in Fig. 4, the yield of the ground-state protons at the laboratory angle of 30° shows a monotone are rather fast rise with the deuteron energy. Since in the energy range investigated in this experiment the forward peak which is characteristic of the stripping process appears at the laboratory angle of about 30°, the behavior of the excitation function at 30° is thought to give some indication of the gradual growth of the deuteron-stripping process. Tobocman and Kalos[14] have shown that the total cross section of the deuteron-stripping reaction is much reduced by Coulomb interaction, so that the growth of the stripping process with the deuteron energy will be, at least in part, due to the decrease of the Coulomb effect.

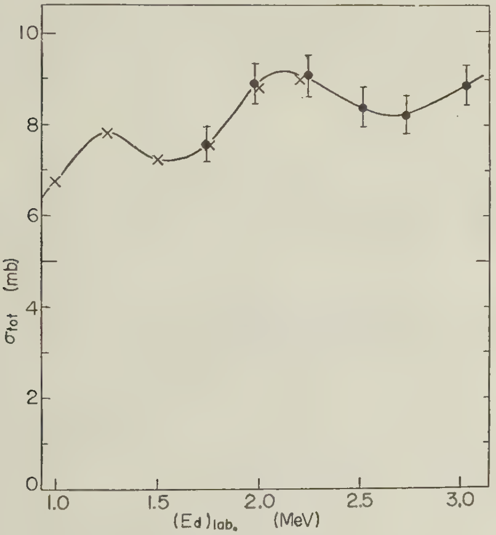

Fig. 5. Excitation function of total cross section of the $Be^9(d, p)Be^{10}$ ground-state reaction. Crosses are points derived from Canavan's results.

On the other hand, it is seen from Fig. 5 that the total cross section of the reaction concerned varies slowly with the deuteron energy, showing a broad maximum at about 2.1 MeV. The general behavior of the total cross section will probably be explained on the basis of the compound-nucleus process. The excitation function at 90° obtained by Canavan also shows a broad peak at about 2.1 MeV of deuteron energy, which was attributed to the overlapping resonances due to the states of about 17.5-MeV excitation in the compound nucleus, B^{11}. Since the stripping process should have little contribution to the excitation function at 90°, the similarity between these two excitation functions suggests that in the $Be^9(d, p)Be^{10}$ ground-state reaction, the contribution of the stripping process to the total cross section is much smaller than that of the compound-nucleus process at deuteron energies below 3 MeV. Neverthless, it must be noticed that even at such a low energy as about 1 MeV, the forward peak in the angular distribution of protons from this reaction is thought to be due to the deuteron-stripping process, because of its growth to a definite stripping peak with increasing deuteron energy.

The authors would like to thank Prof. S. Morita and all other staffs of the nuclear laboratory of Kyusyu University for their supports and discussions throughout this work. Thanks are also due to Mr. T. Maki for the preparation of the beryllium target.

On the Nuclear Interaction of Mu-Mesons*

By Hiroyuki Shibata

Institute of Polytechnics, Osaka City University, Osaka.

(Received November 21, 1960)

The penetrating showers observed with a large multiplate cloud chamber at 50 mwe and 250 mwe underground have been analyzed. The frequencies of the penetrating showers which are experimentally verified to be produced by mu-mesons have been interpreted with the Williams-Weiszäcker method and the constant photonuclear cross section of 1.4×10^{-28} cm^2/nucleon. It has been also shown that the angular distribution of secondary penetrating particles in multiple productions produced by mu-mesons is nearly isotropic in the center-of-mass system of the target nucleon and photon which is virtually associated with the incoming mu-mesons.

§ 1. Introduction

Many investigations on the high energy nuclear interactions produced by mu-mesons were made with cosmic rays underground. It has been pointed out by George and Evans[1] that the frequency of stars underground is understood with the aid of the semiclassical Williams-Weiszäcker method which hereafter will be cited as the W-W method and of the constant photonuclear cross section. Likewise, it has been investigated whether the frequency of the penetrating showers at various depths could be interpreted with the W-W method and a constant or slowly increasing cross section of photonuclear interaction, or not[2-6]. Using a large multiplate cloud chamber, however, we found that about a half of the penetrating showers observed underground had been produced by secondary pi-mesons[7]. Therefore, it can not be realized to investigate the nuclear interactions of mu-mesons, unless they are distinguished from the penetrating showers produced by secondary pi-mesons underground.

The purpose of this paper is to investigate whether or not the frequency of the penetrating showers which are verified to be produced by mu-mesons in the large cloud chamber and its dependence on depth are interpreted in terms of the W-W method with the constant photonuclear cross section and moreover to discuss an angular distribution of the penetrating showers using a kinematics on photo-nucleon interactions.

The observations were performed at 50 mwe and 250 mwe underground from March, 1956 to November, 1957, in the Isohama Tunnel of the National Railway, Yaizu City, Shizuoka, Japan[7].

§ 2. Apparatus and Experimental Results

The experimental arrangement is schematically shown in Fig. 1.

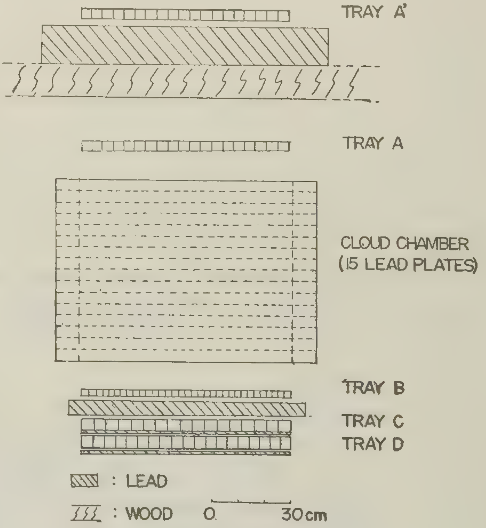

Fig. 1. Experimental arrangement.

The chamber was triggered by coincidences "$(A'\geq1)$ $(A\geq1)$ $(B\geq2)$ $(C\geq2)$ $(D\geq2)$" at 50 mwe, and "$(A'\geq1)$ $(A\geq1)$ $(B\geq2)$ $(C\geq1)$ $(D\geq2)$" or "$(A'\geq1)$ $(A\geq1)$ $(B\geq2)$ $(C\geq2)$ $(D\geq1)$" at 250 mwe, but only the photographs of the cloud chamber which were found to be triggered by the coincidences "$(A'\geq1)$ $(A\geq1)$ $(B\geq2)$

(C≥2)(D≥2)" were analyzed at both the depths. The penetrating showers are classified into two groups, P-showers and S-showers. P-showers are the penetrating showers produced by the particles assumed as mu-mesons at the lead plates inside the cloud chamber, and S-showers are those produced by secondary particles of the nuclear interactions originated by mu-mesons. For further details on the apparatus and the classification of showers, they will be found in the paper of Higashi et al.[7].

The number of P-showers at the receptive time and the cross section of nuclear interactions of mu-mesons are shown in Table I.

Table I. Receptive time, number of P-showers and the cross section of nuclear interactions.

Depth	Receptive time	Number of P-showers	σ_μ (cm²/nucleon)
50 mwe	667.9^h	7	$(2.4\pm0.6)\times10^{-31}$
250 mwe	3603.1^h	12	$(1.7\pm0.3)\times10^{-30}$

The ratio of the cross sections at both depths ($\sigma_\mu(250)/\sigma_\mu(50)$) is found to be 7.0±2.2[7].

The measurement on the angular distribution of secondary penetrating particles was made by stereo analysis, and the errors of the angle measurements were within 2 degrees. The angular distributions were measured on all of the P-showers observed at 50 mwe and 7 events at 250 mwe. The remaining 5 events at 250 mwe were accompanied with large cascade showers so that their angular distribution can not be measured, and 2 events of them seem to be extra-ordinary high energy ones.

Since it is expected that the angular distributions of incident mu-mesons in their unclear interactions from the original direction are very small, the minimum deflected particle among the secondary particles, without any successive nuclear collision with lead plates, included in each nuclear interaction is assumed to be the surviving mu-meson. The angular distribution of the secondary particles regarded as mu-mesons is shown in Fig. 2 and that of the other secondary particles is shown in Fig. 3, putting together the data obtained at 50 mwe and 250 mwe.

The averaged multiplicity ($\bar{n}_s$) of secondary particles except mu-mesons is found as being 3 per shower. Their interaction m.f.p., λ_π, has been recognized as (22±5) cm in lead which may be concluded to be consistent with the geometrical m.f.p.. The averaged multiplicity of heavily ionizing secondary particles was found to be 0.3 per P-shower and this value shows that the P-showers have 10 times smaller number of heavily ionizing particles than the S-showers have.

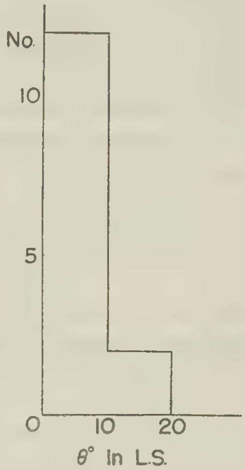

Fig. 2 Angular distribution of the secondary particles regarded as mu-mesons.

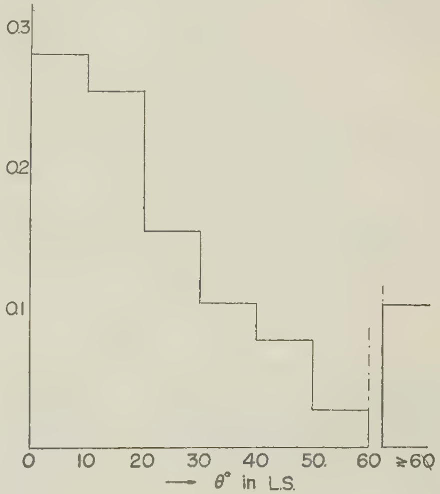

Fig. 3. Angular distribution of the other secondary particles than mu-mesons.

§ 3. Discussion and Conclusions

1) *Cross section of nuclear interactions of mu-mesons and its dependence on depth*

Following the procedure of George and Evans, the nuclear interactions produced by mu-mesons may be accounted for in terms of the interaction of the virtual photon field of mu-mesons with nucleus. If the deflected angle of the incident mu-mesons in nuclear interactions is so small as we may put $\sin\theta \simeq \theta$ and also the transferred energy is small, the virtual photon spectrum may be described by the W-W method[8]. It may be realized from the observed results, as shown in Fig. 2, that the deflection angle of incident mu-mesons is so small that one can now apply the idea of the W-W method for the treatment of the nuclear interactions of mu-mesons.

The number of virtual photons of energy greater than $\mathcal{E}$ associating with a mu-meson of incident energy E is given by[9]

$$\Phi(E,\mathcal{E})=\frac{\alpha}{\pi}\left[\left\{\ln\left(\frac{E}{\mathcal{E}}\right)\right\}^2 2-0.76\ln\left(\frac{E}{\mathcal{E}}\right)\right] \quad \text{for} \quad \mathcal{E} \ll E \qquad (1)$$

where α is the fine structure constant. Here, we assume that $\Phi(E,\mathcal{E})$ is given by the following formula:

$$\left.\begin{aligned}\Phi(E,\mathcal{E})&=\frac{\alpha}{\pi}\left[\left\{\ln\left(\frac{E}{\mathcal{E}}\right)\right\}^2-0.76\ln\left(\frac{E}{\mathcal{E}}\right)\right] && \text{for} \quad \mathcal{E}<\mathcal{E}_0\\ \Phi(E,\mathcal{E})&=0 && \text{for} \quad \mathcal{E}\geq\mathcal{E}_0\end{aligned}\right\} \qquad (2)$$

where $\mathcal{E}_0=\frac{E}{e^{0.76}}\sim\frac{E}{2}$, and equation (1) has a negative value when $\mathcal{E}\geq\mathcal{E}_0$. Hence, the number of photons of energy greater that $\mathcal{E}$ at x mwe underground is given by

$$\Phi(x,\mathcal{E})=\int_{\mathcal{E}}^{\infty}\phi(E,\mathcal{E})\frac{dI_x(E)}{dE}\cdot dE \qquad (3)$$

where $I_x(E)$ is the flux of mu-mesons of energy greater than E at x mwe underground. The photon spectra at 50 mwe and at 250 mwe are obtained by numerical calculations and are shown in Fig. 4. If the photonuclear cross section $\sigma_{h\nu}$ is taken as being independent on the energy of photon at high energy, the cross section $\sigma_\mu(x)$ for shower production by mu-mesons is expressed by:

$$\sigma_\mu(x)=\sigma_{h\nu}\frac{\phi(x,E_{\min})}{I_x} \qquad (4)$$

where I_x is an intensity of the hard component at the depth x mwe, and $E_{\min}$ is threshold energy of the shower observed in the cloud chamber. The expected values of σ_μ(50 mwe) and σ_μ(250 mwe) and the ratio of them, σ_μ(250 mwe)/σ_μ(50 mwe), are given in Table II, as a function of $E_{\min}$*.

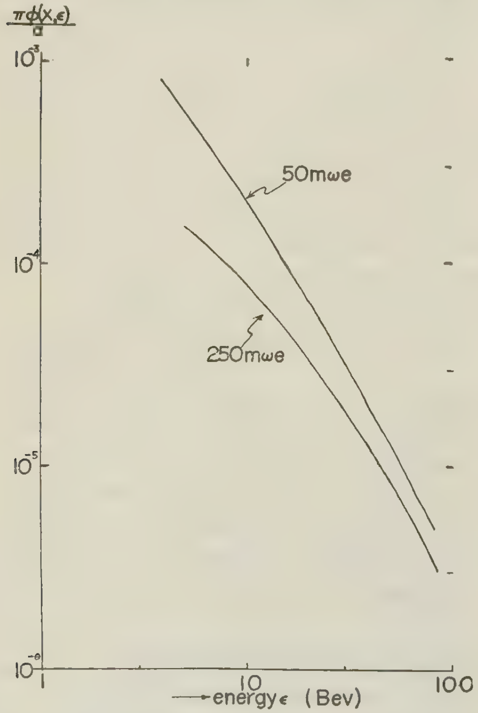

Fig. 4. Integral energy spectra of photons obtained by the W-W method at 50 mwe and at 250 mwe understand.

Table II. The expected values of σ_μ (50 mwe) and σ_μ (250 mwe) and the ratio of them, σ_μ (250 mwe)/σ_μ (50 mwe).

$E_{\min}$ (BeV)	$\sigma_\mu(50)$ (cm²/nucleon)	$\sigma_\mu(250)$ (cm²/nucleon)	$\sigma_\mu(250)/\sigma_\mu(50)$
5	$1.7\times10^{-3}\sigma_{h\nu}$	$10\times10^{-3}\ \sigma_{h\nu}$	5.9
7	1.1 〃	7 〃	6.4
10	0.6 〃	4.5 〃	7.5
20	0.2 〃	2.2 〃	11

Table III. Relation between $E_{\min}$ and $\sigma_{h\nu}$.

5	1.4×10^{-28}
7	2.2 〃
10	4.0 〃

The value of $\sigma_{h\nu}$ was determined by comparing in the observed value of σ_μ(50 mwe) with the above expression, and their results were shown in Table III.

---

* The values of the ratio $\sigma_\mu(250)/\sigma_\mu(50)$, which has been shown in N. C.[7], was obtained from the equation $\Phi(E,\varepsilon)=\alpha/\pi\ [\ln(E/\varepsilon)]^2$ which is given by George and Evans[1].

If the nuclear cross section of virtual photon would be postulated to be identical with that of real photon, and would be taken as a constant at the energy of more than 1 BeV, it may be expected that the value of the photonuclear cross section would be nearly equal to 10^{-28} cm^2/nucleon[10]. The values of cross section of mu-mesons at both the depths and their depth dependence, thus, should be interpreted as a behavior of the showers with the threshold energy of 5 BeV. The threshold energy obtained above is also consistent with the estimated value of $E_{\min}$ from the triggering condition by using the relation between the averaged multiplicity and the shower energy, on the assumption that the nature of the showers of mu-mesons is similar to that of nucleons.

Barrett et al. have obtained the cross section σ_μ(1600 mwe) with a hodoscoped counter arrangement at 1600 mwe underground. They inferred the cross section $\sigma_\mu(1600\ \mathrm{mwe})\geq(4\pm2)\times10^{-29}$ cm^2/nucleon for energies above 5 BeV[12]. The value of σ_μ(1600 mwe) expected from equation (4) is evaluated to be about 6×10^{-30} cm^2/nucleon. But this discrepancy at 1600 mwe is probably not very serious. Because it seems that they did not pay attention to the fact that the tail of a cascade shower is surviving in lead and made them overestimate the number of penetrating showers, and they obtained the maximum cross section of penetrating showers $\sigma_{\max}=3\times10^{-29}/\gamma$ cm^2/nucleon from local absorption[12] at the same depth, where γ is the multiplicity of production resulting from a single interaction of a mu-meson. Therefore, it seems that there is no reason to consider that the value of σ_μ(1600 mwe) is too large.

It should, accordingly, be concluded that the frequencies of penetrating showers produced by mu-measons at the depth down to 1600 mwe are interpreted with the W-W method and the constant photonuclear cross section of 1.4×10^{-28} cm^2/nucleon.

2) *Angular distribution of secondary penetrating particles*

The P-showers, of which secondary penetrating particles are investigated, are occurred in lead plates. It is then doubtful whether or not the angular distribution of the secondary particles of P-showers directly implies that of mu-meson-nucleon interactions. The fact that the heavily ionizing particles are rarely produced in the P-showers, however, suggests that the successive interactions of shower particles in the nucleus may be neglected in the P-showers. It may be therefore considered that the angular distribution of P-showers expresses that of mu-meson-nucleon interactions. As the nuclear interaction of mu-mesons may be understood with the W-W method, the differential energy distribution of the P-showers is given by $\dfrac{d\Phi(x,\mathcal{E})}{d\mathcal{E}}$ where $\Phi(x,\mathcal{E})$ is the number of photons of energy greater than $\mathcal{E}$ at x mwe underground. Then, the angular distribution of secondary penetrating particles of the P-showers at x mwe underground is

$$f(\varphi)d\varphi=\frac{\displaystyle\int_{E_{\min}}^{\infty} n(\mathcal{E})\cdot g(\mathcal{E},\varphi)\frac{d\Phi(x,\mathcal{E})}{d\mathcal{E}}\cdot d\mathcal{E}\cdot d\varphi}{\displaystyle\int_{E_{\min}}^{\infty} n(\mathcal{E})\frac{d\Phi(x,\mathcal{E})}{d\mathcal{E}}\cdot d\mathcal{E}} \qquad (5)$$

where $n(\mathcal{E})$ is the averaged multiplicity and $g(\mathcal{E},\varphi)\,d\varphi$ is the angular distribution of secondary particles of showers produced by photon of energy $\mathcal{E}$. Since the number of photons of energy greater than 40 BeV is less that 10 percents of that of energy greater 5 BeV as shown in Fig. 4 and as a dependence of averaged multiplicity on the incident energy would be expected to be only slight, it does not result so much errors to assume that $n(\mathcal{E})$ is constant. Kessler and Maze[4] have given the anisotropical distribution of the type $(1+\cos\phi)d\Omega$ in the center-of-mass system of photon-nucleon interaction by the use of the F-plot analysis from their observed penetrating showers data. The angle ϕ in the center-of-mass system is transferred to the angle φ in the laboratory system by the relation

$$\tan\varphi=\frac{1}{\gamma_c}\cdot\frac{\sin\phi}{\cos\phi+(\beta_c/\beta_\pi)} \qquad (6)$$

where γ_c and β_c are Lorentz factor and velocity of the center-of-mass system in the laboratory system respectively, and β_π is velocity of the secondary particles in the center-of-mass system. In case that the secondary particles have the angular distribution $(1+\cos\phi)$ $d\Omega$ in the center-of-mass system, the distribution in the laboratory system $f_1(\varphi)\,d\varphi$ was obtained by numerical calculation under such condition as being $\beta_c/\beta_\pi=1$ postulated by Kessler and Maze[4]. The mean value of that expected at both depths is shown in Fig. 5. If we consider the case that there are a few of low energy secondaries in the center-of-mass system, the angular distribution in the laboratory system should tend to increase forward. On the other hand, in case that the angular distribution in the center-of-mass system is isotropic, a different distribution $f_2(\varphi)\,d\varphi$, was evaluated with the same way as above and using the similar momentum distribution of secondary particles in the center-of-mass system as that of pi-meson-nucleon interactions[13] which is shown in Fig. 6. The result is also shown in Fig. 5.

Although the experimental results we obtained till now have still a quite large statistical uncertainties, it seems that the distribution $f_2(\varphi)\,d\varphi$, on the whole, is in better agreement with our results than the distribution $f_1(\varphi)\,d\varphi$ is.

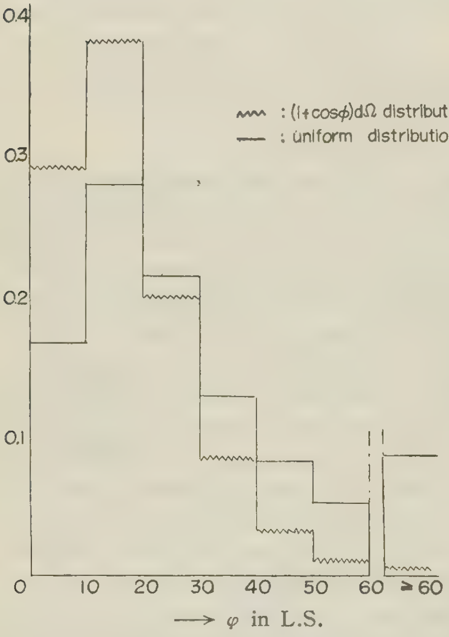

Fig. 5. Expected angular distribution in the lab. system obtained from the distribution $(1+\cos\phi)d\Omega$ in the c.m.s. and from the uniform distribution in the c.m.s.

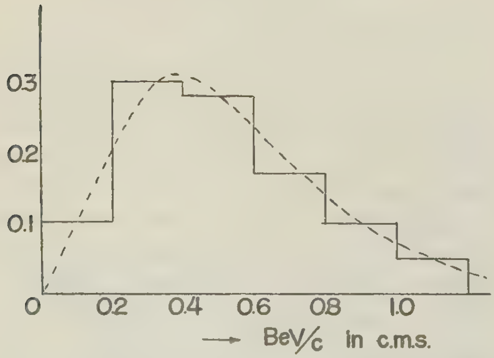

Fig. 6. Assumed momentum distribution of secondary particles in the center-of-mass system.

Namely, the distribution $f_2(\varphi)\,d\varphi$ is similar to the observed one except a few part in 0-10 degrees region. On the other hand, the distribution $f_1(\varphi)d\varphi$ cannot interpret so broad distribution as observed. It may be likely that the anisotropical distribution $(1+\cos\phi)d\Omega$ obtained by Kessler and Maze is due mainly to the narrow arrangement of the observing system. The result that the angular distribution of secondary penetrating particles in multiple productions of photo-nuclear interaction is nearly uniform in the center-of-mass system is of the same behavior as the fact that those of nucleon-nucleon interactions at the energy of 6.2 BeV[15] and of a few tens of BeV[14] and pimeson-nucleon interactions at the energy of 5 BeV[13] seem to be uniform in the center-of-mass system at the first approximation from their observed results. It seems, therefore, that the angular distribution of secondary penetrating particles of multiple production at these energy region is nearly uniform in the center-of-mass system and is not dependent on the character of incident particles.

Acknowledgements

The author wishes to express his great gratitude the Professor Y. Watase of Osaka City University not only for his suggestions, but also for his interest and encouragement. He also wishes to express his thanks to Professors T. Oshio, K. Watanabe, Drs. S. Higashi and S. Mitani for active collaboration, to Professor M. Oda of Tokyo University, Professor S. Ozaki, Drs. T. Kitamura and O. Kusumoto of Osaka City University for suggestions and helpful discussions, and to Mr. H. Nishimura for his aid in measuring.

It is a pleasure to thank the Institute for Food Chemistry for the financial aid.

Quantum Statistics of Surface Effect

By Takuji TSUZUKI

Yokohama Municipal University,
Kanazawa-ku, Yokohama, Japan

(Received December 3, 1960)

The quantum mechanical behaviors of a dilute gas in a vessel with finite volume are considered with special reference to the surface effect. It is shown that the thermodynamic function of the system with weak interaction between particles can be expanded in terms of permutation rings with the use of M. Toda's formula, and the result is shown to be in harmony with that derived from the method of grand partition function. An approximate treatment for molecules with hard cores is also given.

§1. Introduction

The theory of gas of interacting particles has been investigated for many years as one of the most typical problems of statistical mechanics. In classical theory, as is well known, J. Mayer has given the expansion formula in terms of interaction of particles. The first term of Mayer's formula (the zero-th approximation) gives the ideal gas law. The deviation from the ideal gas law is generally represented as the 2nd, 3rd, ⋯ virial coefficient. In quantum statistics, however, the symmetricity of wave function must be considered, and Ursell expansion has to be substituted for Mayer's formula. Many authors[1),2),3)] have developed the theories of quantum corrections for systems of interacting particles.

In the present paper, the quantum statistical theories of a dilute gas in a vessel with finite volume are developed. Especially the effect of boundary wall of a vessel on a dilute gas is discussed. When the volume of a container is restricted to be finite, then thermodynamical quantities of a gas are affected by the surface area. In Section 2, the general formula for the surface free energy is developed by the use of M. Toda's[4)] formula. In Section 3, we treat the surface effect assuming that the interaction between molecules is weak. In Section 4, the equation of state of such a gas with surface effect is given. Especially the results derived from the Toda's[4),5)] formula is shown to be in harmony with the result calculated by the method of grand partition function.

In the present work, the potential energy between molecules $u(r)$ and that between a molecule and the boundary wall $u_w(z)$ are nitroduced. The effect of non-comutability of potential energy and kinetic energy is taken into account, and the statistical effect (effect of symmetricity of wave function) is considered. Our results may be applicable to the surface phenomena of substances in which quantum effect is predominant (for example liquid helium[6),7),8)]), or to atomic nuclei[9)] since they consist of only several hundred nucleons even for the heviest atom. In the latter case, however, we must remark that the boundary surface is not plane, but has curvature.

On the other hand, at room temperature, many interesting chemico-physical phenomena between solid and gas have been observed. Adsorption of gas to solid surface is one of them. Some authors[10),11)] have developed the statistical theories of adsorption by the use of grand canonical ensemble. In this case, generally, the quantum treatment need not to be considered, but the potential energy $u_w(z)$ plays an important role. W. A. Steele and G. D. Halsey, JR.[12)] have calculated the excess volume, assuming the inverse cubic attraction between a gas molecule and the boundary wall. Moreover M. P. Freeman and G. D. Halsey, JR.[13)] have introduced the hard sphere repulsion between molecules and have had a good agreement with experimental results. In the previous paper[14)] we have also introduced square-well potentials for the interaction between molecules and between a molecule and the wall. If the interaction between molecules has hard sphere repulsion, the quantum statistical treatment becomes very difficult. In Section 5, we avoid this difficulty by substituting the effective diameter σ for the classical diameter σ_0 of a molecule as we have done in the previous paper[14)].

§ 2. General Formula for the Surface Free Energy

The system we shall consider is a gas composed of N identical molecules in a vessel with volume $V\,(=L_xL_yL_z)$. Molecules are assumed to be nonpolar and spherically symmetric, i.e., the potential energy $u(r)$ between molecules is assumed to be a function only of the distance r between the centers of the molecules. Moreover we introduce the potential energy between a molecule and a wall $u_w(z)$, which is a function of the shortest distance z from the center of the molecule to the surface of the wall. The total energy H is thus

$$H=H_0+\sum_{i=1}^{N}u_w(\boldsymbol{x}_i)+\sum_{i<j}^{N}u(|\boldsymbol{x}_j-\boldsymbol{x}_i|) \qquad (2.1)$$

where H_0 represents the kinetic energy of gas molecules.

The increment of the free energy due to the presence of walls can be written as γA, where A denotes the total surface area of the walls and γ stands for the surface tension. Here we are assuming that the size of the vessel is large compared with the interaction lengths of u_w and u, and further with a certain multiple of the de Broglie wave length of gas molecules. γ is defined by the derivative of free energy F with respect to the surface area A, keeping the volume constant:

$$\gamma=(\partial F/\partial A)_{V,T,N} \qquad (2.2)$$

with

$$F=-kT\log \mathrm{Tr}\,\rho\,, \qquad (2.3)$$

where ρ stands for the density matrix

$$\rho=e^{-\beta H}\,. \qquad (2.4)$$

It is convenient to use Toda's method[4),5)] to make the derivative in Eq. (2.2). In our case there is potential energy due to the wall, which contribute an extra term. Thus we get an extension of Toda's formula[4)]:

$$\gamma=\mathrm{Tr}\left\{2\left[\sum_{i=1}^{N}H_{0z}(i)-\sum_{i=1}^{N}H_{0x}(i)\right]\rho-\sum_{i=1}^{N}z_i\frac{du_w(z_i)}{dz_i}\rho-\sum_{j>i=1}^{N}\frac{z_{ij}^2-x_{ij}^2}{r_{ij}}\frac{du(r_{ij})}{dr_{ij}}\rho\right\}\Big/A\,\mathrm{Tr}\,\rho \qquad (2.5)$$

where the surface perpendicular to the z-axis, with area A is considered, and $H_{0z}(i)$ and $H_{0x}(i)$ are the kinetic energy, for the z-direction and for the x-direction respectively, of the i-th molecule given by

$$H_{0z}(i)=p_{zi}^2/2m\,, \qquad H_{0x}(i)=p_{xi}^2/2m\,. \qquad (2.6)$$

Now, assuming that the potential energy

$$U=\sum_{i=1}^{N} u_w(i)+\sum_{j>i=1}^{N} u(i,j) \tag{2.7}$$

is sufficiently small compared with the kinetic energy

$$H_0=\sum_{i=1}^{N} p_i^2/2m\ , \tag{2.8}$$

we get the expansion of density matrix of the form

$$\rho=\rho_0-\rho_0\int_0^\beta \exp(sH_0)U\exp(-sH_0)\,ds+\cdots\ , \tag{2.9}$$

where

$$\rho_0=\exp(-\beta H_0) \tag{2.10}$$

stands for the density matrix of an ideal gas.

Noting the fact that $H_{0z}(i)$ and $H_{0x}(i)$ commute with H_0 and ρ_0, we have, for the first term of the right-hand side of Eq. (2.5),

$$\begin{aligned}\mathrm{Tr}\,\{(H_{0z}(1)-H_{0x}(1))\rho\}&=\mathrm{Tr}\,\{(H_{0z}(1)-H_{0x}(1))\rho_0\}\\ &-\beta\,\mathrm{Tr}\,\{\sum_i u_w(i)(H_{0z}(1)-H_{0x}(1))\rho_0\}-\beta\,\mathrm{Tr}\,\{\sum_{i>j} u(i,j)(H_{0z}(1)-H_{0x}(1))\rho_0\}\ ; \end{aligned}\tag{2.11}$$

For the second and the third term of Eq. (2.5) we may substitute ρ_0 for ρ if we neglect terms of higher order with respect to interaction potentials. As will be shown later, diagonal element of $(H_{0z}(1)-H_{0x}(1))\rho_0$ vanishes except in a limited region of the order λ (de Brogie wave length) near the wall. So the second and the third terms in the above equation can be neglected in a rough approximation. All these terms can be rewritten using the reduced density matrix of the form[15]

$$\rho_0^{(N)}(\boldsymbol{x}_1,\cdots \boldsymbol{x}_s;\boldsymbol{x}_1',\cdots \boldsymbol{x}_s')=\int\cdots\int \rho_0^{(N)}(\boldsymbol{x}_1,\cdots \boldsymbol{x}_s,\boldsymbol{x}_{s+1},\cdots \boldsymbol{x}_N;\boldsymbol{x}_1',\cdots \boldsymbol{x}_s',\boldsymbol{x}_{s+1},\cdots \boldsymbol{x}_N)\times d\boldsymbol{x}_{s+1}\cdots d\boldsymbol{x}_N \tag{2.12}$$

where the index (N) is attached to clarify the number of molecules.

§ 3. Explicit Formulas for the Surface Tension

As we are interested in the effect of surface perpendicular to the z-axis, we shall impose periodic conditions with respect to the x and y directions. Thus we think of a gas contained in the space between the walls at $z=0$ and $z=L_z$, and between the periodic boundaries at $x=0$, $x=L$, $y=0$ and $y=L$. For brevity's sake we have put $L_x=L_y=L$.

(i) Boltzmann Statistics

For classical statistics we have[15]

$$\rho_0^{(N)}(\boldsymbol{x}_1;\boldsymbol{x}_1')=\frac{1}{N}f^{(N-1)}(\beta)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1'|\beta)\ , \tag{3.1}$$

$$\rho_0^{(N)}(\boldsymbol{x}_1,\boldsymbol{x}_2;\boldsymbol{x}_1',\boldsymbol{x}_2')=\frac{1}{N(N-1)}f^{(N-2)}(\beta)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1'|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2'|\beta) \tag{3.2}$$

where $f^{(n)}(\beta)$ represents the partition function for an ideal gas with n molecules,

$$\left.\begin{aligned}&f^{(n)}(\beta)=\mathrm{Tr}\,\rho_0^{(n)}=[f^{(1)}(\beta)]^n/n!\ ,\\ &f^{(1)}(\beta)=\mathrm{Tr}\,\rho_0^{(1)}\end{aligned}\right\} \tag{3.3}$$

and $\rho_0(\boldsymbol{x};\boldsymbol{x}'|\beta)$ is the density matrix for a molecule subject to the foresaid boundary conditions[14]:

$$\rho_0(\boldsymbol{x};\boldsymbol{x}'|\beta)=\rho_{0x}\rho_{0y}\rho_{0z} \tag{3.4}$$

where

$$\left.\begin{aligned}\rho_{0x}&=\rho_{0x}(x;x'|\beta)=\lambda^{-1}\exp\{-\pi(x-x')^2/\lambda^2\}\,,\\ \rho_{0y}&=\rho_{0y}(y;y'|\beta)=\lambda^{-1}\exp\{-\pi(y-y')^2/\lambda^2\}\,,\\ \rho_{0z}&=\rho_{0z}(z;z'|\beta)=\frac{2}{L_z}\sum_{n=1}^{\infty}\exp(-\beta\pi^2\hbar^2n^2/L_z^2)\sin\frac{\pi n}{L_z}z\sin\frac{\pi n}{L_z}z'\end{aligned}\right\} \tag{3.5}$$

and

$$\lambda=\sqrt{2\pi\hbar^2\beta/m} \tag{3.6}$$

is the de Broglie wave length. For the lower half $(0\leq z\leq L_z/2)$ of the system we use the integrated form

$$\rho_{0z}(z;z'|\beta)=\lambda^{-1}[\exp\{-\pi(z-z')^2/\lambda^2\}-\exp\{-\pi(z+z')^2/\lambda^2\}]\,, \tag{3.7}$$

as we are assuming that $L_z\gg\lambda$.

We have for the diagonal,

$$[2H_{0z}\rho_{0z}]_{z=z'}=-\frac{\hbar^2}{m}\left[\frac{\partial^2}{\partial z^2}\rho_{0z}\right]_{z=z'}=\frac{kT}{\lambda}\left\{1-\exp(-4\pi z^2/\lambda^2)+\frac{8\pi z^2}{\lambda^2}\exp(-4\pi z^2/\lambda^2)\right\}, \tag{3.8}$$

$$[2H_{0x}\rho_{0x}]_{x=x'}=-\frac{\hbar^2}{m}\left[\frac{\partial^2}{\partial x^2}\rho_{0x}\right]_{x=x'}=\frac{kT}{\lambda}\,. \tag{3.9}$$

Since $L_z\gg\lambda$, we get

$$\int_0^{L_z/2}[2H_{0z}\rho_{0z}]_{z=z'}\,dz=\frac{kT}{\lambda}\frac{L_z}{2}\,, \tag{3.10}$$

$$\int_0^{L_z/2}[\rho_{0z}]_{z=z'}\,dz=\frac{1}{\lambda}\left(\frac{L_z}{2}-\frac{\lambda}{4}\right). \tag{3.11}$$

The same contribution comes from the wall at $z=L_z$. Thus we obtain $(V=L^2L_z,\ A=2L^2)$

$$\mathrm{Tr}\,(2H_{0z}\rho_0)=\frac{kT}{\lambda^3}V\,, \tag{3.12}$$

$$\mathrm{Tr}\,(2H_{0x}\rho_0)=\frac{kT}{\lambda^3}\left(V-\frac{\lambda}{4}A\right), \tag{3.13}$$

$$\mathrm{Tr}\,\rho_0=\frac{1}{\lambda^3}\left(V-\frac{\lambda}{4}A\right). \tag{3.14}$$

Surface tension γ_0 for a gas of free molecules $(u_w=u=0)$ is therefore

$$\begin{aligned}\gamma_0&=N\frac{2\,\mathrm{Tr}\,\{(H_{0z}(1)-H_{0x}(1))\rho_0\}}{A\,\mathrm{Tr}\,\rho_0}\\ &=\frac{N}{V-\lambda A/4}\frac{\lambda}{4}kT\simeq\frac{N}{V}\frac{\lambda}{4}kT\end{aligned} \tag{3.15}$$

which is in agreement with Tada's result[4]. $\lambda/4$ represents the width of the region inaccessible for molecules due to the boundary condition that wave function vanishes at the wall. In fact, it is easy to see in the case of free molecules, that the free energy is

$$F_0^{(N)}=-kT\log\left[\left\{\lambda^{-3}\left(V-\frac{\lambda}{4}A\right)\right\}^N\Big/N!\right] \tag{3.16}$$

and the pressure is given by

$$p_0=-\left(\frac{\partial F_0^{(N)}}{\partial V}\right)_{A,T,V}=NkT\Big/\left(V-\frac{\lambda}{4}A\right). \tag{3.17}$$

Further in this case, we obtain from Eq. (3.15) and Eq. (3.17) the relation

$$(p_0V-\gamma_0A)/kT=N. \tag{3.18}$$

On the other hand, however, from thermodynamical argument, the left-hand side of the last equation is seen to be related to the logarithm of the grand partition function Ξ_0 given by

$$\Xi_0(\zeta)=\sum_{n=0}^{\infty}\zeta^n f^{(n)}=\exp\left\{\zeta\lambda^{-3}\left(V-\frac{\lambda}{4}A\right)\right\}. \tag{3.19}$$

Since the parameter ζ is determined by the condition

$$N=\zeta\,\partial\log\Xi_0(\zeta)/\partial\zeta, \tag{3.20}$$

the thermodynamical relation

$$(p_0V-\gamma_0A)/kT=\log\Xi_0 \tag{3.21}$$

is established.

Since interaction potentials u_w and u are diagonal in the coordinate representation, diagonal elements of ρ_0, $H_{0z}\rho_0$ etc. are sufficient for calculating γ from Eqs. (3.8) and (3.9). We note that for $z<L_z/2$,

$$[2(H_{0z}-H_{0x})\rho_0]_{\boldsymbol{x}=\boldsymbol{x}'}=\frac{kT}{\lambda^3}(-1+8\pi z^2/\lambda^2)\exp(-4\pi z^2/\lambda^2), \tag{3.22}$$

$$[\rho_{0x}]_{x=x'}=[\rho_{0y}]_{y=y'}=\lambda^{-1}, \tag{3.23}$$

$$[\rho_{0z}]_{z=z'}=\lambda^{-1}\{1-\exp(-4\pi z^2/\lambda^2)\}. \tag{3.24}$$

We note the fact that $[2(H_{0z}-H_{0x})\rho_0]_{\boldsymbol{x}=\boldsymbol{x}'}$ is comparable with $kT[\rho_0]_{\boldsymbol{x}=\boldsymbol{x}'}$ only at the distance of the order λ from the wall. We may therefore neglect the terms like

$$\mathrm{Tr}\,\{u_w(i)[H_{0z}(1)-H_{0x}(1)]\rho_0\}$$

and

$$\mathrm{Tr}\,\{u(i,j)[H_{0z}(1)-H_{0x}(1)]\rho_0\}.$$

Thus we get an approximation formula which is valid when the interaction distance of u_w and u are large compared with the de Broglie wave length λ:

$$\begin{aligned}\gamma=N\Bigg[&\frac{kT}{V}\frac{\lambda}{4}-\int z\frac{du_w(z)}{dz}\rho_0(z;z|\beta)dz\Big/\lambda^2f^{(1)}(\beta)\\&-\frac{N-1}{2}\iiiint\frac{z_{12}{}^2-x_{12}{}^2}{r_{12}}\frac{du(r_{12})}{dr_{12}}\rho_0(z_1;z_1|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\\&\times dz_1\,dx_{12}\,dy_{12}\,dz_{12}\Big/\{\lambda^2f^{(1)}(\beta)\}^2\Bigg].\end{aligned} \tag{3.25}$$

(ii) Quantum Statistics

In quantum statistics, we have15),16)

$$\rho_0^{(N)}(\boldsymbol{x}_1;\boldsymbol{x}_1')=\frac{1}{N}\sum_{\nu=1}^{N}(\pm)^{\nu-1}f^{(N-\nu)}(\beta)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1'|\nu\beta) \tag{3.26}$$

$$\rho_0^{(N)}(\boldsymbol{x}_1,\boldsymbol{x}_2;\boldsymbol{x}_1',\boldsymbol{x}_2')=\frac{1}{N(N-1)}\sum_{\mu,\nu}^{\mu+\nu\le N}(\pm)^{\mu+\nu}f^{(N-\mu-\nu)}(\beta)\begin{vmatrix}\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1'|\mu\beta) & \rho_0(\boldsymbol{x}_1;\boldsymbol{x}_2'|\nu\beta)\\ \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_1'|\mu\beta) & \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2'|\nu\beta)\end{vmatrix}_{\pm} \tag{3.27}$$

where the upper sign corresponds to Bose-Einstein statistics and the lower sign to Fermi-Dirac statistics, and $\rho_0(x;x'|\nu\beta)$ is the density matrix given by Eq. (3.4) and Eq. (3.5) but $\nu\beta$ is substituted for β and is a chain integral of the form

$$\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1'|\nu\beta)=\int\cdots\int\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_2|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_3|\beta)\cdots\rho_0(\boldsymbol{x}_\nu;\boldsymbol{x}_1'|\beta)\,d\boldsymbol{x}_2\cdots d\boldsymbol{x}_\nu\,. \tag{3.28}$$

We see that

$$b_\nu=\mathrm{Tr}\,\rho_0(x;x'|\nu\beta)=\lambda^{-3}\left(\frac{V}{\nu^{3/2}}-\frac{A}{\nu}\frac{\lambda}{4}\right) \tag{3.29}$$

means a permutation ring of ν molecules. The average size of this ring is seen to be $\nu^{1/2}\lambda/4$ because the above equation means that $V-\nu^{1/2}\lambda A/4$ is to be substituted for the geometrical volume V. As is known in the theory of polymers or of Brownian motion, the magnitude $\nu^{1/2}\lambda/4$ can ce interpreted as the length of a chain of ν segments with length λ each. The amount of decrease in effective volume and the effect of surface become more predominant when the permutation ring becomes larger even if we ignore the potential energy between molecules and wall.

The surface tension for an ideal gas in quantum statistics is given by

$$\gamma_0=N\frac{\lambda}{4}kT\frac{\sum_{\nu=1}^{N}(\pm)^{\nu-1}f^{(N-\nu)}/\nu^2}{\sum_{\nu=1}^{N}(\pm)^{\nu-1}f^{(N-\nu)}\left(\frac{V}{\nu^{3/2}}-\frac{A}{\nu}\frac{\lambda}{4}\right)} \tag{3.30}$$

in which the second term in the denominator may be neglected. It can be shown (cf. next section) that the equation of state takes the form

$$p_0=\frac{N}{V}kT\frac{\sum(\pm)^{\nu-1}f^{(N-\nu)}V/\nu^{5/2}}{\sum(\pm)^{\nu-1}f^{(N-\nu)}\left(\frac{V}{\nu^{3/2}}-\frac{A}{\nu}\frac{\lambda}{4}\right)}\,. \tag{3.31}$$

Therefore the equation which corresponds to Eq. (3.18) is

$$\frac{p_0V-\gamma_0A}{NkT}=\frac{\sum(\pm)^{\nu-1}f^{(N-\nu)}b_\nu/\nu}{\sum(\pm)^{\nu-1}f^{(N-\nu)}b_\nu}\,. \tag{3.32}$$

On the other hand, from Eq. (3.26) we see that

$$f^{(n)}=\frac{1}{n}\sum_{\nu=1}^{n}(\pm)^{\nu-1}f^{(n-\nu)}b_\nu\,;\qquad n\ge 1 \tag{3.33}$$

and that the grand partition function $\Xi_0(\zeta)=\sum_{n=0}^{\infty}\zeta^n f^{(n)}$ satisfies the equation

$$\zeta\frac{d}{d\zeta}\Xi_0(\zeta)=\Xi_0\sum_{\nu=1}^{\infty}(\pm)^{\nu-1}\zeta^\nu b_\nu\,. \tag{3.34}$$

Solving this equation with the initial condition that $\Xi_0(0)=f^{(0)}=1$, we get

$$\log\Xi_0(\zeta)=\sum(\pm)^{\nu-1}\zeta^\nu b_\nu/\nu\,. \tag{3.35}$$

ζ is determined by the condition

$$N=\zeta\,\partial\log\Xi_0/\partial\zeta=\sum(\pm)^{\nu-1}\zeta^\nu b_\nu\,. \tag{3.36}$$

The general thermodynamic relation $(pV-\gamma A)/kT=\log \Xi$ can be written as

$$\frac{p_0 V-\gamma_0 A}{NkT}=\frac{\sum(\pm)^{\nu-1}\zeta^\nu b_\nu/\nu}{\sum(\pm)^{\nu-1}\zeta^\nu b_\nu} \tag{3.37}$$

which is to be identified with Eq. (3.32).

To establish this identity we multiply η^N to both the denominator and the numerator of the right-hand side of Eq. (3.32). We note that for an appropriate value of η

$$\eta^N \sum(\pm)^{\nu-1} f^{(N-\nu)} b_\nu=\eta^N f^{(N)} \tag{3.38}$$

has a sharp maximum for a certain value of N, which therefore can be replaced by the average

$$N=\frac{\sum n\eta^n f^{(n)}}{\sum \eta^n f^{(n)}}=\eta\frac{\partial \log \Xi_0(\eta)}{\partial\eta} . \tag{3.39}$$

Comparing Eq. (3.39) with Eq. (3.36), we see that $\eta=\zeta$. For this value of ζ, the right-hand side of Eq. (3.32) can be replaced by the average as follows:

$$\frac{\sum_{\nu=1}^{N}(\pm)^{\nu-1} f^{(N-\nu)} b_\nu/\nu}{\sum_{\nu=1}^{N}(\pm)^{\nu-1} f^{(N-\nu)} b_\nu}=\frac{\sum_{n=1}^{\infty}\zeta^n\sum_{\nu=1}^{n}(\pm)^{\nu-1} f^{(n-\nu)} b_\nu/\nu}{\sum_{n=1}^{\infty}\zeta^n\sum_{\nu=1}^{n}(\pm)^{\nu-1} f^{(n-\nu)} b_\nu}=\frac{\Xi_0(\zeta)\sum_{\nu=1}^{\infty}(\pm)^{\nu-1}\zeta^\nu b_\nu/\nu}{\Xi_0(\zeta)\sum_{\nu=1}^{\infty}(\pm)^{\nu-1}\zeta^\nu b_\nu} . \tag{3.40}$$

Therefore Eq. (3.32) has the same implication to that of Eq. (3.37).

For ideal gas, $\log \Xi_0$ can be written as

$$\log \Xi_0=Q_V V+Q_A A , \tag{3.41}$$

in which both Q_V and Q_A do not depend on the volume V and the surface area A of the system. Thus we get the pressure p as the derivative of $\log \Xi_0$ with respect to the volume V, keeping the surface area A, the chemical potential μ $(\mu=kT\log\zeta)$ and the temperature T constant:

$$p=kT\left(\frac{\partial \log \Xi_0}{\partial V}\right)_{A,\mu,T} . \tag{3.42}$$

We also obtain the surface tension γ as the derivative of $\log \Xi_0/V$ with respect to the volume V, keeping A, μ and T constant:

$$\gamma A=kTV^2\left\{\frac{\partial}{\partial V}\left(\frac{\log \Xi_0}{V}\right)\right\}_{A,\mu,T} . \tag{3.43}$$

Even if there are interactions it can be shown that the above relations (Eqs. (3.42) and (3.43)) hold when Ξ_0 is replaced by Ξ. In this case (non-ideal gas) the explicit expression which corresponds to Eq. (3.25) for surface tension, becomes lengthy which will be published elsewhere. The equation of state becomes complicated, and we shall discuss, in the next section, its relation to the grand partition function.

§4. The Equation of State and the Grand Partition Function

We have seen in the foregoing sections that the formula for surface tension is rather complicated. The reason why the combination $pV-\gamma A$ yields simpler consequence lies in the fact that complicated contributions from the effect of surface on pressure and surface tension cancel out in this combination. To see the circumstances in more detail we have to investigate the pressure equation.

It should be noted that pressure, in general, depends on the surface area of the container.

Even if the wall does not exert any interaction on gas molecules, the volume available for the molecules is diminished if the molecules have hard cores. If the wall repells gas molecules the available volume is decreased and if it attracts molecules the effective number of molecules in gas state is decreased. These affect the pressure which would change proportionally to the surface area. Pressure is given by

$$p=-(\partial F/\partial V)_{A,T,N} \tag{4.1}$$

where the derivative is to be taken keeping the surface area A constant. For the system under consideration Toda's method[5)] gives (Appendix I)

$$pV=\left\{\mathrm{Tr}\,(2\sum_i H_{0z}(i)\rho)-\mathrm{Tr}\left(\sum_i z_i\frac{du_w(i)}{dz_i}\rho\right)-\mathrm{Tr}\left(\sum_{i<j}\frac{z_{ij}^2}{r_{ij}}\frac{du(i,j)}{dr_{ij}}\rho\right)\right\}\Big/\mathrm{Tr}\,\rho\,. \tag{4.2}$$

We make combination $pV-\gamma A$ from Eqs. (4.2) and (2.5), to get

$$pV-\gamma A=\left\{\mathrm{Tr}\,(2\sum_i H_{0x}(i)\rho)-\mathrm{Tr}\left(\sum_{i<j}\frac{x_{ij}^2}{r_{ij}}\frac{du(i,j)}{dr_{ij}}\rho\right)\right\}\Big/\mathrm{Tr}\,\rho\,. \tag{4.3}$$

This is much simpler than Eq. (2.5) or Eq. (4.2), because in the x-direction the system is periodic. In the second term in the right-hand side of Eq. (4.3), we may substitute ρ_0 for ρ just as discussed in Eq. (2.11).

On the other hand, on the assumption that the work done on the system is of the form $dW=-pdV+\gamma dA$ (cf. Eqs. (2.2) and (4.1)), thermodynamic argument leads to the theorem that

$$pV-\gamma A=kT\log\Xi$$

where Ξ denotes the grand partition function. For the case of ideal gas this relation is Eq. (3.21). When the potential energy is present, grand partition function Ξ becomes

$$\Xi=\sum_n^\infty\zeta^n\,\mathrm{Tr}\,\rho^{(n)}=\sum_n^\infty\zeta^n\,\mathrm{Tr}\left\{\left(1-\beta\sum_i^n u_w(i)-\beta\sum_{i<j}^n u(i,j)\right)\rho_0^{(n)}\right\}. \tag{4.4}$$

By the aid of Eqs. (3.26) and (3.27), we get[15)]

$$\begin{aligned}(pV-\gamma A)/kT=\log\Xi=\log\Xi_0&-\beta\sum_n\zeta^n n\,\mathrm{Tr}\,(u_w(1)\rho_0^{(n)})\\&-\beta\sum_n\zeta^n\frac{n(n-1)}{2}\,\mathrm{Tr}\,(u(1,2)\rho_0^{(n)})\,.\end{aligned} \tag{4.5}$$

It should be noted that Eq. (4.5) does not represent the surface tension, but is only a combination of pV and γA. In other words, the derivative of Eq. (4.5) with respect to A (surface area) does not give the surface tension, because the pressure p also depends on the surface area of container.

Eq. (4.3) which is derived from Toda's formula, must be identical with Eq. (4.5) obtained by the use of grand partition function. To verify this identity we shall evaluate Eqs. (4.5) and (4.3) as follows.

(i) Boltzmann Statistics

In Boltzmann statistics, Eq. (4.5) is written

$$\begin{aligned}(pV-\gamma A)/kT=\log\Xi_0&-\beta\zeta\int u_w(\boldsymbol{x})\rho_0(\boldsymbol{x};\boldsymbol{x}|\beta)\,d\boldsymbol{x}\\&-\frac{\beta}{2}\zeta^2\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2\,.\end{aligned} \tag{4.6}$$

The average number N of particles in the system is

$$N=\zeta\frac{\partial\log\Xi}{\partial\zeta}=\zeta\frac{\partial\log\Xi_0}{\partial\zeta}-\beta\zeta\int u_w(\boldsymbol{x})\rho_0(\boldsymbol{x};\boldsymbol{x}|\beta)\,d\boldsymbol{x}$$
$$-\beta\zeta^2\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2\,. \tag{4.7}$$

The first term in the right-hand side of Eq. (4.7) is by Eq. (3.19)

$$\zeta\lambda^{-3}(V-A\lambda/4)=\zeta f^{(1)}\,. \tag{4.8}$$

Thus the equation of state derived from the grand partition function becomes

$$\frac{pV-\gamma A}{kT}=N+N^2\frac{\beta}{2}\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\,\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2\Big/\{f^{(1)}\}^2 \tag{4.9}$$

higher order terms in u_w and u being neglected.

On the other hand, Eq. (4.3) becomes

$$pV-\gamma A=\frac{\mathrm{Tr}\,\{(1-\beta\sum_i u_w(i)-\beta\sum_{i<j}u(i,j))2NH_{0x}(1)\rho_0{}^{(N)}\}}{\mathrm{Tr}\,\{(1-\beta\sum_i u_w(i)-\beta\sum_{i<j}u(i,j))\rho_0{}^{(N)}\}}$$
$$-\frac{N(N-1)}{2}\frac{\iint\left\{x_1\dfrac{\partial u(1,2)}{\partial x_1}+x_2\dfrac{\partial u(1,2)}{\partial x_2}\right\}\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2}{\{f^{(1)}\}^2}\,. \tag{4.10}$$

The numerator of the first term in the right-hand side of Eq. (4.10) can be evaluated by the aid of Eq. (3.9), and become just NkT times the denominator. The numerator in the second term can be integrated partially and becomes

$$\iint\left\{x_1\frac{\partial u}{\partial x_1}+x_2\frac{\partial u}{\partial x_2}\right\}\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2$$
$$=2\Big\{L\iiint_{x_2<L}[u(\boldsymbol{x}_1,\boldsymbol{x}_2)]_{x_1=L}[\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)]_{x_1=L}\,\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,dy_1\,dz_1\,d\boldsymbol{x}_2$$
$$-\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\,\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\,\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2\Big\}\,. \tag{4.11}$$

The factor 2 in the above equation comes from the fact that the coordinate x_1 and x_2 play the same roles. The first term in the right-hand side of Eq. (4.11) gives the half value of the second term, thus we obtain

$$\frac{pV-\gamma A}{kT}=N+\frac{N(N-1)}{2}\beta\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\,\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\beta)\,\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\beta)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2\Big/\{f^{(1)}\}^2\,. \tag{4.12}$$

We may put $N(N-1)\approx N^2$ for large N, thus the selfconsistency of two different methods is satisfied.

(ii) Quantum Statistics

In quantum statistics the verification of identity of two different methods (Eq. (4.3) and Eq. (4.5)) becomes much more cumbersome. For brevity's sake we put

$$\left.\begin{aligned}
b_\nu&=\int\rho_0(\boldsymbol{x};\boldsymbol{x}|\nu\beta)\,d\boldsymbol{x}\,,\\
w_\nu&=\int u_w(\boldsymbol{x})\,\rho_0(\boldsymbol{x};\boldsymbol{x}|\nu\beta)\,d\boldsymbol{x}\,,\\
u(\mu,\nu)&=\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\begin{vmatrix}\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1|\mu\beta) & \rho_0(\boldsymbol{x}_1;\boldsymbol{x}_2|\nu\beta)\\ \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_1|\mu\beta) & \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\nu\beta)\end{vmatrix}_\pm d\boldsymbol{x}_1\,d\boldsymbol{x}_2\,.
\end{aligned}\right\} \tag{4.13}$$

By Eqs. (3.26) and (3.27), Eq. (4.4) becomes

$$\Xi=\Xi_0\left\{1-\beta\sum_{\nu}(\pm)^{\nu-1}\zeta^{\nu}w_{\nu}-\frac{\beta}{2}\sum_{\mu,\nu}(\pm)^{\mu+\nu}\zeta^{\mu+\nu}u(\mu,\nu)\right\}. \tag{4.14}$$

Thus the thermodynamical relation derived from the grand partition function becomes

$$(pV-\gamma A)/kT=\log\Xi=\sum(\pm)^{\nu-1}\zeta^{\nu}b_{\nu}/\nu-\beta\sum(\pm)^{\nu-1}\zeta^{\nu}w_{\nu}-\frac{\beta}{2}\sum_{\mu,\nu}(\pm)^{\mu+\nu}\zeta^{\mu+\nu}u(\mu,\nu). \tag{4.15}$$

A more explicit expression of Eq. (4.15) is given in Appendix II.

On the other hand, Eq. (4.3) becomes

$$pV-\gamma A=\left[N\,\mathrm{Tr}\left\{(1-\beta\sum_{i}u_w(i)-\beta\sum_{i<j}u(i,j))2H_{0x}(1)\rho_0^{(N)}\right\}\right.$$
$$\left.-\frac{N(N-1)}{2}\mathrm{Tr}\left\{\frac{x_{12}^2}{r_{12}}\frac{du(1,2)}{dr_{12}}\rho_0^{(N)}\right\}\right]\Big/\mathrm{Tr}\,\rho^{(N)}. \tag{4.16}$$

The terms in the numerator of the right-hand side of Eq. (4.16) are calculated as the following. First, by Eq. (3.26) and Eqs. (3.4) and (3.5) with β substituted by $\nu\beta$, we get

$$\mathrm{Tr}(2H_{0x}(1)\rho_0^{(N)})=\frac{kT}{N}\sum(\pm)^{\nu-1}f^{(N-\nu)}(\beta)b_{\nu}/\nu. \tag{4.17}$$

Eq. (3.27) gives

$$N(N-1)\beta\int d\boldsymbol{x}_1[2H_{0x}(1)\rho_0^{(N)}(\boldsymbol{x}_1,\boldsymbol{x}_2;\boldsymbol{x}_1',\boldsymbol{x}_2)]_{\boldsymbol{x}_1=\boldsymbol{x}_1'}$$
$$=\sum_{\mu,\nu}(\pm)^{\mu+\nu}f^{(N-\mu-\nu)}(\beta)\left\{\frac{b_{\mu}}{\mu}\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\nu\beta)\pm\frac{1}{\mu+\nu}\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|[\mu+\nu]\beta)\right\}$$
$$=\sum_{\mu,\nu}(\pm)^{\mu+\nu}f^{(N-\mu-\nu)}(\beta)\frac{b_{\mu}}{\mu}\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|\nu\beta)+\sum_{s}(\pm)^{s-1}f^{(N-s)}(\beta)\left(1-\frac{1}{s}\right)\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2|s\beta) \tag{4.18}$$

where we have used the identity

$$\int\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_1|\mu\beta)\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_2'|\nu\beta)\,d\boldsymbol{x}_1=\rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2'|[\mu+\nu]\beta).$$

Thus we get

$$N(N-1)\beta\,\mathrm{Tr}\,(u_w(2)2H_{0x}(1)\rho_0^{(N)})=\sum_{\mu,\nu}(\pm)^{\mu+\nu}f^{(N-\mu-\nu)}(\beta)\frac{b_{\mu}}{\mu}w_{\nu}$$
$$+\sum(\pm)^{s-1}f^{(N-s)}(\beta)w_s-\sum(\pm)^{s-1}f^{(N-s)}(\beta)\,w_s/s. \tag{4.19}$$

Similarly

$$N\beta\,\mathrm{Tr}\,(u_w(1)2H_{0x}(1)\rho_0^{(N)})=\sum(\pm)^{\nu-1}f^{(N-\nu)}(\beta)\,w_{\nu}/\nu. \tag{4.20}$$

To calculate terms including $u(i,j)$ we have to use

$$\rho_0^{(N)}(\boldsymbol{x}_1,\boldsymbol{x}_2,\boldsymbol{x}_3;\boldsymbol{x}_1',\boldsymbol{x}_2',\boldsymbol{x}_3')=\frac{1}{N(N-1)(N-2)}\sum_{\mu,\nu,\tau}^{\mu+\nu+\tau\leq N}(\pm)^{\mu+\nu+\tau-1}f^{(N-\mu-\nu-\tau)}(\beta)$$
$$\times\begin{vmatrix}\rho_0(\boldsymbol{x}_1;\boldsymbol{x}_1'|\mu\beta) & \rho_0(\boldsymbol{x}_1;\boldsymbol{x}_2'|\nu\beta) & \rho_0(\boldsymbol{x}_1;\boldsymbol{x}_3'|\tau\beta)\\ \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_1'|\mu\beta) & \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_2'|\nu\beta) & \rho_0(\boldsymbol{x}_2;\boldsymbol{x}_3'|\tau\beta)\\ \rho_0(\boldsymbol{x}_3;\boldsymbol{x}_1'|\mu\beta) & \rho_0(\boldsymbol{x}_3;\boldsymbol{x}_2'|\nu\beta) & \rho_0(\boldsymbol{x}_3;\boldsymbol{x}_3'|\tau\beta)\end{vmatrix}_{\pm}. \tag{4.21}$$

After some calculations we get

$$\frac{N(N-1)(N-2)}{2}\beta\,\mathrm{Tr}\,(u(2,3)2H_{0x}(1)\rho_0{}^{(N)})+N(N-1)\beta\,\mathrm{Tr}\,(u(1,2)2H_{0x}(1)\rho_0{}^{(N)})$$
$$+\frac{N(N-1)}{2}\,\mathrm{Tr}\left\{\frac{x_{12}{}^2}{r_{12}}\frac{du(1,2)}{dr_{12}}\rho_0{}^{(N)}\right\}$$
$$=\frac{1}{2}\sum_{\mu,\nu,\tau}(\pm)^{\mu+\nu+\tau-1}f^{(N-\mu-\nu-\tau)}(\beta)\frac{b_\mu}{\mu}u(\nu,\tau)+\frac{1}{2}\sum_{\nu,\tau}(\pm)^{\nu+\tau}f^{(N-\nu-\tau)}(\beta)u(\nu,\tau)\,. \qquad (4.22)$$

These together give

$$(pV-\gamma A)/kT=\Big\{\sum(\pm)^{\nu-1}f^{(N-\nu)}(\beta)(b_\nu/\nu-\beta w_\nu)$$
$$-\beta\sum(\pm)^{\mu+\nu}f^{(N-\mu-\nu)}(\beta)\frac{b_\mu}{\mu}w_\nu-\frac{\beta}{2}\sum(\pm)^{\mu+\nu+\tau-1}f^{(N-\mu-\nu-\tau)}(\beta)\frac{b_\mu}{\mu}u(\nu,\tau)$$
$$-\frac{\beta}{2}\sum(\pm)^{\nu+\tau}f^{(N-\nu-\tau)}(\beta)u(\nu,\tau)\Big\}\Big/\mathrm{Tr}\,\rho^{(N)}\,. \qquad (4.23)$$

Multiplying ζ^N to both the numerator and the denominator of the right-hand side of the above equation, we sum up over N. Thus the numerator in the right-hand side of Eq. (4.23) becomes

$$\Xi_0\Big\{\sum(\pm)^{\nu-1}\zeta^\nu b_\nu/\nu-\beta\sum(\pm)^{\nu-1}\zeta^\nu w_\nu-\beta\sum(\pm)^{\mu-1}\zeta^\mu b_\mu/\mu\sum(\pm)^{\nu-1}\zeta^\nu w_\nu$$
$$-\frac{\beta}{2}\sum(\pm)^{\nu+\tau}\zeta^{\nu+\tau}u(\nu,\tau)-\frac{\beta}{2}\sum(\pm)^{\nu+\tau}\zeta^{\nu+\tau}u(\nu,\tau)\sum(\pm)^{\mu-1}\zeta^\mu b_\mu/\mu\Big\}$$
$$=\Xi_0\Big\{\sum(\pm)^{\nu-1}\zeta^\nu b_\nu/\nu-\beta\sum(\pm)^{\nu-1}\zeta^\nu w_\nu-\frac{\beta}{2}\sum(\pm)^{\mu+\nu}\zeta^{\mu+\nu}u(\mu,\nu)\Big\}$$
$$\times\Big\{1-\beta\sum(\pm)^{\nu-1}\zeta^\nu w_\nu-\frac{\beta}{2}\sum(\pm)^{\mu+\nu}\zeta^{\mu+\nu}u(\mu,\nu)\Big\}\,, \qquad (4.24)$$

neglecting terms of the second order in u and w. The denominator gives $\Xi(\zeta)$ or

$$\Xi_0(\zeta)\Big\{1-\beta\sum(\pm)^{\nu-1}\zeta^\nu w_\nu-\frac{\beta}{2}\sum(\pm)^{\mu+\nu}\zeta^{\mu+\nu}u(\mu,\nu)\Big\}\,.$$

Then thermodynamical relation derived from Toda's method gives

$$(pV-\gamma A)/kT=\sum(\pm)^{\nu-1}\zeta^\nu b_\nu/\nu-\beta\sum(\pm)^{\nu-1}\zeta^\nu w_\nu-\frac{\beta}{2}\sum(\pm)^{\mu+\nu}\zeta^{\mu+\nu}u(\mu,\nu)\,. \qquad (4.25)$$

This is just the same to Eq. (4.15). The selfconsistency of two different methods, in quantum statistics, is thus satisfied.

§ 5. Formulation when Interaction has Hard Sphere Repulsion

If there exists strong repulsion between molecules at short range, Eq. (2.1) diverges because of the infinite value of potential energy, and we have to take into account the fact that the probability density $|\varphi(x)|^2$ becomes very small in the range $r-\sigma_0\ll\sigma_0$ (r is the relative distance between the centers of two molecules and σ_0 means geometrical diameter of the molecule). To avoid these difficult circumstances, we have introduced in the previous paper[14] effective diameter σ and the effective distance a which are related to the geometrical diameter σ_0 and to the geometrical distance a_0 respectively by

$$\sigma=\sigma_0+\lambda/2\sqrt{2}\,,\qquad a=a_0+\lambda/4 \qquad (5.1)$$

where a_0 means the classical distance of approach to the wall. That is, any molecule can not come closer to the wall than the distance a_0 because of the strong repulsion between a gas molecule and the wall.

In this section we shall assume the potential energies which have strong repulsions and weak attractions given by the following:

$$u_w(z)=\begin{cases} \infty & \text{for } 0\leq z\leq a\,, \\ v_w(z) & \text{for } a<z\,, \end{cases} \tag{5.2}$$

$$u(r)=\begin{cases} \infty & \text{for } 0\leq r\leq \sigma\,, \\ v(r) & \text{for } \sigma<r\,, \end{cases} \tag{5.3}$$

where a and σ are defined by Eq. (5.1). $u_w(z)$ stands for the interaction between a molecule and wall and $u(r)$ the mutual interaction between two molecules.

We shall calculate the effect of surface on the free energy given as[17)]

$$F=-kT\log B^{(1)}-\frac{kT}{2}N^2\frac{B^{(2)}}{(B^{(1)})^2} \tag{5.4}$$

where

$$B^{(1)}=\mathrm{Tr}\,\{\exp\,(-\beta[H_0(1)+u_w(1)])\}\,, \tag{5.5}$$

$$\begin{aligned} B^{(2)}=\mathrm{Tr}\,\{&\exp\,(-\beta[H_0(1)+H_0(2)+u(1,2)+u_w(1)+u_w(2)]) \\ &-\exp\,(-\beta[H_0(1)+u_w(1)])\exp\,(-\beta[H_0(2)+u_w(2)])\} \end{aligned} \tag{5.6}$$

in which $H_0(i)$ means the kinetic energy of the i-th molecule. As we assume that both $v_w(z)$ and $v(r)$ are small, we can use plane waves in the range $a<z$ and $\sigma<r$ as the eigenfunctions of molecules. Thus Eqs. (5.5) and (5.6) become

$$\begin{aligned} \lambda^3 B^{(1)}=A\int_a^{L_z}\exp\{-\beta v_w(z)\}\,dz+\frac{\hbar^2}{2m}A\int_a^{\infty}\Big[&-\frac{\beta^2}{6}\frac{d^2}{dz^2}v_w(z) \\ &+\frac{\beta^3}{12}\Big\{\frac{d}{dz}v_w(z)\Big\}^2\Big]\exp\{-\beta v_w(z)\}\,dz\,, \end{aligned} \tag{5.7}$$

$$\begin{aligned} \lambda^6 B^{(2)}=&\iint_{(V)}[\exp\{-\beta u(r)\}-1][\exp\{-\beta u_w(\boldsymbol{x}_1)-\beta u_w(\boldsymbol{x}_2)\}]\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2 \\ &\pm\iint_{(V)}\exp(-2\pi r^2/\lambda^2)\exp\{-\beta u(r)\}[\exp\{-\beta u_w(\boldsymbol{x}_1)-\beta u_w(\boldsymbol{x}_2)\}]\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2 \\ &\qquad+\frac{\hbar^2}{m}\iint_{(V)}\Big[-\frac{\beta^2}{6}\Big\{\frac{d^2}{dr^2}u(r)\Big\}+\frac{\beta^3}{12}\Big\{\frac{d}{dr}u(r)\Big\}^2\Big] \\ &\qquad\qquad\times\exp\{-\beta u(r)\}[\exp\{-\beta u_w(\boldsymbol{x}_1)-\beta u_w(\boldsymbol{x}_2)\}]\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2 \\ &\equiv\lambda^6(B_0{}^{(2)}\pm B_{\pm}{}^{(2)}+B_{qu}{}^{(2)})\,. \end{aligned} \tag{5.8}$$

in which $r=|\boldsymbol{x}_2-\boldsymbol{x}_1|$.

If we assume the attractive energy between a gas molecule ($\boldsymbol{x}$) and a molecule in the wall ($\boldsymbol{x}_w$) to be of van der Waals type[12)], we get

$$v_w(z)=-\sum_w\frac{\text{const.}}{|\boldsymbol{x}-\boldsymbol{x}_w|^6}=\frac{-\mathcal{E}a^3}{z^3} \tag{5.9}$$

in which $-\mathcal{E}$ means the energy of a gas molecule when it touches the wall. Putting $-\beta\mathcal{E}=w$, we get from Eq. (5.7) the expansion

$$\begin{aligned} \lambda^3 B^{(1)}=V-Aa+Aa\Big(\frac{w}{2}+\frac{w^2}{10}+\frac{w^3}{48}+\cdots\Big) \\ +A\frac{1}{\pi}\frac{\lambda^2}{a}\Big(\frac{w}{8}+\frac{w^2}{112}+\frac{7}{160}w^3+\cdots\Big) \end{aligned} \tag{5.10}$$

and the first term in the right-hand side of Eq. (5.8) becomes

$$\lambda^6 B_0{}^{(2)} = A\int_0^{L_z} dz\Big[\sum_{\mu=0}^{\infty}\frac{(wa^3)^\mu}{z^3}\frac{1}{\mu!}\int_0^{z-a} 2\pi\sum_{\nu=0}^{\infty}\left\{\frac{(wa^3)^\nu}{(z-r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\right\}\{e^{\;\beta u(r)}-1\}\,dr$$
$$+\sum\frac{(wa^3)^\mu}{z^3}\frac{1}{\mu!}\int_{z-a}^{\infty} 2\pi\sum\left\{\frac{(wa^3)^\nu}{a^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\right\}\{e^{-\beta u(r)}-1\}\,dr$$
$$-\sum\frac{(wa^3)^\mu}{z^3}\frac{1}{\mu!}\int_0^{\infty} 2\pi\sum\left\{\frac{(wa^3)^\nu}{(z+r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\right\}\{e^{-\beta u(r)}-1\}\,dr\Big]. \tag{5.11}$$

Assuming that $v(r)$ is small, above equation is expanded in Appendix III. If we substitute $\exp(-2\pi r^2/\lambda^2)\exp(-\beta u)$ for $\{\exp(-\beta u)-1\}$ in integrand of Eq. (5.11), we can get $B_\pm{}^{(2)}$, and in the same way substituting

$$\frac{\hbar^2}{m}\left[-\frac{\beta^2}{6}\left\{\frac{d^2}{dr^2}u(r)\right\}+\frac{\beta^3}{12}\left\{\frac{d}{dr}u(r)\right\}^2\right]\exp(-\beta u) \qquad \text{for} \quad \{\exp(-\beta u)-1\}\,,$$

$B_{qu}{}^{(2)}$ can be obtained.

§ 6. Conclusion Remarks

In general, quantum statistical theory of gas is treated in the limit of infinite volume, keeping the density constant. Under the restriction of the volume to be finite, the integral region can not be extended to infinity. This circumstance makes the theory more cumbersome. For example, the integral of Gauss's error function $\phi(x)$ appears as is shown in Appendix, which has definite value $\phi(\infty)=1$ when the volume extends to infinity.

When the density of gas increases, our treatments are not suitable. However the circumstance that, in quantum statistics, the surface effect increases with the length of permutation rings will be valid even if the density becomes large.

The surface free energy is affected by the potential energy $u_w(z)$, which does not appear in the treatment of systems with infinite volume. When we make the gas in a vessel very dilute, it is observed that many molecules of the gas adhere to the boundary wall. This tendency may be intensified for large negative value of $u_w(z)$.

Acknowledgement

The author would like to express his sincere thanks to Professor M. Toda of Tokyo University of Education for valuable discussions, suggestions and advices through this work, and to Dr. T. Kotera for useful conversations.

Appendix I

Pressure p is given by

$$p = -\mathrm{Tr}\left\{\left(\frac{\delta H}{\delta V}\right)_A e^{-\beta H}\right\}\Big/\mathrm{Tr}\,(e^{-\beta H})\,. \tag{A.1.1}$$

For the system in the box with volume $V=L^2L_z$ and surface area $A=2L^2$, we write, according to Toda's method[5],

$$x=L\xi\,,\qquad y=L\eta\,,\qquad z=L_z\zeta \qquad (0\leq\xi,\eta,\zeta\leq 1)$$
$$r_{ij}{}^2=L^2(\xi_{ij}{}^2+\eta_{ij}{}^2)+L_z{}^2\zeta_{ij}{}^2\,. \tag{A.1.2}$$

Hamiltonian becomes then

$$H=-\frac{\hbar^2}{2m}\sum_i \nabla_i{}^2+\sum_i u_w(z_i)+\sum_{i<j}u(r_{ij})$$
$$=-\frac{\hbar^2}{2mL^2}\sum_i\left(\frac{\partial^2}{\partial\xi_i{}^2}+\frac{\partial^2}{\partial\eta_i{}^2}\right)-\frac{\hbar^2}{2mL_z{}^2}\sum_i\frac{\partial^2}{\partial\zeta_i{}^2}+\sum_i u_w(L_z\zeta_i)$$
$$+\sum_{i<j}u(\sqrt{L^2(\xi_{ij}{}^2+\eta_{ij}{}^2)+L_z{}^2\zeta_{ij}{}^2}\,)\,. \tag{A.1.3}$$

Keeping A constant we differentiate H:

$$\delta L=0\ ,\qquad \delta V=L^2\delta L_z$$

$$\begin{aligned}\frac{\delta H}{\delta V}&=\frac{1}{L^2}\left\{\frac{1}{L_z}\frac{\hbar^2}{mL_z^2}\sum_i\frac{\partial^2}{\partial\zeta_i^2}+\sum_i\zeta_i\frac{du_w(i)}{dz_i}+\sum_{i<j}\frac{L_z}{r_{ij}}\zeta_{ij}^2\frac{du(i,j)}{dr_{ij}}\right\}\\&=\frac{1}{V}\left\{\frac{\hbar^2}{m}\sum\frac{\partial^2}{\partial z^2}+\sum z_i\frac{du_w(i)}{dz_i}+\sum\frac{z_{ij}^2}{r_{ij}}\frac{du(i,j)}{dr_{ij}}\right\}\ .\end{aligned}\tag{A.1.4}$$

Thus (A.1.1) gives Eq. (4.2).

If we impose the condition that wave functions vanish at $x=0, L$ and $y=0, L$ instead of the periodic condition we have $A=2L^2+4LL_z$. However, as we assume that $L\gg L_z$, the result does not change as is easily verified.

Appendix II

The grand partition function can be written as follows

$$\begin{aligned}\Xi&=\Xi_0\left\{1-\beta\int u_w(\boldsymbol{x}_1)\,\sigma(\boldsymbol{x}_1,\boldsymbol{x}_1)\,d\boldsymbol{x}_1+\frac{1}{2}\beta\iint u(\boldsymbol{x}_1,\boldsymbol{x}_2)\begin{vmatrix}\sigma(\boldsymbol{x}_1,\boldsymbol{x}_1)&\sigma(\boldsymbol{x}_1,\boldsymbol{x}_2)\\\sigma(\boldsymbol{x}_2,\boldsymbol{x}_1)&\sigma(\boldsymbol{x}_2,\boldsymbol{x}_2)\end{vmatrix}_\pm d\boldsymbol{x}_1\,d\boldsymbol{x}_2\right\}\\&=\Xi_0\{1-\beta Q\}\end{aligned}\tag{A.2.1}$$

where

$$Q=\sum_p u_{w\cdot pp}\,g_p+\frac{1}{2}\sum_p\sum_q g_pg_q(u_{pq\cdot pq}+u_{pq\cdot qp})\tag{A.2.2}$$

in which

$$\sigma(\boldsymbol{x},\boldsymbol{x}')=\sum_k g_k\varphi_k^*(\boldsymbol{x}')\varphi_k(\boldsymbol{x})\tag{A.2.3}$$

$$g_k=\{\zeta^{-1}\exp(\beta E_k)\mp1\}^{-1}\tag{A.2.4}$$

and

$$\begin{aligned}u_{w\cdot pq}&=\int\varphi_p^*(\boldsymbol{x})u_w(\boldsymbol{x})\varphi_q(\boldsymbol{x})\,d\boldsymbol{x}\\u_{pq\cdot rs}&=\iint\varphi_p^*(\boldsymbol{x}_1)\varphi_q^*(\boldsymbol{x}_2)u(\boldsymbol{x}_1,\boldsymbol{x}_2)\varphi_r(\boldsymbol{x}_1)\varphi_s(\boldsymbol{x}_2)\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2\ ,\end{aligned}\tag{A.2.5}$$

$\varphi(\boldsymbol{x})$ is eigenfunction of a molecule. Thus the equation of state becomes

$$pV-\gamma A=kT\log\Xi_0-Q\ .\tag{A.2.6}$$

The first term in the right-hand side of Eq. (A.2.2) is

$$\sum_{n_x,n_y,n_z}\frac{1}{\zeta^{-1}\exp\left\{\frac{\pi}{4}\lambda^2\left(\frac{n_x^2}{L_x^2}+\frac{n_y^2}{L_y^2}+\frac{n_z^2}{L_z^2}\right)\right\}\mp1}\frac{A}{\lambda^2}\frac{2}{L_z}\int_0^{L_z}u_w(z)\sin^2\frac{\pi n_z}{L_z}z\,dz\tag{A.2.7}$$

and considering that $u_w(z)$ does not vanish only when z or L_z-z is small, we get

$$\sum_p g_pu_{w\cdot pp}=\frac{1}{\lambda^3}\sum(\pm)^{\nu-1}\frac{\zeta^\nu}{\nu^{3/2}}A\int_0^\infty u_w(z)\{1-\exp(-4\pi z^2/\nu\lambda^2)\}\,dz\ .\tag{A.2.8}$$

In the calculation of the second and the third terms of Eq. (A.2.2), we use the spherical coordinate for $\boldsymbol{x}_2$, and the volume integral of a function takes the form

$$\begin{aligned}\iint_{(V)}F\,d\boldsymbol{x}_1\,d\boldsymbol{x}_2&=\int_0^{L_z}dz_1A\iint F\,2\pi r^2\sin\theta\,dr\,d\theta\\&=A\int_0^{L_z}dz_1\left\{\int_0^{z_1}2\pi r^2\,dr\int_0^\pi F\sin\theta\,d\theta+\int_{z_1}^\infty2\pi r^2\,dr\int_{\cos^{-1}(z/r)}^\pi F\sin\theta\,d\theta\right\}\ .\end{aligned}\tag{A.2.9}$$

Thus we obtain after some calculations

$$\begin{aligned}\frac{1}{2}\sum_{p}\sum_{q} g_p g_q u_{pq\cdot pq} &= \frac{1}{2}\frac{1}{\lambda^6}\sum_{\mu}\sum_{\nu}(\pm)^{\mu+\nu}\frac{\zeta^\mu}{\mu^{3/2}}\frac{\zeta^\nu}{\nu^{3/2}}A\int_0^\infty \{1-\exp(-4\pi z^2/\mu\lambda^2)\}\,dz \\ &\times\Bigg[\int_0^\infty u(r)2\pi r^2\,dr\Bigg\{2-\frac{\lambda\sqrt{\nu}}{4r}\phi\Bigg(\frac{2\sqrt{\pi}}{\lambda\sqrt{\nu}}[z+r]\Bigg)\Bigg\} \\ &+\int_0^z u(r)2\pi r^2\,dr\,\frac{\lambda\sqrt{\nu}}{4r}\phi\Bigg(\frac{2\sqrt{\pi}}{\lambda\sqrt{\nu}}[z-r]\Bigg)+\int_z^\infty u(r)2\pi r^2\,dr\Bigg(\frac{z}{r}-1\Bigg)\Bigg],\end{aligned}\tag{A.2.10}$$

$$\left.\begin{aligned}&\text{where}\qquad \phi(x)=\frac{2}{\sqrt{\pi}}\int_0^\infty \exp(-s^2)\,ds \\ &\text{with}\qquad \phi(\infty)=1 \quad\text{and}\quad \phi(0)=0\,.\end{aligned}\right\}\tag{A.2.11}$$

The third term in the right-hand side of Eq. (A.2.2) is

$$\begin{aligned}\frac{1}{2}\sum_{p}\sum_{q} g_p g_q u_{pq\cdot qp} &= \frac{1}{2}\frac{1}{\lambda^6}\sum_{\mu}\sum_{\nu}(\pm)^{\mu+\nu}\frac{\zeta^\mu}{\mu^{3/2}}\frac{\zeta^\nu}{\nu^{3/2}}A\int_0^\infty dz \\ &\times\Bigg[\int_0^\infty u(r)2\pi r^2\,dr\exp\Bigg(-\frac{\pi}{\lambda^2}\Bigg[\frac{1}{\mu}+\frac{1}{\nu}\Bigg]r^2\Bigg)\Bigg\{2+\frac{\lambda^2\mu}{4\pi zr}\exp\Bigg(-\frac{\pi}{\lambda^2}\frac{4}{\mu}[z^2+zr]\Bigg) \\ &+\frac{\lambda^2\nu}{4\pi zr}\exp\Bigg(-\frac{\pi}{\lambda^2}\frac{4}{\nu}[z^2+zr]\Bigg)-\frac{\lambda^2\mu\nu}{4\pi zr(\mu+\nu)}\exp\Bigg(-\frac{4\pi}{\lambda^2}\Bigg[\frac{1}{\mu}+\frac{1}{\nu}\Bigg][z^2+zr]\Bigg)\Bigg\} \\ &+\int_0^z u(r)2\pi r^2\,dr\exp\Bigg(-\frac{\pi}{\lambda^2}\Bigg[\frac{1}{\mu}+\frac{1}{\nu}\Bigg]r^2\Bigg)\Bigg\{-\frac{\lambda^2\mu}{4\pi zr}\exp\Bigg(-\frac{\pi}{\lambda^2}\frac{4}{\mu}[z^2-zr]\Bigg) \\ &-\frac{\lambda^2\nu}{4\pi zr}\exp\Bigg(-\frac{\pi}{\lambda^2}\frac{4}{\nu}[z^2-zr]\Bigg)+\frac{\lambda^2\mu\nu}{4\pi zr(\mu+\nu)}\exp\Bigg(-\frac{4\pi}{\lambda^2}\Bigg[\frac{1}{\mu}+\frac{1}{\nu}\Bigg][z^2-zr]\Bigg)\Bigg\} \\ &+\int_z^\infty u(r)2\pi r^2\,dr\exp\Bigg(-\frac{\pi}{\lambda^2}\Bigg[\frac{1}{\mu}+\frac{1}{\nu}\Bigg]r^2\Bigg)\Bigg\{\frac{z}{r}-1-\frac{\lambda^2}{4\pi zr}(\mu+\nu)+\frac{\lambda^2\mu\nu}{4\pi zr(\mu+\nu)}\Bigg\}\Bigg].\end{aligned}\tag{A.2.12}$$

Thus the equation of state $pV-\gamma A$ is obtained from Eqs. (A.2.6), (A.2.8), (A.2.10) and (A.2.12).

Appendix III

By the use of Eq. (5.3) and Eq. (5.9) can be written as follows

$$\begin{aligned}\lambda^6 B_0^{(2)} = A\int_{a+\sigma}^{L_z} dz\,2\pi\Bigg\{&\int_\sigma^{z-a} dr\sum_{\mu=0}^\infty\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum_{\nu=0}^\infty\frac{(wa^3)^\nu}{(z-r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\sum_{\tau=1}^\infty\frac{[v^*(r)]^\tau}{\tau!} \\ &+\int_{z-a}^\infty dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{a^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\sum\frac{[v^*(r)]^\tau}{\tau!} \\ &-\int_\sigma^\infty dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{(z+r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\sum\frac{[v^*(r)]^\tau}{\tau!}\Bigg\} \\ -A\int_{a+\sigma}^{L_z} dz\,2\pi\Bigg\{&\int_0^\sigma dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{(z-r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1} \\ &-\int_0^\sigma dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{(z+r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\Bigg\} \\ +A\int_a^{a+\sigma} dz\,2\pi\Bigg\{&\int_\sigma^\infty dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{a^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\sum\frac{[v^*(r)]^\tau}{\tau!} \\ &-\int_\sigma^\infty dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{(z+r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\sum\frac{[v^*(r)]^\tau}{\tau!}\Bigg\} \\ -A\int_a^{a+\sigma} dz\,2\pi\Bigg\{&\int_0^{z-a} dr\sum\frac{(wa^3)^\mu}{z^{3\mu}}\frac{1}{\mu!}\sum\frac{(wa^3)^\nu}{(z-r)^{3\nu-1}}\frac{r}{\nu!}\frac{1}{3\nu-1}\end{aligned}$$

$$+\int_{z-a}^{\sigma} dr \sum \frac{(wa^3)^\mu}{z^{3\mu}} \frac{1}{\mu!} \sum \frac{(wa^3)^\nu}{a^{3\nu-1}} \frac{r}{\nu!} \frac{1}{3\nu-1}$$

$$\left. -\int_0^{\sigma} dr \sum \frac{(wa^3)^\mu}{z^{3\mu}} \frac{1}{\mu!} \sum \frac{(wa^3)^\nu}{(z+r)^{3\nu-1}} \frac{r}{\nu!} \frac{1}{3\nu-1} \right\}, \tag{A.3.1}$$

where $v^*(r) \equiv -\beta v(r)$ is the function of r. If we put $w=0$ and $v^*=0$ (hard sphere particle), Eq. (A.3.1) becomes

$$\lambda^6 B_0^{(2)} = \frac{4\pi}{3}\sigma^3 V + A\pi\left(\frac{\sigma^4}{4} + \frac{4}{3}\sigma^3 a\right). \tag{A.3.2}$$

This formula is identical with the result of our previous paper[14].

$\lambda^6 B_\pm^{(2)}$ is a small quantity, in which we have only to calculate the hard sphere part and becomes

$$\begin{aligned} \lambda^6 B_\pm^{(2)} = {} & V\sigma\lambda^2 \exp(-2\pi\sigma^2/\lambda^2) + \frac{\lambda^3}{4\sqrt{2}}(V-aA) \\ & - A\sigma a\lambda^2 \exp(-2\pi\sigma^2/\lambda^2) - \frac{\lambda^3}{4\sqrt{2}} A\sigma\phi(\sqrt{2\pi}\,\sigma/\lambda) \\ & - A\sigma^2 \frac{\lambda^2}{4} \exp(-2\pi\sigma^2/\lambda^2) + \frac{\lambda^3 A}{4\sqrt{2}} \int_{\sigma}^{L_z-a} \phi(\sqrt{2\pi}\, s/\lambda)\, ds \end{aligned} \tag{A.3.3}$$

in which ϕ was defined in Eq. (A.2.11). In the high temperature approximation ($\lambda \ll \sigma$), we may put $\phi(\sqrt{2\pi}\,\sigma/\lambda) \approx 1$, and Eq. (A.3.3) becomes

$$\lambda^6 B_\pm^{(2)} \approx A(L_z-a-\sigma)\lambda^3/2\sqrt{2}\ . \tag{A.3.4}$$

This formula is identical with the term in the virial coefficient due to exchange of two free particles in the volume $A(L_z-a-\sigma)$.

$\lambda^6 B_{qu}^{(2)}$ can be obtained substituting

$$\sum_{\tau=0}^{\infty} \frac{\hbar^2}{m} \left\{ -\frac{\beta^2}{6} \frac{1}{(\tau-2)!} v^{*\tau-2}(v^{*\prime})^2 - \frac{\beta^2}{6} \frac{1}{(\tau-1)!} v^{*\tau-1} v^{*\prime\prime} + \frac{\beta^3}{12} \frac{\tau}{(\tau-1)!} (v^{*\tau-1})^2 (v^{*\prime})^2 \right\} \tag{A.3.5}$$

for $\sum_{\tau=1}^{\infty} [v^*(r)]^\tau/\tau!$ in the integrand of Eq. (A.3.5) and omitting the terms which do not include $\sum_{\tau=1}^{\infty} [v^*(r)]^\tau/\tau!$. In Eq. (A.3.5) $v^{*\prime}$ and $v^{*\prime\prime}$ represent the first and the second order derivatives of $-\beta v(r)$ respectively with respect to variable r.

Effects of the Special Heat-treatment on Permalloys

By Sadami TOMITA

Kinzoku Kogyo Kenkyusho

(Received June 6, 1959, Revised November 29, 1960)

The magnetic property and the electrical resistance of Mumetal and 50-permalloy were measured after low temperature heat-treatment ranging from 200°C to 600°C. It is observed that the maximum permeability of Mumetal is remarkably increased by this heat-treatment. These results can not be explained simply by the existing theories proposed by Néel et al. From the comparison between experimental results obtained in binary permalloy and polynary permalloy and the analysis of the relation between the maximum permeability and the electrical resistance, we introduce the idea of inhomogeneous internal structure to explain the change of μ_0, μ_m of permalloys by this low temperature heat-treatment.

§ 1. Introduction

In the alloy of Fe–Ni–Mo, Fe–Ni–Cu–Mo, it is known that the permeability of these alloys is sensitive to the heat-treatment at a relatively low temperature, and it was reported that the specific resistance of Ultraperm[1] was changed by the low temperature heat-treatment. In these high permeability alloys, the dependence of permeability and electrical resistace on the heat-treatment can not be explained satisfactorily in terms of "superlattice-transformation"[2]. By using two high permeability alloys, namely, Mumetal and 50-permalloy, we measured the magnetic properties and the electrical resistance, and then we try to explain the experimental results.

§ 2. Experimental Method

Specimen: We prepared two kinds of high permeability alloy, namely, (1) 50–Ni–Fe alloy (binary alloy) and (2) Mumetal (Ni; 77% Fe; 16% Cu; 5% Cr; 2%). We used high purity electrolytic nickel, electrolytic iron and other electrolytic elements. They were melted carefully in vacuum. The test samples were punched in the ring-form with 0.6 m/m thickness for Mumetal and 0.35 m/m thickness for 50-permalloy. The mechanical stress due to cold-working was released by an annealing at high temperature. To protect them from oxidation and reduce non-metalic impurities, test samples were annealed at about 1100°C in an atmosphere of pure hydrogen gas. In this way, the scattering of the values of magnetic properties i. e. μ_0, μ_m of each sample was limited within 5%.

Measurement: The magnetic property was measured by the ballistic-galvanometer-method. The specific electrical resistance was measured by the potentiometer, using the knifeedge as a contact with the specimen.

§ 3. Experimental Results

After the annealing at 1100°C, the sample were reheated to 650°C in the non-inductive furnace of small heat capacity, held for 1 hr. at this temperature, and then rapidly cooled in the furnace with the mean cooling rate of about 600°C/hr.. After this treatment, the samples were again heated rapidly in the same furnace to each temperature, ranging from 200°C to 650°C, in order to observe its annealing effect. The samples were annealed for 1 hr. at each temperature.

Fig. 1 shows initial permeability μ_0, maximum permeability μ_m and the fractional change of electrical resistance $\Delta\rho/\rho$ (%) as a function of annealing temperature in the case of Mumetal. The $\Delta\rho/\rho$-value increases in the temperature range from 300°C to 500°C and then decreases from 500°C to 600°C. The decrease of the $\Delta\rho/\rho$ in the range from 500°C to 600°C has not been observed in the case of Ultraperm[3]. The μ_0-curve has a steep maximum at 520°C.

The μ_m-curve is more complicated than the μ_0-curve. The maximum permeability shows a sharp maximum value nearly at the temperature of 400°C which is lower than the Curie-point of Mumetal, 440°C. Another maximum is nearly at 500°C. The minimum point of the μ_m-curve occurs nearly at the Curie-point of this material. The shape of the μ_m-curve is similar to that of $\Delta\rho/\rho$-curve in the whole range of temperature, except the range from 500°C to 600°C where the μ_m-curve has a broad maximum. But, if we plot the magnetic induction value $B_{\mu_m}=\mu_m\cdot H_{\mu_m}$ at the state of maximum permeability instead of μ_m-value, it is noticeable that the temperature-dependence of the B_{μ_m} coincides with that of the $\Delta\rho/\rho$, as shown in Fig. 5.

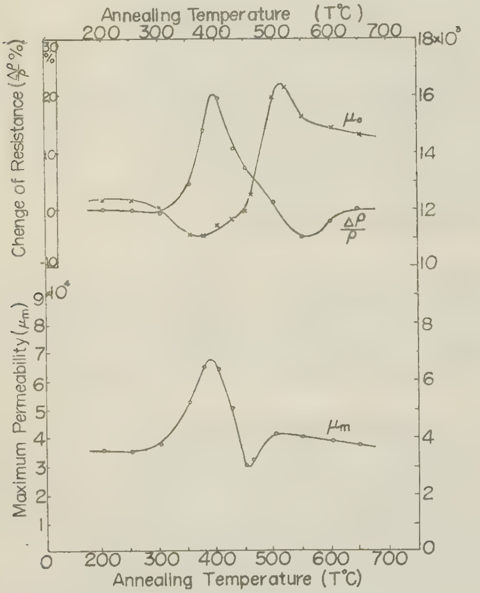

Fig. 1. μ_0, μ_m and $\Delta\rho/\rho$ for Mumetal. The samples were held for 1 hr. at each temperature after rapidly cooled from 650°C.

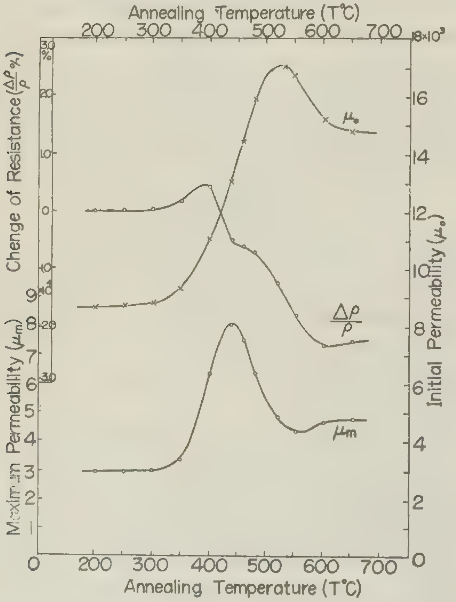

Fig. 2. μ_0, μ_m and $\Delta\rho/\rho$ for Mumetal. The samples were held for 1 hr. at each temperature after cooling in a furnace.

Fig. 2 shows the results which we obtained by the different heat-treatment; i. e. the samples were furnace-cooled before the low temperature heat-treatment. The mean cooling rate of the furnace cooling was about 100°C/hr. between 600°C and 300°C, and the final heat-treatment is the same with the above case.

The curves were not affected by the heat-treatment below 300°C as shown in the figure. The $\Delta\rho/\rho$-curve has a small maximum at about 400°C which coincides with that of Fig. 1. But, the shapes of $\Delta\rho/\rho$-curve in Fig. 1 and Fig. 2, differ from each other. This phenomena at the temperature range from 350°C to 550°C is remarkable. The μ_m-curve has the maximum at 440°C and falls down with slow slope at about 500°C. On the other hand, the μ_0-curve has the maximum at 520°C similarly to the case of Fig. 1. In Fig. 2, the temperature corresponding the peak of $\Delta\rho/\rho$ and μ_m-curve does not coincide, but if we plot the B_{μ_m} instead of μ_m as shown in Fig. 5 (b), the maximum point of this curve coincides with that of $\Delta\rho/\rho$ in Fig. 2 nearly at 400°C, and also the minimum point coin-

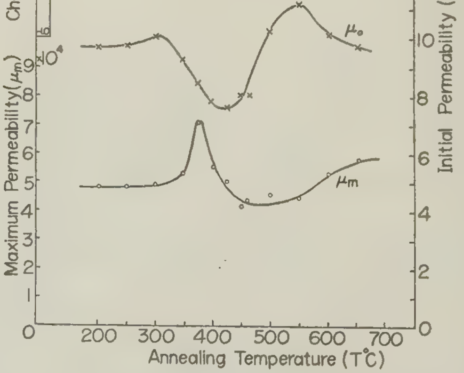

Fig. 3. μ_0, μ_m and $\Delta\rho/\rho$ for Mumetal. The samples were held for 1.5 hr. at 400°C in addition to the heat-treatment for the case of Fig. 1. The $\Delta\rho/\rho$-values are given by adding the change by the heat-treatment at 400°C to that by the initial heat-treatment.

cides at 550°C.

Fig. 3 shows the results of the superposed heat-treatment by the additive annealing for 1.5 hr. at 400°C, giving the largest change of $\varDelta\rho/\rho$ and μ_m. Specimens are initially heat-treated in the same way as in the case of Fig. 1.

The $\varDelta\rho/\rho$-values were obtained by adding the change of resistance by this heat-treatment to those $\varDelta\rho/\rho$-value in Fig. 1. The relation between the increase or decrease of permeability and electrical resistance is complicated by the initial heat-treatment. Namely, in the case of the initial heat-treatment at temperature below 350°C and above 600°C, the change of $\varDelta\rho/\rho$-value by the additive heat-treatment is simple, but in the rest range of temperature, the rate of increasing of $\varDelta\rho/\rho$-value by the additive heat-treatment is not uniform. The μ_0 decreases by the additive heat-treatment at the whole range. But, the μ_m increases by the additive heat-treatment, except for case in which the initial heat-treatment is carried out near 400°C.

Fig. 4 shows the results in the case of 50-permalloy which was annealed for 15 hrs. at each temperature ranging from 350°C to 600°C. The effect of the heat-treatment for few hours on this alloy is not so conspicuous as for Mumetal.

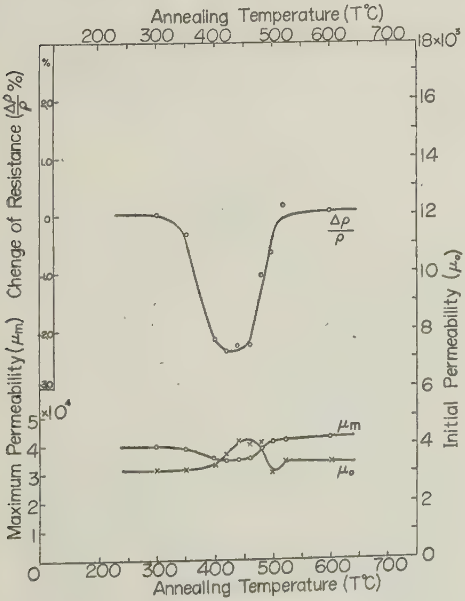

Fig. 4. μ_0, μ_m and $\varDelta\rho/\rho$ for 50-permalloy. The samples were annealed for 15 hrs. at each temperature.

The initial permeability increases ranging from 420°C to 480°C and decreases at 500°C slightly. The maximum permeability decreases ranging from 350°C to 500°C. But these changes are smaller than those in Mumetal. As shown Fig. 4, the fractional change of electrical resistance is similar to the change of the maximum permeability, and the electrical resistance decreases ranging from 350°C to 500°C. These results resemble to 75-permalloy's.

In our experimental results as shown above, we have attached great importance to the fact that the change of maximum permeability caused by the special heat-treatment is analogous to change of electrical resistance. As characteristic quantities for the magnetized state at maximum permeability, we have tried to use the B_{μ_m} and H_{μ_m}-value instead of μ_m-value. We show these values given as a function of annealing temperature in Fig. 5. The B_{μ_m} and H_{μ_m} are obtained by the relation of $\mu_m = B_{\mu_m}/H_{\mu_m}$ from the B-H curve, and

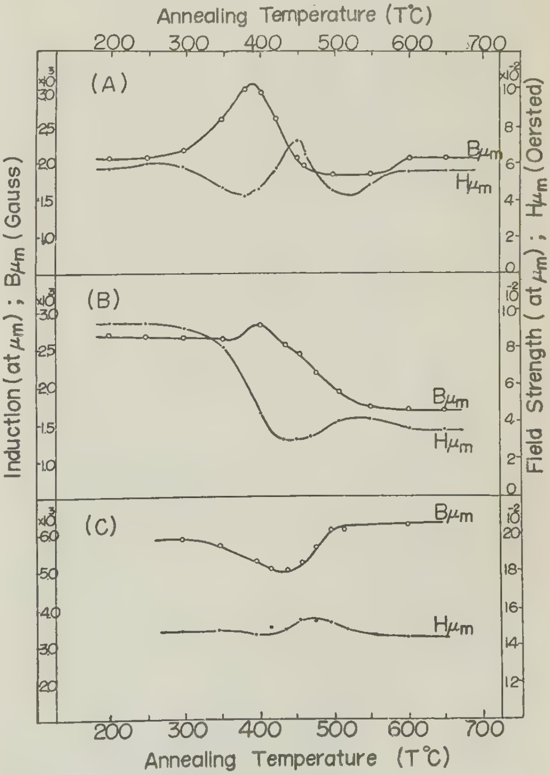

Fig. 5. $H_{\mu m}$ and $B_{\mu m}$-curves: (A) corresponds to μ_m-curve of Fig. 1, (B) corresponds to μ_m-curve of Fig. 2, and (C) corresponds to μ_m-curve of Fig. 4.

each of curves in the figure corresponds to the μ_m-curve of Figs. 1, 2, 4 respectively.

It is noticeable that the variation of the B_{μ_m} in Fig. 5 as a function of the temperature of the heat-treatment is similar to that of $\Delta\rho/\rho$ in Figs. 1, 2, 4. Regarding the variation of maximum permeability, we can find that the peak of the μ_m-curve at 400°C in Fig. 1, corresponds to the highest B_{μ_m} and the small H_{μ_m}, the minimum of μ_m-curve at 450°C to the largest H_{μ_m} and the small peak of μ_m-curve at 520°C to the small H_{μ_m}. The H_{μ_m}-curve for the samples furnace-cooled before the low temperature heat-treatment shows steep slope at the temperature range below the Curie-point, 440°C, and we can find that the peak of μ_m-curve at 440°C is induced by the minimum of H_{μ_m}-value, and the low value of μ_m at 550°C is induced by the increasing H_{μ_m} and the decreasing B_{μ_m}. From the curves illustrated in (C), we can find that the lowering of μ_m between 400°C and 500°C in 50-permalloy, is mainly induced by the lowering of the B_{μ_m}.

§ 4. Discussion

The magnetic properties and the electrical resistance of Mumetal and 50-permalloy are changed remarkably by the low temperature heat-treatment. The correlation between the magnetic property and electrical resistance affected by the special heat-treatment on permalloy have been interpreted by the idea of an atom-ordering[4]. For example, in the case of 79-permalloy[5], the origin of high permeability and high electrical resistance obtained by a rapid cooling from 600°C was explained by the freezing of the disordered phase. However, our experimental results show that such an explanation is not satisfactory for the general kind of permalloy. Namely, in the case of polynary permalloy such as Mumetal, the affected electrical resistance is not always decreased by the heat-treatment in the temperature range of atom-ordering, and is remarkably increased by the annealing near by the Curie-point of Mumetal.

And moreover, the change of magnetic properties of μ_0 and μ_m by the special heat-treatment are not explained by the former theory. The theoretical explanation about the magnetic property on permalloy was proposed by Néel et al.[6),7),8),9)]. But, considering our experimental results, the following facts remain in question.

(1) The magnetic property by the special heat-treatment is very sensitive to the history of heat-treatment.

(2) The variation of μ_0 and μ_m as a function of annealing temperature is very complicated, and the each value can not be explained by the existing atom-ordering theories.

(3) The sign of the change of magnetic property by the special heat-treatment is opposite to each other for the binary permalloy and polynary permalloy.

§ 5. Conclusion

The maximum permeability of Mumetal is remarkably increased by a relatively low temperature heat-treatment. The existing theories for the effects of the heat-treatment are not consistent with our experimental results. In our investigation, however, the assumption of the origination of inhomogeneous structure in the permalloy material such as (1) internal strain caused by the third element added to binary permalloy, (2) lattice defects and (3) short range order of the superlattice seems to be very useful to explain the complex phenomena for the polynary permalloy.

In conclusion, the author wishes to express his hearty thanks to Director Dr. Tamatsu Nishina for his kind guidance and also to those who gave me many advices to my investigation.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 16, No. 3, MARCH, 1961

Direct Observation of Subgrain-Growth of Cold-Worked Aluminium by means of Electron Microscopy*

Hiroshi FUJITA

Institute of Scientific and Industrial Research, Osaka University, Osaka Japan

(Received April 18, 1960)

Transmission electron micrographs of cold-worked aluminium show that the crystal grain consists of many subgrains the smallest size of which is less than 0.1μ. On subsequent heating, the subgrains grow by two kinds of process, i.e. the formation of subgrain-groups and the usual growth, and finally they grow up to a stable polygonal shape of $3\sim10\mu$ in size. The total area and the structure of sub-boundaries are likely to play a very important role for recrystallization because they act as the sinks of lattice defects in the intermediate course of migration to the recrystallization boundaries, but *the recrystallization in situ* is not found as a special stage of subgrain-growth.

The results obtained in the present work are discussed in relation to a mechanism of the recrystallization which was proposed by the author.

§1. Introduction

It is known that the presence of substructures within a crystal is closely related to the physical phenomena such as deformation, recovery and recrystallization. Formerly the present writer studied the subgrain formation in cold-worked aluminium by electron microscopy using the replica method[1]. Although this method is very convenient for observing the surface details such as slip bands and deformation bands, it is difficult to observe the internal structures of metals. Therefore, some other methods must be used which can directly reveal the internal structure. Heidenreich[2] was the first who observed the structure of metals by transmission electron microscopy. It should be noted that since, in this method, no replica is used, the resolving power of the electron microscope is the only limitation for disclosing fine structure details such as dislocations. Therefore the direct observation method was applied to the study of the subgrains, and some of the results obtained were already reported[3]. The object of the work presented here is to investigate in detail the subgrain-growth of cold-worked aluminium and its relation to the recrystallization.

§2. Specimen Preparation and Experimental Method

Specimens were taken from 99.99% purity aluminium foil which had previously been cold-rolled to 0.01 mm in thickness, well annealed, and hammered at room temperature to 0.5μ or less in thickness. The specimens were annealed at various temperatures and then chemically polished in a two percent aqueous solution or several percent alcohol solution of hydrofluoric acid untill the thickness was reduced to less than 1000Å. Another method of preparation of specimen was also used as follows: The specimens were wet with oil, sandwiched between thin foils of tin and cold-rolled to a thickness less than 1000Å. The final thickness of the specimens prepared by any of these two methods was fairly uniform throughout the specimens. The specimens were finally washed with alcohol and acetone, and were picked up with a mesh for observation.

The transmission electron microscope used had a resolving power of 20Å and was operated at 60 kV. To find the relationships between subgrains and the structure of sub-boundaries, observation was made (A) with different angles of incidence of the electron beam obtained by varying the current of condenser lens, or (B) by tilting the specimen. Method (A) in which the maximum change of angle would be about a few degrees was very useful for changing the image contrast between subgrains. The relative contrast between subgrains and the positions of extinction contours could be varied with the angle of incidence, while the other images, the position of sub-boundaries and the

darkness variation depending on the specimen thickness, were not influenced. It was therefore easy to distinguish each of them from the others.

Method (B) was convenient for examination of the structure of sub-boundaries. The specimen could be rotated up to 45° around an axis perpendicular to the incident beam.

§ 3. Experimental Results

(a) *Cold-worked state*

Figs. 1 and 2(a) are of the specimens as beaten: there are found many relatively dislocation-free regions of $0.1\sim1\mu$ dia., which seem to be bounded by diffused lines (↑) constructing irregular dislocation networks. In some regions where the deformation may be severe, these lines are so more clearly observed that they may be called the sub-boundary. The possibility of formation of such small subgrains was already shown by the replica method[1]. In Figs. 1 and 2, the segmentation of extinction contours (C) and the existense of the nodes of the boundaries (N) are helpful to detect the sub-boundaries.

The misfit angles between the subgrains mentioned above were roughly estimated with method (A) to be less than one degree for the small subgrains and a few degrees for the large ones. Furthermore, it is recognized in Figs. 1 and 2 that the boundaries of larger subgrains are of the dislocation cross-grid structure (G), which means that the sub-boundary is composed of two or more families of dislocations. On the other hand, most sub-bounda-

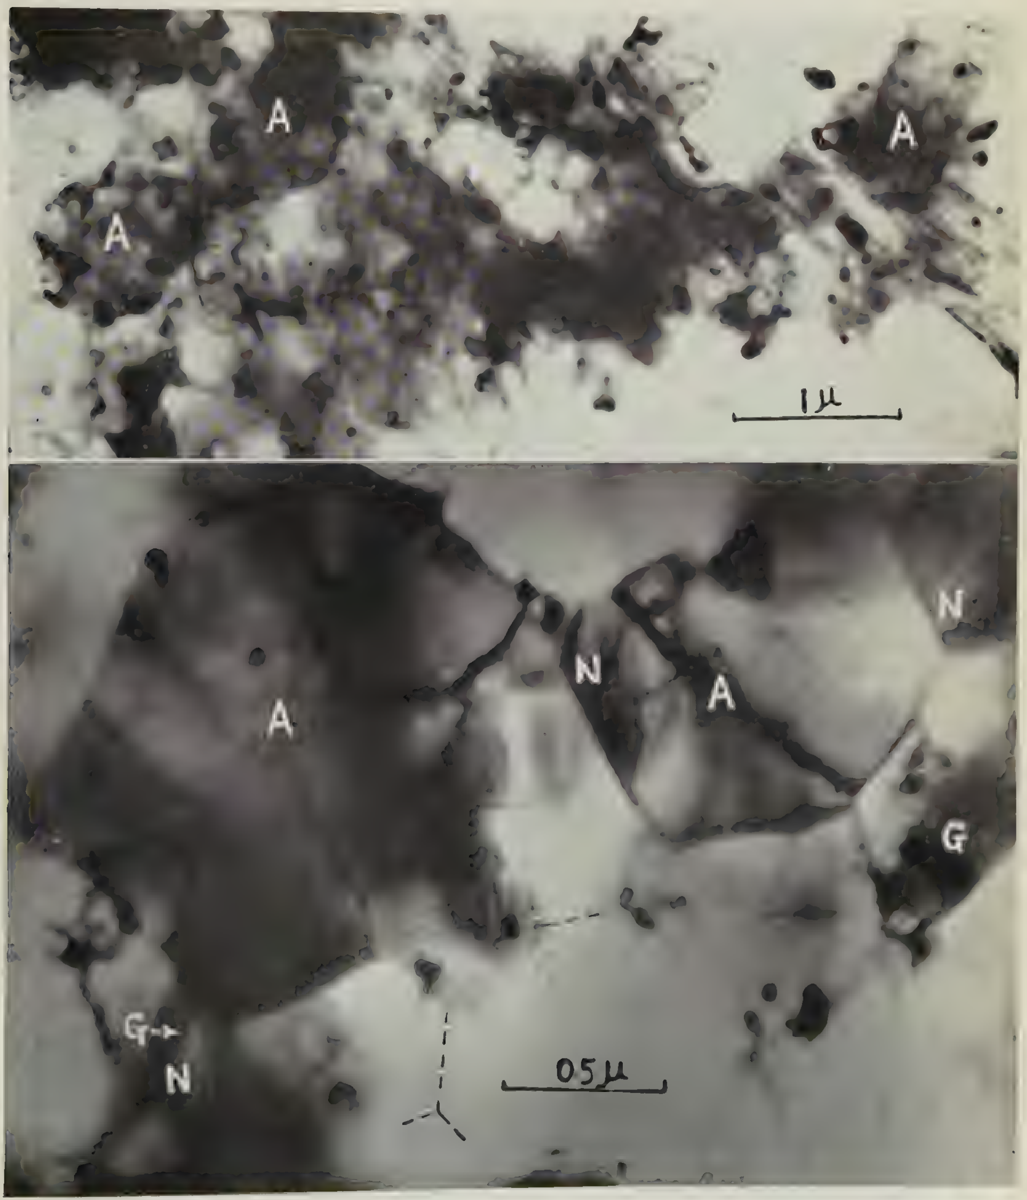

Fig. 4. Subgrain-groups appeared in the course of subgrain-growth. The specimens were annealed for 1 hr. at 260°C. Sign A indicates a subgrain-group consisting of smaller subgrains. (a), (b) were taken from different specimens.

ries of smaller ones seem to have a tendency to take the simple tilt type as slightly seen at the region noted by T in the photographs, which might correspond to K-band[1] reported already.

The temperature rise of the specimen owing to electron-bombardment under observation in the electron microscope was estimated as follows: Fig. 2 (a) and (b) were obtained before and after a strong electron-bombardment in the electron microscope for 30 mins. In these figures it is noticed that there is no visible change in the positions of sub-boundaries. On the contrary, the specimen annealed at 200°C for one hour shows a more marked change, i.e. straightening and sharpening of sub-boundaries as in Fig. 3. It is therefore reasonable to make an estimation that the temperature of the specimen under electron-bombardment was lower than 200°C.

(b) *Subgrain-growth*

On annealing cold-worked specimens, the subgrain-growth occurred in succession to polygonization, as seen in Figs. 3~7 in which the annealing was 200°C×1 hr., 260°C×1 hr., 260°C×2 hrs. and 350°C×1.5 hrs., respectively. These specimens are considered to have still been in the recovery stage, as no recrystallization grain was found by optical microscopy combined with chemical etching. Prolonged annealing caused remarkable subgrain-growth as in Figs. 5 and 7. From these photographs it is recognized that the subgrain-growth proceeds with two kinds of processes; (a) With the sub-boundary migration in the usual sense, (b) with formation of groups of subgrains as region A in Fig. 4(a) which has the size of about 1μ, and it was general that a few groups were formed in the region of 10μ in size. The latter process will be very important not only in the case of subgrain-growth but also in the recrystallization process. In Fig. 4(b) the subgrain-groups are clearly observed.

At the biginning of formation, the subgrain-group has such behaviors as follows: (1) Misfit angles between subgrains composing the group are very small. (2) The sub-boundary of the group is not so smooth but it is only a simple connection of the individual boundaries of composite small subgrains.

Figs. 4 and 5 are examples showing the process of stabilization of the boundary of the group which might be produced due to the absorption of the sub-boundaries within the group.

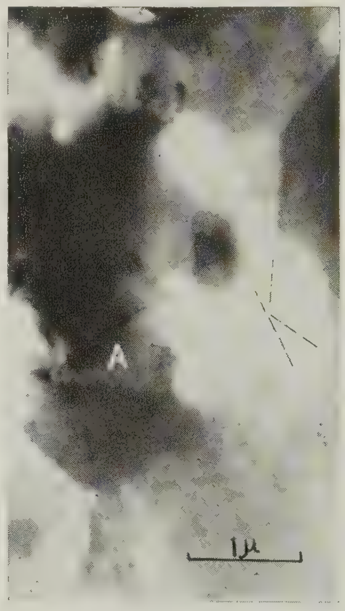

Fig. 5. Annealed for 2 hrs. at 260°C.

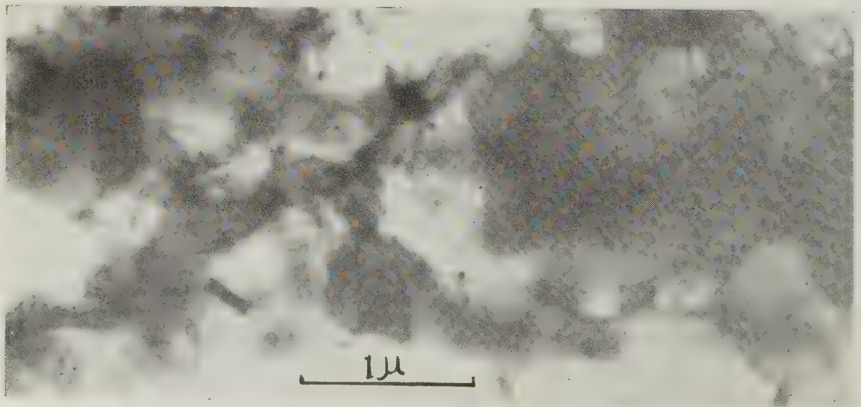

Fig. 6. Annealed for 1.5 hrs. at 350°C, a region outside a recrystallization grain.

On further annealing, the subgrain-growth by the two processes becomes conspicuous as in Fig. 5 (260°C×2 hrs), and finally recrystallization occurs. In the region existing between the groups in Fig. 4(a) (260°C×1 hr) there is no considerable change in size of the subgrains comparing to that of the specimen annealed for one hour at 200°C. After 260°×2 hrs. annealing, however, the subgrains existing between the groups also grew by the usual subgrain growth process. Fig. 6 was obtained with a specimen annealed for 1.5 hrs at 350°C, the photographed region being outside the recrystallization grain where subgrain-growth was delayed.

Fig. 7 is of another region of the specimen (260°C×1 hr.) which is likely to be considered as the beginning of formation of a recrystallization boundary. In order to estimate the misfit angles between subgrains existing inside the boundary noted by *R-R*, Fig. 7(b) was taken at the same region as 7(a) under the different glancing angle of incident beam. Comparing these two photographs it seems

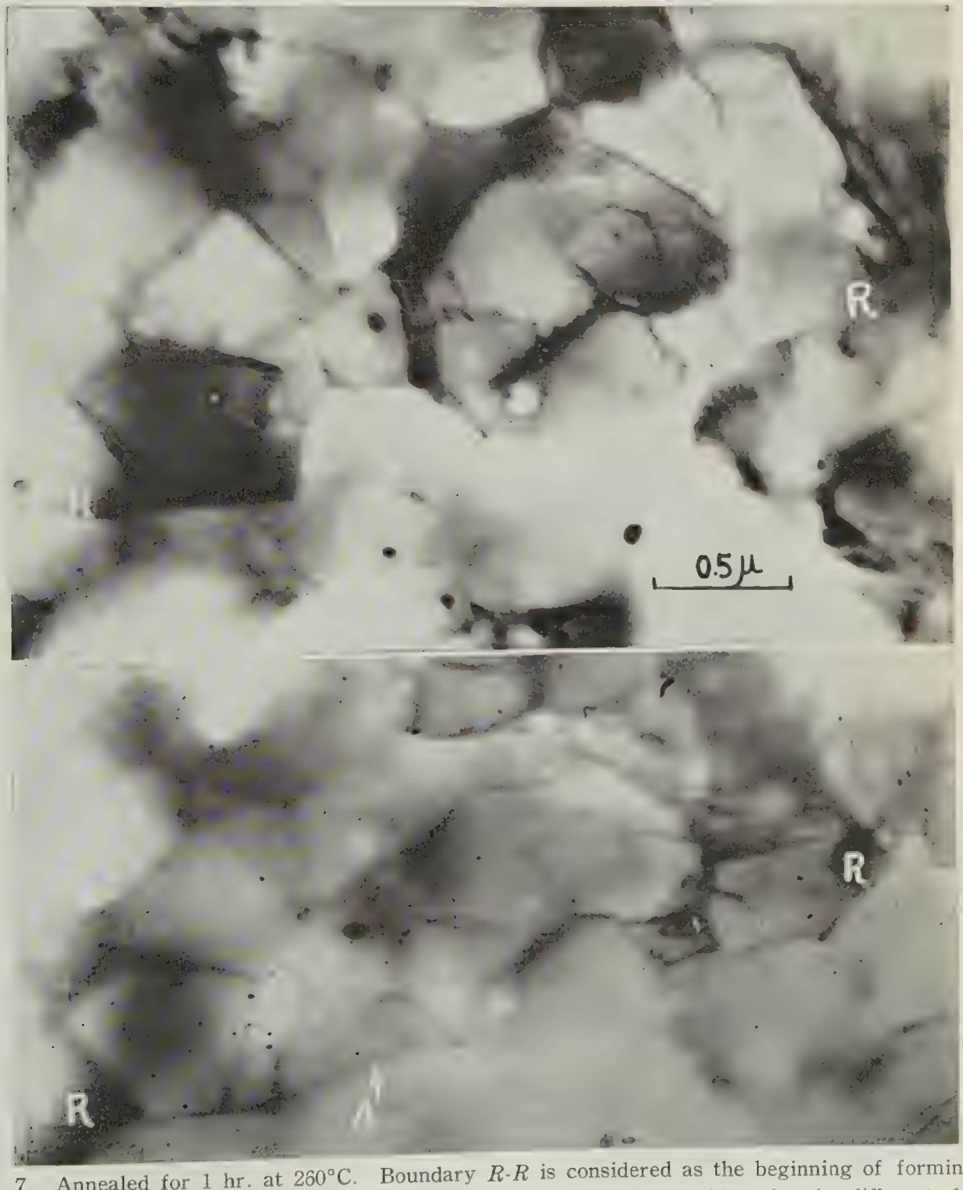

Fig. 7. Annealed for 1 hr. at 260°C. Boundary *R-R* is considered as the beginning of forming a recrystallization boundary. (b) was taken at the same region as (a) under the different glancing angle of incident beam.

that the *R-R* boundary has characters as follows: (1) *R-R* is a boundary of the subgrain-group in a certain sense, because it is a smooth boundary in spite of the presence of many boundaries of small subgrains inside the *R-R* boundary. (2) The grain size of the region surrounded by the *R-R* boundary is much larger than the usual subgrain-group, which is the same order as that of the beginning of recrystallization, 3~10μ in size. (3) The misfit angles between subgrains existing inside the *R-R* boundary are very small as that of the usual subgrain-groups. (4) Outside the *R-R* boundary the recovery process is so delayed that subgrains are not so clearly seen. Furthermore, a part of the boundary, noted by A in Fig. 7 is very faint compared with the other part, and a subgrain exisiting inside the boundary at this part (above the boundary A) has a large misfit angle to any neighbouring subgrains inside the *R-R* boundary. The remainder of this subgrain is observable in the outside region, that is, in the lower part of the photograph. It is, therefore, supposed that the formation of the *R-R* boundary is owing to the deposition of vacancies and dislocations which had existed near the boundary, and this process will be as schematically illustrated in Fig. 8, though more detailed

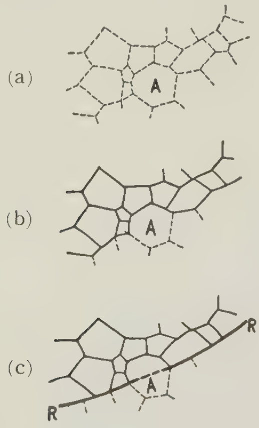

Fig. 8. Schematic illustration of forming a recrystallization boundary.

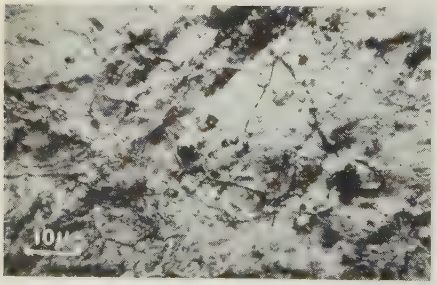

Fig. 9. Optical micrograph of a recrystallized foil specimen annealed for 1.5 hrs. at 350°C.

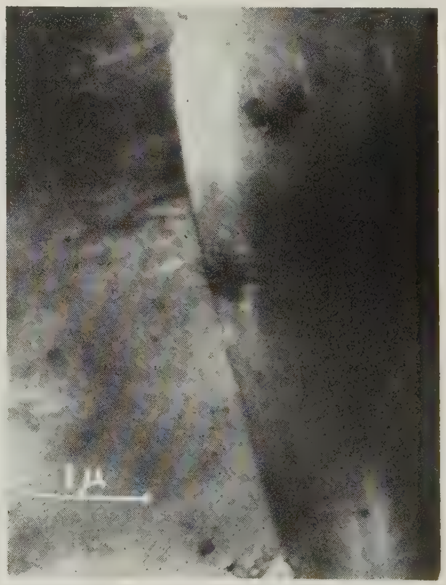

Fig. 11. Recrystallization boundary appeared in a specimen which was subjected to annealing for 3 hrs. at 350°C.

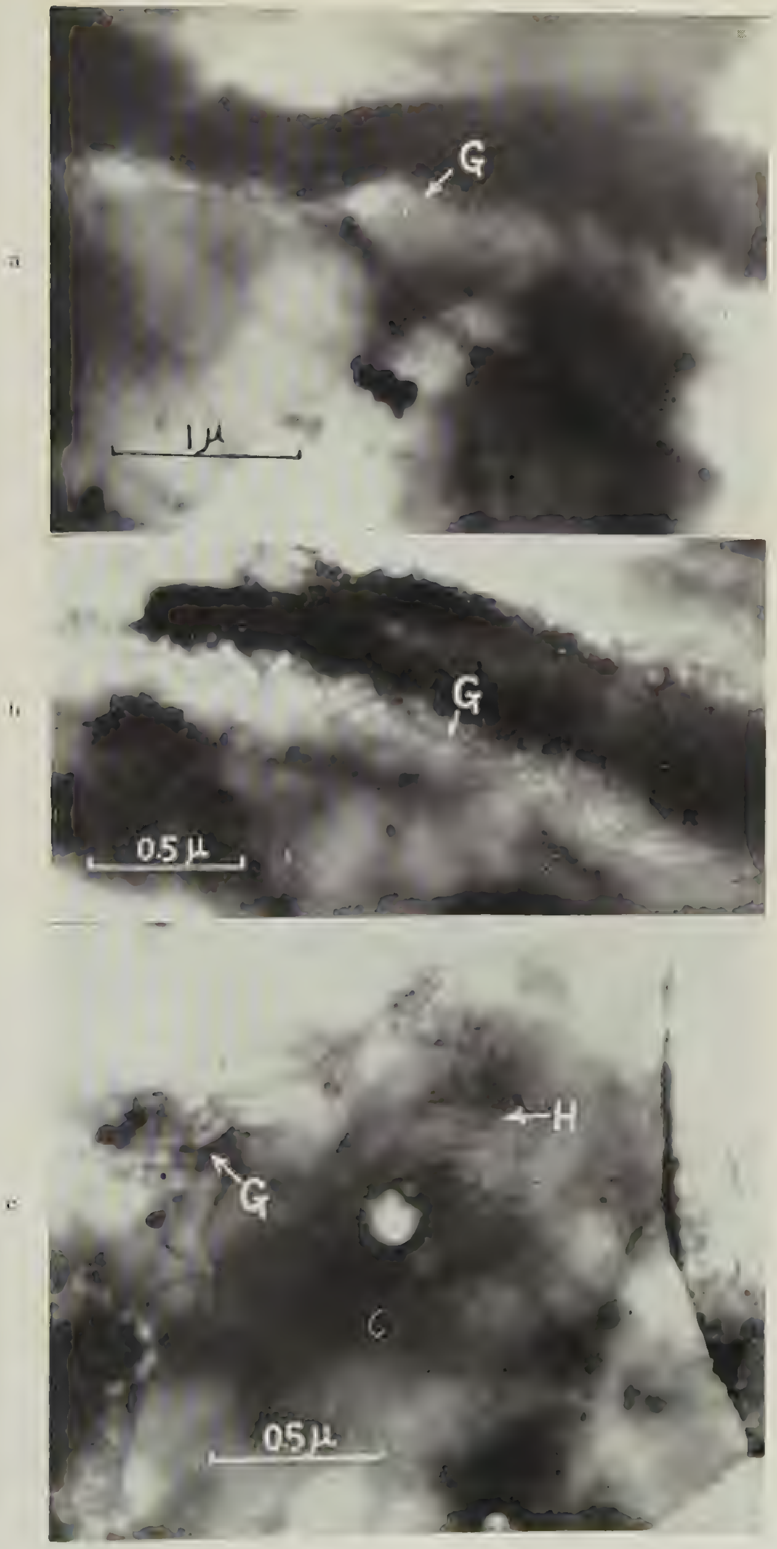

Fig. 12. Dislocation grid appeared in specimens annealed (a) for 1 hr. at 260°C, (b) for 1.5 hrs. at 350°C, (c) for 2.5 hrs at 350°C. H: dislocation hexagonal network.

study is necessary to get the decisive conclusion. Although it is considered that the stage mentioned above corresponds to something like the beginning of the recrystallization, the contrast between the recrystallization grain and the matrix became not yet so strong that it was difficult to observe the recrystallization boundary by optical microscopy. This might be owing to the fact that subgrains inside the boundary *R-R* still play a strong role as the sink for vacancies and dislocations in the intermediate course of migration to the recrystallization boundary so that the formation of the recrystallization boundary was suppressed.

Here, there is some doubt about that in the case of thin foils of metals the recrystallization mentioned above is suppressed by the size effect. To solve this doubt, the specimen used was also observed by optical microscopy and it was verified that the recrystallization occurred even in such thin foils of 0.5μ in thickness as follows. After further annealing (350°C × 1.5 hrs.), the recrystallized grain becomes observable by optical microscopy as in Fig. 9 which was taken of the foil specimen after etching with a reagent (10 g $NaOH$ + 100 cc H_2O) at 40°C. Although there is seen in Fig. 9 a recrystallization boundary which shows only a little growth, it was general that the size of the recrystallization grain at this stage was usually 10～40μ which was one-second to one-third of that before cold-working.

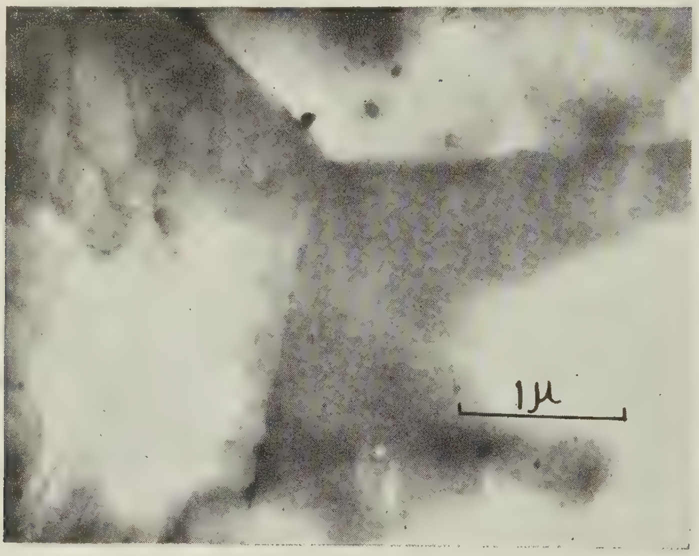

Fig. 13. Annealed for 3 hrs. at 560°C.

By electron microscopy it was found in a specimen annealed for 1.5 hrs. at 350°C that most subgrains grew up to 1～3μ in size as in Fig. 10, and that there were scarcely found both subgrain-groups and small subgrains less than 1μ in size. From the annealing history of this specimen the subgrains in Fig. 10 are considered to have been produced by *the recrystallization in situ* as observed by Crussard[4]. So it is very interesting that they appeared when the recrystallization boundary became observable. However, it is quite clear that they do not belong to a special stage as the subgrain-growth. These subgrains have the size and the shape as similar as those of the stable subgrains that will be mentioned in a later page.

Next, Fig. 11 is an example showing a recrystallization boundary. Comparing Fig. 11 with Fig. 7, it is very interesting that the recrystallization boundary become sharper with the prolonged annealing. This fact is quite reasonably understood if the formation of recrystallization boundary is owing to coagulation of the lattice defects.

Fig. 12 (c) shows a dislocation net-work structure in a sub-boundary formed by *the recrystallization in situ*. In this stage, however, the cross-grid structure of dislocations is apt to take a hexagonal net-work structure under the thermal vibration (compare Fig. 12 (c) with (a) and (b)). It is interesting that in Fig. 12(c) both the cross-grid (G) and the hexagonal net-work structure (H) are observed in a sub-boundary.

After long annealing at high temperatures just below the melting point, the subgrain grows more and more and finally it takes a stable polygonal shape, whose size is 5∼10μ, as in Fig. 13 which were taken of a specimen annealed for 3 hrs. at 560°C. At this stage, it was recognized by optical microscopy that recrystallization grains had grown further.

§ 4. Discussion

About six years ago[5], the author proposed a mechanism* concerning the nucleation of recrystallization. This mechanism is based on the idea that the positions of the recrystallization boundaries are originally decided at the time of cold-working and the nucleus in the usual sense is not needed for the recrystallization. In other words, subgrain-growth plays a very important role for disappearance of the stored energy, but it is not so much important for the formation of recrystallization boundary which needs the coagulation of lattice defects. Since the sub-boundary acts as a sink for lattice defects, it is necessary for formation of the recrystallization boundary that the number of subgrains within the recrystallization boundary decreases to a certain value. Because, for the coagulation of lattice defects to the recrystallization boundary, the defects have to travel for a long distance compared with that in the case of polygonization. In case polygonization has not proceeded so much, most of the lattice defects formed by cold-working may be exhausted for polygonization in the intermediate course of migration to the recrystallization boundary. Furthermore, for the recrystallization boundary the difference of bulk free energy between the recrystallization grain and the matrix around it must be larger than a certain value. So, first of all the subgrains must grow and take the thermally stable structure in order to form the recrystallization boundary.

This idea might be supported by the following experimental results obtained in the present work: (1) remarkable growth of subgrains was observed before the recrystallization, (2) grown subgrains, i.e, so called *the recrystallization in situ*, were observed within the recrystallization grain, (3) outside the recrystallization grain, there remain the subgrains where subgrain-growth was delayed, (4) at the beginning of the recrystallization, boundaries of the recrystallization grain were rather faint and broad.

Fact (1) proceeds by two kinds of process, i.e. (a) formation of subgrain-groups and (b) subgrain-growth in the usual sense. A few subgrain-groups were formed in a region of several micron in size which corresponded to the initial size of a recrystallization grain, and even after the recrystallization, *tne recrystallization in situ* was observed within the recrystallization grain. Thus it is considered that a subgrain-group is not an embryo of recrystallization but it belongs to the category of subgrain.

The fact that some subgrains have a special behavior such as composing the subgrain-group leads us to an imagination that such subgrains were already given a suitable condition for forming the subgrain-group by cold-working so that misfit angles between them are very small. Since the boundary of the group has a larger misfit angle compared with those of subgrains inside the group, it becomes a strong sink for lattice defects such as dislocations and point defects. That is the reason why dislocations composing a sub-boundary within a subgrain-group are absorbed so easily that finally sub-boundaries within a group disappear. This process is one kind of subgrain-growth. Subgrain-growth in the usual sense may also proceed by the same process more or less, in which case formation of subgrain-groups was not observed.

Fact (2) shows that a recrystallization grain is not a resultant formed by the process of subgrain-growth. Because it is hardly possible that there exist some large subgrains within a recrystallization grain, if the recrystallization boundary was formed by means of subgrain-growth.

Fact (3) indicates, however, that the subgrain-growth plays a very important role for recrystallization process. Accordingly, stored energy given by cold-working is released by the process of subgrain-growth so that the recrystallization boundary is thermally stabilized.

---

* Orowan[6] proposed independently the similar idea concerning recrystallization, which was called as *the homogeneous nucleation.*

Fact (4) indicates that a recrystallization boundary is formed by some coagulation of lattice defects, especialy point defects. Such positions playing a role as the sink for lattice defects may be formed during cold-working in the same way as in the case of the subgrain-group. The author reported[7)] already that unpredicted slips occurred in small regions divide a crystal into many domains of a few microns in size. The domain boundary is not so clear that it is recognized only by a difference of slip system or reflected light on both sides of the boundary. Even in the boundary region of the domain, small subgrains less than 1μ in size are formed as well as within the domain with small sink and slip bands[1)]. So, as far as the strained state of the subgrain is concerned, it is rather difficult to find out anything discontinuous at the boundary of the domain.

It should be emphasized, however, that such domains have large misfit angles with each other, so that small subgrains formed within a domain have large relative misfit angles to those within the neighbouring domain, but the subgrains belonging to the same domain have small misfit angles with each other. So, it is reasonable to consider that the boundary region of the domain is a strong sink for coagulation of lattice defects in the case of forming a recrystallization boundary.

From the consideration mentioned above, the following equation* will be deduced, which shows a relationship between the experimental (α) and a theoretical specific surface energy (α_0) of the boundary determined from both misfit angles and boundary structures.

$$\frac{2\alpha}{r_c}=\frac{2\alpha_0}{r_c}-\Delta n\Gamma=\delta F$$

where r_c is a critical size of a recrystallization grain, δF and Δn are the differences of bulk free energies and of the densities of dislocations terminating at the boundary, respectively, between the matrix and the recrystallization grain. Hence

$$r_c=\frac{2\alpha_0}{\delta F+\Delta n\Gamma}\ .$$

α_0 will be very small at the beginning of recrystallization, since the misfit angle is very small because of the diffused structure. If we assume $\Delta n=10^{10}/\text{cm}^2$, $\Gamma=10^{-4}$ ergs/cm, $\alpha_0=$a few ergs/cm$^2\sim 500$ ergs/cm^2, and $\delta F=$the order of 10^6 ergs/cm^3, r_c becomes $1\mu\sim10\mu$ in size, which is in agreement with the experimental results[5)] observed.

Cavity Growth by Vancancy Condensation and Transformation to Dislocation Loop in the Graphite Structure

By Takuro TSUZUKU

College of Science and Engineering, Nihon University,
Kanda-Surugadai, Chiyoda-Ku, Tokyo.

(Received September 22, 1960)

The growth of cavities by vacancy condensation in graphite and the transformation to dislocation loops have been theoretically investigated.

During the heat treatment of carbonaceous substances for graphitization, numerous vacancies and cavities presumably exceeding 10^{-3} atomic per cent are introduced in several ways, *e.g.*, decomposition and evaporation of various impurities. By taking account of the internal surface energy and the configurational entropy of them, it has been concluded that these vacancies and cavities are driven to consolidate to fewer and larger ones lying extensively on the $(00l)$-planes.

In the course of the steady dimensional growth, the cavity is expected to collapse to a prismatic dislocation loop under the compressive thermal stress in c-direction (graphitization stress) caused by the interference between the anisotropically expanding crystallites. The criterion of such transformation has been determined by comparing the self-energy of the dislocation loop with the sum of the surface energy of the original cavity and the compressive strain energy to be released by the collapse; *i.e.*, the critical diameters are ranging from about 100 Å to 1100 Å in accordance with the various conditions concerning the crystal modification and the cavity thickness. These values are in fairly good agreement with the experimental results. It has been remarked that along this course the characteristic intercrystallite voids can be explained.

§ 1. Introduction

In the previous paper[1], the author pointed out that the dislocations in the graphite structure might be produced by the so-called graphitization stress owing to the interference of the anisotropic thermal expansion of each crystallite in some polycrystalline carbons. At the same time, it was remarked that the condensation of point vacancies to fewer flat cavities would be another powerful source of the dislocations in accordance with the suggestion of Seitz[2]. These two origins of the dislocations are both in close connection with the two characteristics of graphite, *i.e.* the heat treatment at elevated temperatures for synthesis and the remarkable anisotropy in the crystal structure.

As generally known, a crystal in thermodynamical equilibrium has to contain a number of lattice vacancies and other imperfections by which the free energy of the system is lowered through the contribution of the configurational entropy. In the case of graphite, since the crystal grows up through the pyrolysis of raw carbonaceous substances, much higher concentration of vacancies are expected to be generated in various ways of impurity dissipation; *e.g.*, (1) volatilization of light organic components at temperature below 1000°C, (2) dehydrogenation arising nearby 1000°C and lasting up to about 1700°C, and (3) evaporation of inorganic impurities* taking place in the final stage of graphitization above 1800°C, *et al.*

Conclusively, the graphite crystal is considerable to be so exceedingly supersaturated with vacancies that the condensation of them to fewer cavities would occur more actively than other crystals. Recently, in the course of the electron microscope study of some graphite flakes, Fujita and Izui[3] have observed circular *moiré* patterns having the diameters of several hundred angstroms. The patterns of this kind can be explained by supposing that such disciform cavities as considered above collapse to the edge dislocation loops, *i.e.*, the peripheral lattice distorsion may give rise to the Bragg reflection of electron waves responsible for the *moiré* patterns.

---

* This is well known to take place sometimes through the intermediate formation and the following decomposition of various metal carbides, *e.g.* silicon carbide, cementite *etc.*

Now, it is worthy to examine a theoretical investigation on the mechanism of vacancy condensation to a small number of cavities in the graphite structure and the following transformation to the same number of dislocation loops.

§ 2. Growth of Cavity by Vacancy Condensation

2.1 *Basic Model*

Owing to the characteristic anisotropy in the crystal structure, an arbitrary cavity lying in graphite may easily take a flat cylindrical form as widely accepted; the diameter and the height in angstroms are denoted by D and h respectively. On the other hand, the area of each unit hexagon containing two C-atoms (Fig. 1) is computed at 5.22 angstrom square. Therefore, the number of atoms emerging on the basal face of such a cylindrial cavity is $m_{\text{basal}}=2.61(\pi D^2/4)=0.30D^2$.

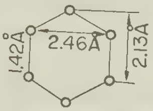

Fig. 1. Unit hexagon of graphite net plane.

Nextly, since the interplanar spacing in c-direction is known to be about 3.36 Å*, the number of point vacancies composing the cavity is $i=3.36m_{\text{basal}}/h=0.089D^2h$.

Finally, supposing that along the periphery of the cavity C-atoms are aligned 2.46 Å apart, one can give the total number of the free bonds (atoms) which are exposed all over the side-face of the cavity,

$$m_{\text{side}}=(\pi D/2.46)(3.36/h)=0.38Dh.$$

2.2 *Surface Energy of Cavity*

According to Pauling[4], the graphite structure is considered to be resulted from the infinite aromatic condensation, so that each carbon-carbon bond achieves one-third double-bond character. Since the energies of pure C–C and C=C valence bonds are known to be 58.6 and 100 kcal/mol respectively, the cohesive energy of graphitic net plane is computed at 58.6×(2/3)+100×(1/3)=72.4 kcal/mol in approximation. On the other hand, the energy of interplanar van der Waals bond of graphite has been calculated by Brennan[5] to be about 4 kcal/mol. At the time of the destruction of these chemical bond, in general, the binding energy may be shared by half with each surface newly exposed. Thus, the total surface energy of such a cylindrical cavity as considered above is given by

$$\begin{aligned}E_s&=2m_{\text{basal}}\times 2+m_{\text{side}}\times 36.2\\&=1.2D^2+13.8Dh \quad \text{(kcal/mol)} \qquad (1)\end{aligned}$$

where the first term in the right-side corresponds to the contribution of the upper and lower basal faces, and the second to that of the side face.

Hereupon, let introduce a quantity "specific surface energy", γ_s, defined by the next equation,

$$\gamma_s=\frac{E_s}{i}=\frac{155}{D}+\frac{13.5}{h} \quad \text{(kcal/mol)} \qquad (2)$$

The physical meaning of γ_s is "the increment (decrement) of the surface energy when a point vacancy pours into (out of) the cavity considered here". For example, if a point vacancy leaves a cavity of $D=20$Å and $h=3.36$Å (one atomic plane missing) and pours into another of $D=80$ Å and $h=6.72$ Å (two plane missing), the internal energy of the crystal is reduced by the difference of the specific surface energies, *i.e.*,

$$\begin{aligned}\Delta\gamma_s&=\left(\frac{155}{20}+\frac{13.5}{3.36}\right)-\left(\frac{155}{80}+\frac{13.5}{6.72}\right)\\&=11.8-3.9=7.9 \quad \text{(kcal/mol).}\end{aligned}$$

Thus, those vacancies and minute cavities generated in the aforesaid ways (§1) are expected to condense successively, through the heat treatment at elevated temperatures for graphitization, to a small number of much larger ones. From Eq. (2), moreover, one can see that the specific surface energies are equalized by degrees with the consolidation of cavities, and, when the vacancies and minute cavities are mostly exhausted the dimensional growth may almost terminate. Such a state can be regarded as a metastable balance, and

---

* The spacing varies in accordance with the degree of graphitization. The lowest value has been reported to be 3.354 Å (at 18°C) on natural graphite of Ceylon, which corresponds to the best graphitization.

γ_s is considerable to give a negative measure of the stability.

2.3 *Configurational Entropy and Free Energy*

In order to describe the mechanism of vacancy condensation (cavity consolidation) more exactly, the contribution of the configurational entropy has to be taken into account. For simplicity, let suppose that n_i cavities consisting of i point vacancies respectively are arranged on N lattice points $(N \gg i)$. This supposition corresponds not only to the aforesaid metastable balance but to the actual state in approximation, if the cavity-size distribution is not so much broad. Thus, the number of possible arrangement, W, is generally given by

$$W = \frac{i^{n_i} \cdot \left(\frac{N}{i}\right)!}{\left(\frac{N}{i} - n_i\right)!\ n_i!} .$$

Putting $n = n_i \times i$ and $c = n/N$, which represent the total number and the concentration of point vacancies (consisting the cavities) respectively, and using Stiring's formula, the configurational entropy, S_{cf}, is expressed in the following form,

$$S_{cf} = k \ln w = \frac{kN}{i}\left[c \ln \frac{i}{c} - (1-c)\ln(1-c)\right]$$
$$= \frac{kN}{0.089D^2h}\left[c \ln \frac{0.089D^2h}{c} - (1-c)\ln(1-c)\right] . \tag{3}$$

Now, in the similar way to that concerning the surface energy, one can define the "specific configurational entropy",

$$\xi = S_{cf}/n = S_{cf}/Nc$$

which may give a measure of entropy change by vacancy migration from a cavity to another.

Hereupon, combining γ_s and ξ, the so-called "specific free energy", φ, is defined by the next equation,

$$\varphi = \gamma_s - T\xi$$
$$= \left(\frac{155}{D} + \frac{13.5}{h}\right) - T\frac{k}{0.089D^2hc}\left[c \ln \frac{0.089D^2h}{c} - (1-c)\ln(1-c)\right]. \tag{4}$$

Now, let make an estimation of the vacancy concentration, c, by using the well-known expression[6)]

$$c = \frac{n}{N} = \left(\frac{\nu}{\nu'}\right)^{3x} \cdot \exp\left(-\frac{E_v}{kT}\right) ,$$

where x is the number of the atoms neighbouring a vacancy, ν' is the Einstein frequency of them, ν is that of the perfect lattice part, and E_v is the formation energy of a vacancy. In approximation, $\nu/\nu' \approx 2$, $x=3$ (taking only the co-planar neighbours around a vacancy) and $T=3000°K$ (temperature of usual industrial graphitization furnace). Moreover, since the three conjugated double-bonds are broken in removing an atom from a lattice point, and, 3/2 bonds are recovered on average in placing it to the periphery of the net plane,

$$E_v = 72.4 \times \{3 - (3/2)\} = 108.6 \text{ kcal/mol}$$

is obtained. Substituting these values to the above equation, vacancy concentration is computed at $10^{-5.2}$. However, as mentioned in § 1, graphite is considerable to be highly supersaturated with the vacancies and cavities in the way of active impurity dissipation, and hence one can put approximately $c \approx 10^{-5}$.

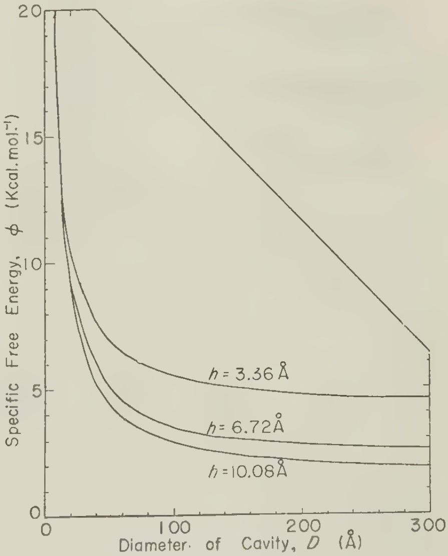

Fig. 2. Dependency of specific free energy on cavity-size.

Thus, the $D-\varphi$ relaction curves at 3000°k are plotted in Fig. 2 for the parameters of $h=3.36$, 6.72 and 10.08 Å (corresponding to that one, two and three planes are deficient respectively). As shown there, the contribution of the configurational entropy is so small that φ decreases monotonically with the growth of cavity-size, indicating no minimum value. Moreover, one can see that when D mounts up to several hundreds angstroms the cavity is hard to make further growth in actual owing to the equalization of φ, similar to the case of the specific surface energy discussed before. In other words, these cavities are possible to be existent only in the so-called metastable balance but impossible in thermodynamical equilibrium, somewhat alike the dislocations.

§ 3. Transformation to Dislocation Loop

3.1 *Geometry of Transformation*

By means of X-ray and electron diffraction it has been established that graphite has two crystal modification[7)8)], the hexagonal (AB-type stacking sequence of $\boldsymbol{c}$-planes) and the rhombohedral (ABC-type sequence), as schematically illustrated in Fig. 3. This gives a cause of the variety of the dislocation loops to be introduced, being in company with the various conditions on the deficient planes, as itemized in the following paragraphs:

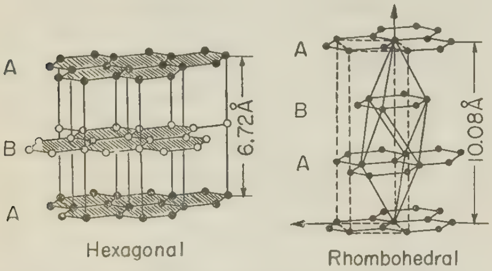

Fig. 3. Two crystal modifications of graphite.

Hexagonal Modification

(h1) One plane missing (h=3.36 Å)

In addition to the prismatic partial dislocation which closes the cavity, another partial dislocation with a Burgers vector connecting the nearest neighbours in (00l)-plane is introduced so as to fit the subtending basal faces. Denoting them by $\boldsymbol{b}_c$ and $\boldsymbol{b}_a$ respectively, the resultant slip is represented by

$$\boldsymbol{b}=\boldsymbol{b}_c+\boldsymbol{b}_a=\tfrac{1}{2}\boldsymbol{c}\cdot[001]+\tfrac{1}{3}\boldsymbol{a}\cdot\langle 210\rangle\ .$$

This causes such a stacking fault as

ABABCBCBC or *ABABACAC*.

(h2) Two planes missing (h=6.72 Å)

$$\boldsymbol{b}=\boldsymbol{b}_c=\boldsymbol{c}\cdot[001]\quad\text{(perfect dislocation).}$$

The dislocation loop can glide along the cylindrical face perpendicular to the basal plane as in Fig. 4 (a), though it might be not so easy.

(h3) Three planes missing (h=10.08 Å)

$$\boldsymbol{b}=\boldsymbol{b}_c+\boldsymbol{b}_a=\tfrac{3}{2}\boldsymbol{c}\cdot[001]+\tfrac{1}{3}\boldsymbol{a}\cdot\langle 210\rangle\ .$$

The possible stacking faults are quite same as those in (h1).

*Rhombohedral Modification**

(r1) One plane missing (h=3.36 Å)

$$\boldsymbol{b}=\boldsymbol{b}_c=\tfrac{1}{3}\boldsymbol{c}\cdot[001].$$

The stacking faults are as follows;

····*ABCBCABC*···· (A-plane missing), or
····*ABCACABC*···· (B-plane missing), or
····*ABCABABC*···· (C-plane missing)

(r2) Two planes missing (h=6.72 Å)

$$\boldsymbol{b}=\boldsymbol{b}_c+\boldsymbol{b}_a=\tfrac{2}{3}\boldsymbol{c}\cdot[001]+\tfrac{1}{3}\boldsymbol{a}\cdot\langle 210\rangle$$

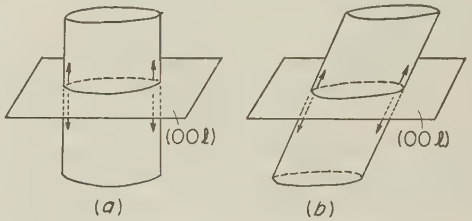

Fig. 4. Clide motion of prismatic dislocation loop.

Table I. Combination of missing planes and basal translation in rhombohedral graphite.

Missing planes	Translation by $\boldsymbol{b}_a$	Stacking disorder
A, B	$C\to\underline{B}$	$\cdots ABC\underline{B}CABC\cdots$
	$C\to A$	None
B, C	$A\to\underline{C}$	$\cdots ABCA\underline{C}ABC\cdots$
	$A\to B$	None
C, A	$B\to\underline{A}$	$\cdots ABC\underline{A}BABC\cdots$
	$B\to C$	None

The under-lined planes in this column correspond just to those in the left-hand column respectively.

In this case, various combinations of the missing planes and the translations by b_a's give rise sometimes to the stacking disorder and sometimes to none. When the stacking order is not altered, the dislocation loop can glide along the surface of such an oblique cylinder as in Fig. 4 (b). All the possible combinations are summarized in Table I.

(r3) Three planes missing (h=10.08 Å)

$$\boldsymbol{b}=\boldsymbol{b}_c=\boldsymbol{c}\cdot[100]\quad\text{(perfect dislocation).}$$

It is easily understood that the same rules as mensioned above can be applied repeatedly and correspondingly to the cases that more than four planes are deficient.

---

* The $\boldsymbol{c}$-dimension of the unit cell is 10.08 Å.

3.2 *Self-Energy of Dislocation Loop*

Several years ago, Foreman showed the expression of the elastic energy per unit length of a dislocation line in an anisotropic crystal as follows[9],

$$E_d=\frac{Kb^2}{4\pi}\ln\left(\frac{R}{r_0}\right), \qquad (5)$$

where b, R and r_0 represent the Burgers vector, radii of the stress field arround it and the effective core respectively. The so-called "energy factor" K in every case of our problem considered before is evaluated in the following way, taking use of his treatise on the hexagonal system. However, the elastic constants c_{ij}'s referred to the dislocation axis in his general expression are rewritten so as to be referred to the normal crystal axis.

(1) Prismatic dislocation (either perfect or partial) with the Burgers vector perpendicular to the basal plane

$$K_{\text{edge}}(\text{prismatic})$$
$$=(\bar{c}_{11}+c_{13})\left\{\frac{c_{44}(\bar{c}_{11}-c_{13})}{c_{11}(\bar{c}_{11}+c_{13}+2c_{44})}\right\}^{1/2} \qquad (6)$$

(2) Partial dislocation connecting the nearest neighbours in the basal plane

$$K_{\text{edge}}(\text{basal})=(\bar{c}_{11}+c_{13})\left\{\frac{c_{44}(\bar{c}_{11}+c_{13})}{c_{33}(\bar{c}_{11}+c_{13}+2c_{44})}\right\}^{1/2} \qquad (7)$$

$$K_{\text{screw}}=\left\{\frac{c_{44}(c_{11}-c_{12})}{2}\right\}^{1/2} \qquad (8)$$

$$K_{\text{mix}}(\text{basal})=K_{\text{edge}}(\text{basal})\sin^2\theta+K_{\text{screw}}\cos^2\theta \qquad (9)$$

where $\bar{c}_{11}=(c_{11}\cdot c_{33})^{1/2}$, and θ is the angle between the slip vector and the dislocation line. In the case of such a dislocation loop as considered here, by averaging Eq. (9) arround it the energy factor is given by

$$\bar{K}(\text{basal})=\frac{1}{2}[(\bar{c}_{11}+c_{13})]\left\{\frac{c_{44}(\bar{c}_{11}-c_{13})}{c_{33}(\bar{c}_{11}+c_{13}+2c_{44})}\right\}^{1/2}+\left\{\frac{c_{44}(c_{11}-c_{12})}{2}\right\}^{1/2} \qquad (10)$$

(3) Combination of prismatic and basal dislocations

Since there is no interaction energy between the orthogonal dislocation components, the separate energy components are additive, and therefore the combined K-factor in this case may be given by the next equation,

$$K\boldsymbol{b}\cdot\boldsymbol{b}=K_{\text{edge}}(\text{prismatic})\boldsymbol{b}_c\cdot\boldsymbol{b}_c+K(\text{basal})\boldsymbol{b}_a\cdot\boldsymbol{b}_a\,. \qquad (11)$$

Table II. Elastic constants of graphite lattice.

c_{11}	c_{12}	c_{13}	c_{33}	c_{44}	(unit)
107	−21.4	−6.3	2.6	1.3	(10^{11} dynes/cm^2)

The elastic constants of graphite lattice, c_{ij}'s, can be determined from the corresponding elastic coefficients, s_{ij}'s, written in the previous paper[1], and are tabulated in Table II. Moreover, substituting them into the above equations from (6) to (10), the energy factors are evaluated as shown in Table III.

Table III. Energy factors of various dislocations.

K_{edge} (prismatic)	K_{edge} (basal)	K_{screw}	$\bar{K}$ (basal)	(unit)
1.53	9.8	9.1	9.5	(10^{11} dynes/cm^2)

Using these K-factors, the elastic energies of the dislocations in various cases itemized in the last sub-section can be calculated from Eq. (5), where R is appropriately assumed to be about $D/2$ (radius of the dislocation loop).

The energy in the dislocation core (residual part of the self-energy) is very difficult to estimate exactly. However, in the case of the prismatic dislocation as considered here, it may be approved to say roughly that the core energy of the dislocation loop is given by the peripheral free bonds exposed at the ends of the extra half-planes. In the other words, the core energy can be said to correspond to the side-face energy of the original cavity represented by the second term in the right side of Eq. (1).

3.3 *Criterion of Transformation*

As previously pointed out, when a polycrystalline carbon is heat-treated for graphitization each crystallite is subjected to the compressive thermal stress and the corresponding elastic strain in $\boldsymbol{c}$-direction. These stress and strain may be partly released by the collapse of the aforesaid flat cavity to the dislocation loop lying on the basal plane. The thermal strain energy owing to this mechanism, E_t, is generally given per unit volume by half of the product of the compressive stress and the constrained expansion in **c**-direction,

$$E_t=\tfrac{1}{2}\times\sigma_r(\varepsilon_r-\alpha_r \mathrm{T})\ ,$$

where the notations are used in the same way as those in the previous paper[1]. For instance, assuming T=3000−1300=1700 (°K)*, and using the expressions for the filamentarily textured polycrystal (typical soft carbon) cited in the previous paper[1], one can obtain such a radial distribution curve of the thermal strain energy as shown in Fig. 5, which indicates the maximum value, 1.87×10^8 ergs/cm^3, at the centre. Therefore, the collapse of a cavity in the neighbourhood of the central axis of the filament is expected to release the energy by

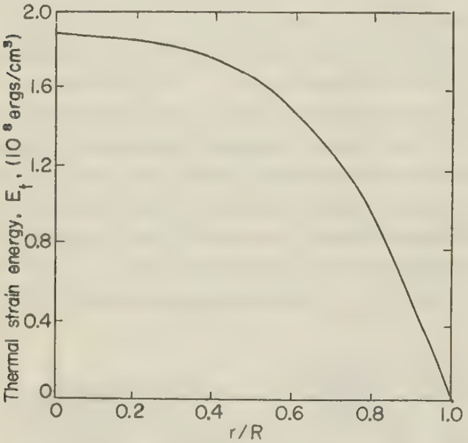

Fig. 5. Distribution curve of thermal strain energy along the radius of the "filamentary polycrystal", owing to the graphitization stress.

$$E_t\times(\text{cavity volume})=\frac{1.87}{4}\pi D^2h\times10^{-16}\quad\text{(ergs).}\tag{12}$$

Thus, the criterion of this transformation is determined by comparing the self-energy of the dislocation loop with the sum of the total surface energy of the original cavity and the thermal strain energy to be released by its collapse. It needs not to compare the free energies, for the contribution of the entropy term is so small that the difference can be neglected in approximation. Besides, as mentioned before, the core energy of the dislocation loop is nearly equal to the side surface energy of the cavity in the present case. Accordingly, one can put

(elastic energy of dislocation loop)
=(basal surface energy of the cavity)
+(thermal strain energy to be released).

Operating in c.g.s. unit, and using Eqs. (2), (5) and (12), this equality is arranged as follows,

$$\frac{Kb^2}{4}\ln\left(\frac{D_c}{2r_0}\right)=D_c(833+0.47\pi h)\times10^{-8}\tag{13}$$

where D_c represents the critical diameter (in angstroms) of the cavity-dislocation transformation. Substituting the K-factors in Table III and the proper Burgers vectors on the assumption that $r_0=3b$, the critical diameters corresponding to the six cases in the subsection 3.1 have been determined as shown in Table IV.

Table IV. Critical diameters of transformation from disciform cavities to dislocation loops, corresponding to various geometrical conditions.

Crystal modification and number of defficient planes	HEXAGONAL			RHOMBOHEDRAL		
	1	2	3	1	2	3
Critical diameter, D_c, in angstrom	225	425	1070	102	535	910

From Table IV, firstly, one can see that the aforesaid round *moiré* patterns having the diameters of several hundreds angstroms, observed by Fujita and Izui[3], correspond to the dislocation loops born of such thin cavities missing one or two atomic plance respectively. On the contrary, those thick cavities missing more than three planes may be hardly transformed to dislocation loops in the crystallite of usual artificial graphite which is seldom over thousands angstroms in diameter. Natural graphite and some special artificial ones carefully prepared may be possible to contain even such large dislocation loops, since the crystallite-size can be up to several micron. However, as mentioned in § 2, when the point vacancies and minute cavities have mostly condensed to fairly large ones, several hundreds angstroms in diameter, the driving force of cavity growth is expected to decline so remarkably that the rate of further consolidation becomes negligible, *i.e.* the state in metastable equilibrium. Accordingly, those large dislocation loops exceeding thousands angstroms in diameter may be scarcely generated except for some special treatment, *e.g.* hard quenching and radiation damage *etc.*.

---

* In this case, T denotes the difference between the graphitization and baking (solidification) temperatures.

Finally, it is worth to point out that the mechanism of cavity consolidation considered here may be applicable to the formation of the characteristic intercrystallite voids extending in nearly parallel to the basal layers. Formerly, by means of the combination of liquid displacement, gas absorption and X-ray diffraction methods, Loch and Austin[10] have evaluated the thickness of those opened voids to be ranging between 3–8 Å, which is in fairly good agreement with our supposition used in the above discussions.

§ 4. Concluding Remarks

The principal results of the preceding theoretical investigation are summerized as follows: (*1*) Through the extremely high temperature treatment for the synthesis of graphite, numerous vacancies and cavities exceeding 10^{-3} atomic per cent are introduced in several ways. (*2*) The so-called "specific free energy" of a cavity has been defined as a measure of the stability, from which it has been concluded that all the cavities and vacancies are driven to consolidate to fewer and larger ones extending on the basal planes. (*3*) In the course of the dimensional growth, the flat cavity is expected to collapse to a prismatic dislocation loop under the compressive graphitization stress in c-direction. The critical size has been determined, by comparing the energies before and after the transformation, to be ranging between, 100∼1100 Å in accordance with the geometrical conditions concerning the crystal modification and the cavity thickness, which is in fairly good agreement with the experimental observation. (*4*) The formation of the characteristic inter-crystallite voids can be explained in the similar way.

Ferroelectric Properties of X-ray Damaged Rochelle Salt

By Kenkichi OKADA

Department of Natural Science, Nagoya Branch, Aichi-Gakugei University, Nagoya

(Received October 7, 1960)

Radiation damage effects by X-ray in rochelle salt are studied experimentally and theoretically. Double hysteresis loop is explained as a superposition of two biased single loops. Each biased single loop corresponds to each of the two oppositely polarized domains, of which the crystal is composed. Single domain crystals show biased single loops when damaged, and the internal bias thus induced can be compensated by an external dc biasing field. But the Curie point of the damaged crystals compensated by this suitable external field is lower than that of the virgin by ΔT, which depends upon the X-ray dosage. In this respect the effect of damage differs from that of the stress. It is assumed that the irradiation gives rise to polar anisotropy centers which produce effective bias fields in undamaged ferroelectric regions. Irradiation time dependences of the spontaneous polarization, the coercive field and the internal bias are studied. A phenomenological theory is developed to explain the various phenomena. The polarization within the polar anisotropy center is estimated to be the order of 100 esu near the shifted Curie point.

§ 1. Introduction

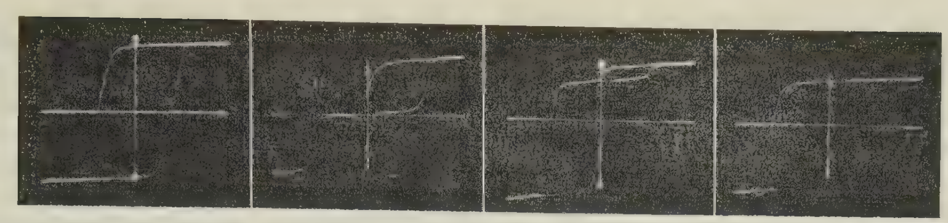
Since Vigness[1)] found coloring and disintegration in rochelle salt irradiated by X-rays in 1935, there has been no investigation on the radiation damage effects in ferroelectric substances. In 1956 Rogers[2)] observed that dielectric constant of $BaTiO_3$ is decreased and its 120°C peak disappears by pile irradiation. On the same substance several investigators[3-5)] have studied the changes of their properties by radiation damages. Recently, Lefkowitz[6)] found in $BaTiO_3$ with $PbTiO_3$ additive shifts of the Curie point and the other changes of properties due to pile irradiation. On the other hand, Iurin[7)] found double hysteresis loop of γ-irradiated rochelle salt, and Eisner[8)] observed that the dielectric constant of X-ray irradiated rochelle salt is increased by dc biasing field. Chynoweth[9)] studied in detail the same effects and time-dependent phenomena of X-ray damaged triglycine sulfate. Then several investigators gradually became interested in the field of the radiation damage of ferroelectric materials. By Krueger[10)] γ-effects of rochelle salt, by Moulton *et al.*[11)] paramagnetic resonance of X-ray damaged rochelle salt and by Toyoda *et al.*[12)] diffused scattering in X-ray photograph of a heavily γ-damaged rochelle salt have been studied.

Investigations on impure or mixed ferroelectric materials which have similar phenomena to those of damaged crystals have been reported by several authors[13-16)]. But the radiation damage of ferroelectric materials has not been studied theoretically as yet. We developed a phenomenological theory of X-ray damaged rochelle salt and made related observations. Since by the preceding study[17)] it was suggested that there are similar phenomena near the upper and lower Curie points, only the upper Curie point is considered in connection with the ferro-para transition in this report.

§ 2. Specimen and Experimental Apparatus

Specimens were A-cut plates of about $0.1 \times 1.2 \times 1.5\,\mathrm{cm}^3$ cut out from a single crystal of rochelle salt. Electrodes were gold leaves which were attached on the polished surfaces moitsend by breathing without any adhesive. During the X-ray irradiation, the specimen was held in a copper vessel, the temperature of which was kept at about 5°C, unless mentioned otherwise.

The X-ray tube had a tungsten target and a beryllium window, and was running at 40 kV and 15 mA. The electroded specimen was irradiated through two sheets of aluminium foil 0.02 mm thick each (the window of the copper vessel and the electrode of the sample holder) and a bakelite plate 1 mm thick. Hysteresis loops were obtained by means of the well-known Sawyer-Tower circuit at 60 cps on



(A) (B) (C) (D)

Fig. 1. Anomalous hysteresis loops of X-ray damaged rochelle salt crystals. (A) normal loop of the virgin. (B) symmetrical double loop. (C) asymmetrical double loop. (D) biased single loop of a damaged single domain crystal.

a cathode-ray oscilloscope. For the measurement of the dielectric constant an ac bridge of frequency 1000 cps and amplitude 5 V/cm was used.

§ 3. Hysteresis Loops of Damaged Crystal and Stressed Crystal

The hysteresis loop of a virgin crystal in in Fig. 1 (A) was changed to a double loop in Fig. 1 (B) after 3 hours irradiation. Sometimes an asymmetrical double loop shown in Fig. 1 (C) was also obtained. By application of a dc field of about 80 V/cm or of a shear stress during irradiation, the loop always became a biased single loop shown in Fig. 1 (D). When the dc field is positive the bias of the loop is negative and *vice versa*. These anomalous hysteresis loops resemble closely those of electrically or mechanically stressed virgin crystals, shown in Fig. 2.

Anomalous hysteresis loops have been found on GASH by Holden *et al.*[18)]. The shape of the loop has been correlated with the location of the specimen in the mother crystal. This anomaly of the loop may be due to an internal stress in the crystal grown in the ferroelectric state. Therefore, at a first glance, the anomalous hysteresis loops of these damaged crystals also may be considered as due to an internal stress produced by lattice imperfections. It will be, however, shown below that they can not be entirely attributed to the internal stresses, and a new mechanism will be proposed.

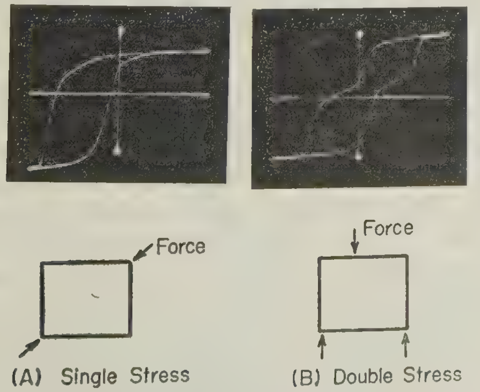


Fig. 2. Hysteresis loops of stressed crystals.

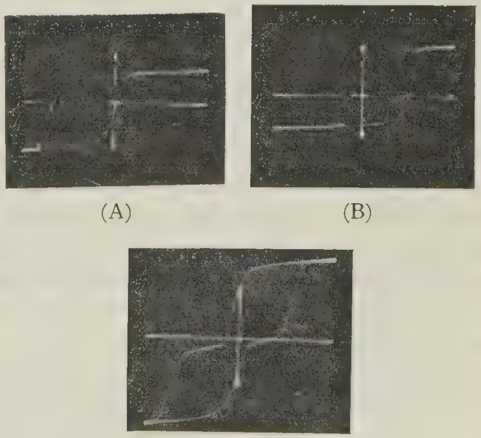
§ 4. Qualitative Explanation of Anomalous Hysteresis Loop of Damaged Crystal

It was shown experimentally that when two ferroelectric condensers showing single loops are biased in the opposite directions, as in Fig. 3 (A) and (B), and are connected in parallel, the resultant hysteresis loop becomes double as illustrated in Fig. 3 (C). This result leads us to a qualitative explanation of anomalous loops of damaged crystals, making use of the method developed by Sawaguchi *et al.*[16)] in the study of aging and double loops of $Pb_{\lambda}Ca_{1-\lambda}TiO_3$.

By the effects of radiation damage, some



(A) (B)

(C)

Fig. 3. Superposition of two biased loops. (C) is a resultant loop of two ferroelectric condensers of (A) and (B) connected in parallel.

dipoles may be stabilized in the direction of the spontaneous polarization and the crystal may be given a property to be called "polar anisotropy". When a single domain crystal which has positive spontaneous polarization under a mechanical or an electrical bias is brought into a state of positive polar anisotropy, the polarization will become difficult to reverse, and the hysteresis loop will be shifted to the negative E-direction, and *vice versa*. When a multi-domain crystal is damaged, each 180° domain is brought into a state of anti-parallel polar anisotropy. Its hysteresis loop will change into a double loop which is obtained as a superposition of two loops biased in the opposite directions. Therefore, relative height of each partial loop in the double loop will be equal to the volume fraction of each domain.

No change of the domain structure occurs by the damage, but the damage causes the impression of the domain structure in the crystal, that is, the domain walls are stabilized and becomes unable to move until a strong electric field is applied, which is a function of the degree of the polar anisotropy[17]. Recently Abe[19] also proposed a theory to explain the double loop in which the domain wall energy was taken to be a function of the position.

§ 5. Dielectric Susceptibilities *vs.* External DC Biasing Fields* of Damaged Crystal and Stressed Crystal

Fig. 4 is a plot of the dielectric constants of a damaged crystal having a double loop of Fig. 1 (B) and of a virgin crystal at temperatures from −27° to 35°C. Heights of the peaks are reduced and the transitions are blurred in the damaged crystal. Peaks are shifted slightly to get closer to each other. Outside the two peaks, the Curie-Weiss law is no longer satisfied. By applying an external dc biasing field of proper sign and magnitude, the peaks can be sharpened, clear transitions revealed, and the upper peak shifted further to low temperature and the lower peak to high temperature[17].

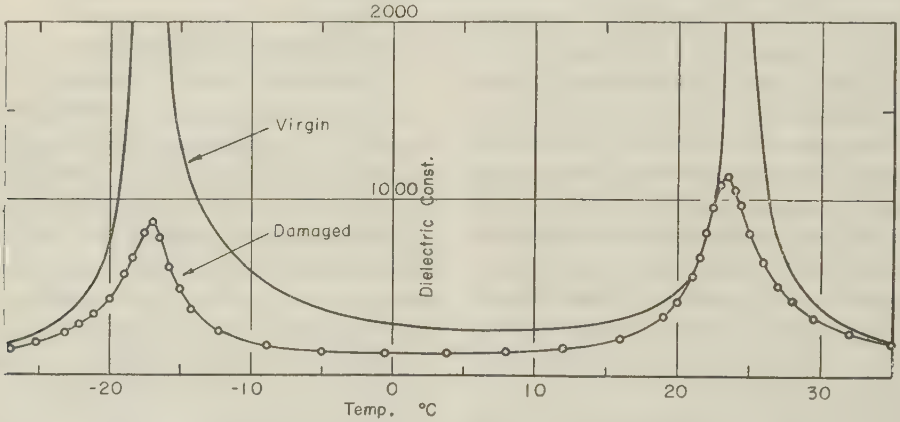


Fig. 4. Temperature dependences of dielectric constant of a double loop crystal damaged by 3 hours irradiation and that of the virgin.

In order to consider theoretically, temperature dependences of susceptibilities of bised single loop crystals and effects of the external dc biasing field on them near the upper Curie point were measured in detail. For comparison those of a stressed crystal were also measured.

(1) *Biased Single Loop Crystal*

On application of a negative external dc biasing field to a crystal having a negatively biased single loop, the clear transition reappears, and re-application of a positive field causes further blurring of the transition. Fig. 5 (A) illustrates this on a specimen having a loop of Fig. 1 (D). Under the external dc biasing field of −220 V/cm, its peak was the sharpest and the position was shifted to the lowest temperature. Negative fields stronger than this blurred the peak and shifted its position to high temperature again as shown by dotted lines in Fig. 5(A). By positive fields, only decreases in the peak height and shifts of the position to the high temperature occurred. Fig. 5(B) is the plot of the reciprocal susceptibility. Under the external biasing field of −220 V/cm, it satisfies the Curie-Weiss law, the constant of which is the same as that of the virgin crystal above the Curie point. The difference of the Curie temperature between the damaged and the virgin is about −1.3°C.

---

* "External dc biasing fiield" means a dc field superposed to the ac field in dielectric constant measurement, distingushing from "internal bias" which means a shift of the hysteresis loop.

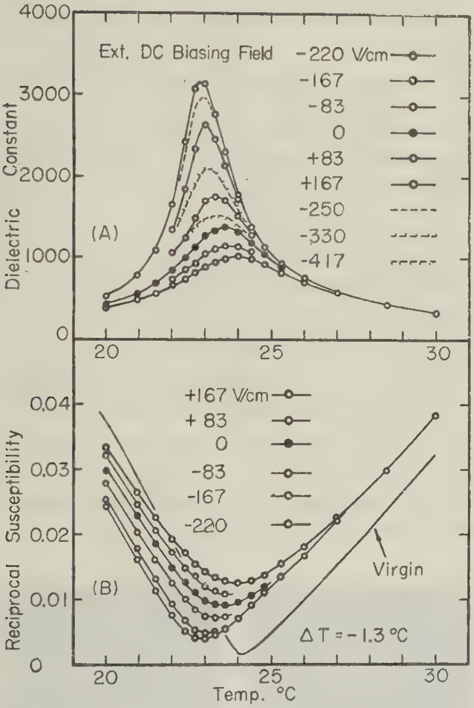

Fig. 5. Effects of external dc biasing fields on dielectric constant and reciprocal susceptibility of a biased single loop crystal damaged by 3 hours irradiation.

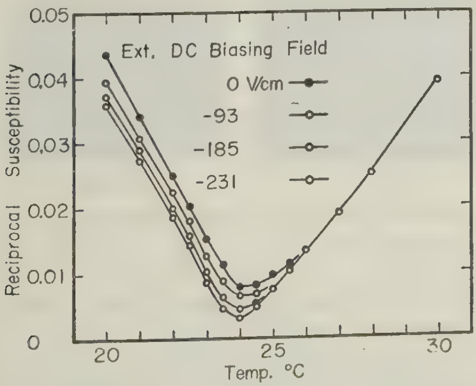

Fig. 6. Effects of external dc biasing fields on reciprocal susceptibility of a stressed crystal of Fig. 2 (A).

(2) *Comparison of Damaged Crystal and Stressed Crystal*

Fig. 6 gives effects of external dc biasing fields on reciprocal susceptibility of a stressed crystal of Fig. 2(A). The same phenomenon is found as in the damaged crystal, but one of the difference is the absence of shift of the Curie point in the case of the stressed crystal. Therefore, it turns out that the effect of radiation is not to introduce some internal stresses into the crystal. Reciprocal susceptibilities of some specimens damaged to different degrees are given as functions of the external dc biasing fields at temperatures near each Curie points in Fig. 7.

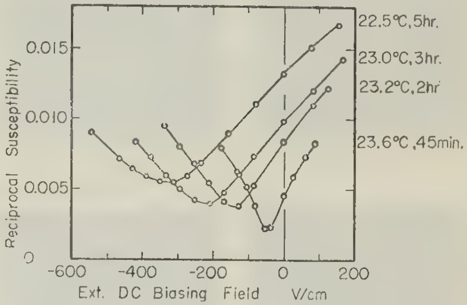

Fig. 7. External dc biasing field *vs.* reciprocal susceptibilities of various damaged crystals of biased single loops at temperatures near each minimum positions in the plot of $1/\eta$ *vs.* T as Fig. 5 (B). Irradiation time of each specimen and the temperature at dielectric constant measurement are written in the figure. Irradiation temperature is 5°C.

§ 6. Temperature Dependence of Internal Bias

Relation between the temperature and the internal bias as defined by Fig. 8 for the oscilloscope data is given in Fig. 9. The internal bias has a weak temperature dependence. Fig. 10 shows hysteresis loops at various temperatures.

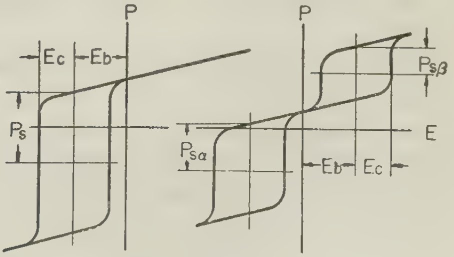

Fig. 8. Definitions of spontaneous polarization P_s, coercive field E_c and internal bias E_b.

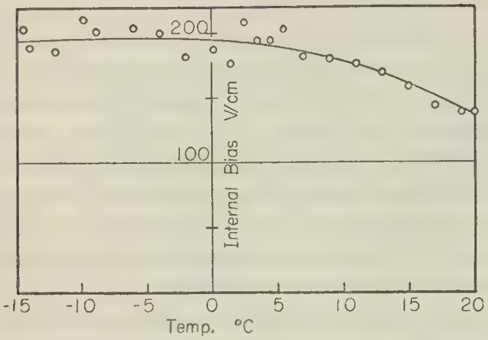

Fig. 9. Temperature dependence of internal bias obtained from oscilloscope data.

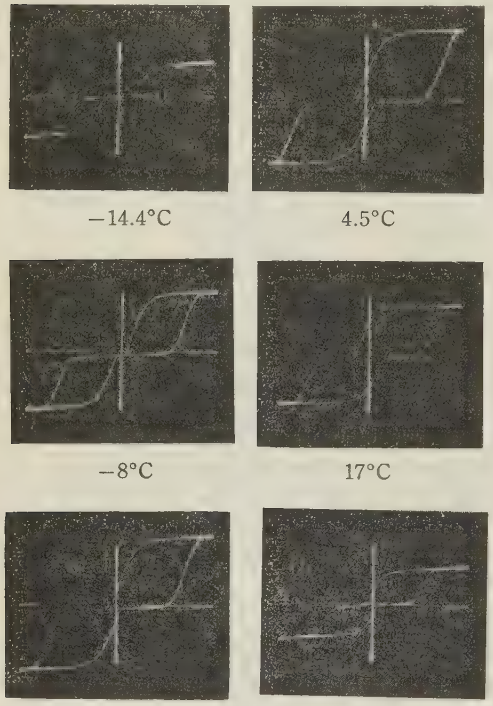

−14.4°C 4.5°C

−8°C 17°C

−2°C 21°C

Fig. 10. Variation of the shape of double loop with temperature.

§ 7. Spontaneous Polarization, Coercive Field and Internal Bias *vs.* X-ray Irradiation Time

Variation of P_s, E_c and E_b with irradiation time are given in Fig. 11 (A). No electric field was applied except an ac field of about 1 minute duration necessary for taking oscillograms. Fig. 12 shows changes of the shape of the hysteresis loop. P_s decreases slightly but steadily, E_c increases and E_b increases almost linearly with irradiation time. These features are somewhat different from those of triglycine sulfate[9]. The sweep amplitude for the loop observation was made sufficiently large in anticipation of increases in E_c and E_b.

Irradiation under influences of an ac field larger than coercive field didn't give any bias effect in the hysteresis loop. As shown in Fig. 11 (B), in comparison to the case of no field in Fig. 11 (A), P_s decreased in the same manner but the increase in E_c was more rapid.

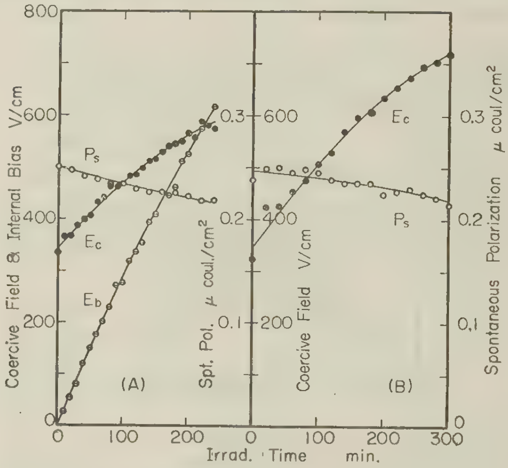

Fig. 11. Spontaneous polarization, coercive field and internal bias *vs.* irradiation time. (A) referes to irradiation without and (B) to with ac field of 2000 V/cm at about 5°C.

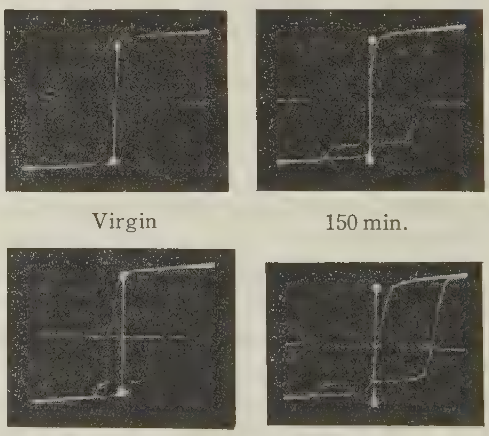


Virgin 150 min.

60 min. 240 min.

Fig. 12. Variation of the hysteresis loop with irradiation time.

This specimen damaged under the influences of the ac field had time-dependent phenomena. At the removal of the ac field there appeared a meta-stable internal bias in the loop which was annealed out gradually either by re-application of the ac field or by heating.

Crystals damaged above the Curie point had the same feature. On the other hand, the internal bias produced by irradiation without an ac field at the ferroelectric temperature region which is treated in this report is stable against electrical and thermal agitations. It seems that the spontaneous polarization which stays constant while the crystal is irradiated is necessary to obtain the permanent internal bias. These phenomena which are important for study of the radiation damage mechanism will be investigated in the near future.

§ 8. Basis for Theoretical Treatment

In order to explain the various phenomena mentioned above theoretically, we assumed, following Sawaguchi *et al.*[16)], a simple model as below.

(1) When a crystal is damaged at the ferroelectric temperature region without an ac field, some dipoles are stabilized in the direction of the spontaneous polarization, that is, polar anisotropy centers are introduced.

(2) The polar anisotropy centers show a paraelectric behavior in response to their external field.

(3) The polar anisotropy centers interact with the other ferroelectric region.

Symbols to be used are;

λ: volume fraction of the ferroelectric part in the crystal,

μ: volume fraction occupied by polar anisotropy centers, where $\lambda+\mu=1$,

P_f: polarization of the λ region,

P_a: polarization of the μ region,

P_0: polarization of the μ region without field,

P: resultant polarization of the crystal observable on the oscilloscope,

E_f: electric field of the λ region,

E_a: electric field of the μ region,

E: external field of the crystal,

k: interaction constant between the λ and μ regions,

σ: dielectric susceptibility of the μ region.

It is assumed that,

$\frac{1}{2}\chi P_f{}^2+\frac{1}{4}\xi P_f{}^4$: free energy of unit volume of the λ region,

$\frac{1}{2}\frac{1}{\sigma}(P_a-P_0)^2$: free energy of unit volume of the μ region, and

$\frac{1}{2}\lambda\mu k(P_f-P_a)^2$: interaction energy between the λ and μ regions.

Then, the free energy of a unit volume of a damaged single domain crystal U is

$$U=\lambda\left(\frac{1}{2}\chi P_f{}^2+\frac{1}{4}\xi P_f{}^4\right)+\frac{1}{2}\frac{\mu}{\sigma}(P_a-P_0)^2+\frac{1}{2}\lambda\mu k(P_f-P_a)^2\,.$$

From $\partial U/\partial P_f=\lambda E_f$ and $\partial U/\partial P_a=\mu E_a$, we obtain

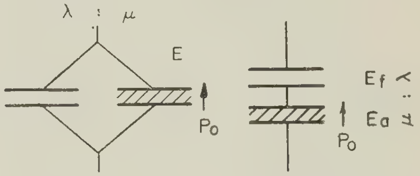
$$E_f=\chi P_f+\xi P_f{}^3+\mu k)(P_f-P_a)\,, \qquad (1)$$

and

$$E_a=\frac{1}{\sigma}(P_a-P_0)-\lambda k(P_f-P_a)\,. \qquad (2)$$

§ 9. Fundamental Formula

Since the distributions and the shapes of the two regions λ and μ in the crystal are unknown, two special cases shown in Fig. 13 are considered.



(A) Paraller Type (B) Series Type

Fig. 13. Two types of distribution of polar anisotropy centers.

(1) *Parallel Type*, Fig. 13 (A)

Polarization observed on the oscilloscope is

$$P=\lambda P_f+\mu P_a\,. \qquad (3)$$

External field is $E=E_f=E_a$. Hence, from Eq. (1) and (2)

$$\chi P_f+\xi P_f{}^3+k(P_f-P_a)-\frac{1}{\sigma}(P_a-P_0)=0\,. \quad (4)$$

Reciprocal susceptibility $1/\eta$ as a function of P_f is obtained from Eqs. (1), (3) and (4), that is,

$$\frac{1}{\eta}=\frac{dE}{d(\lambda P_f+\mu P_a)}=\frac{(1+\lambda\sigma k)(\chi+3\xi P_f{}^2)+\mu k}{\mu\sigma(\chi+3\xi P_f{}^2)+\lambda+\sigma k}\,. \qquad (5)$$

From Eqs. (1) and (4) E as a function of P_f is

$$E=\frac{1}{1+\sigma k}\left[-\mu kP_0+(\chi+\lambda\sigma k\chi+\mu k)P_f+(1+\lambda\sigma k)\xi P_f{}^3\right]. \qquad (6)$$

(2) *Series Type*, Fig. 13 (B)

From Eqs. (1) and (2)

$$E=\lambda E_f+\mu E_a=\lambda(\chi P_f+\xi P_f^3)+\frac{\mu}{\sigma}(P_a-P_0)\ . \tag{7}$$

Assuming that the boundary of the two regions has no charge accumulation, electric displacement D is $D=E_f+4\pi P_f=E_a+4\pi P_a$. Therefore,

$$D=\chi P_f+\xi P_f^3+\mu k(P_f-P_a)+4\pi P_f\ , \tag{8}$$

$$D=\frac{1}{\sigma}(P_a-P_0)-\lambda k(P_f-P_a)+4\pi P_a\ . \tag{9}$$

From Eqs. (8) and (9)

$$(\chi P_f+\xi P_f^3)+(4\pi+k)(P_f-P_a)-\frac{1}{\sigma}(P_a-P_0)=0\ . \tag{10}$$

Using Eqs. (7), (8) and (10),

$$\frac{1}{\varepsilon}=\frac{1}{1+4\pi\eta}=\frac{dE}{dD}$$

is calculated, where ε is the dielectric constant. As a result, $1/\eta$ and E are the same functions of P_f as those of the parallel type respectively, but $(4\pi+k)$ substituted for k:

$$\frac{1}{\eta}=\frac{[1+\lambda\sigma(4\pi+k)](\chi+3\xi P_f^2)+\mu(4\pi+k)}{\mu\sigma(\chi+3\xi P_f^2)+\lambda+\sigma(4\pi+k)}\ ,$$

and

$$E=\frac{1}{1+\sigma(4\pi+k)}\{-\mu(4\pi+k)P_0+[\chi+\lambda\sigma(4\pi+k)\chi+\mu(4\pi+k)]P_f+[1+\lambda\sigma(4\pi+k)]\xi P_f^3\}\ .$$

§ 10. Calculation

From the preceding section it is suggested that both the parallel and the series type distribution contribute to changes of ferroelectric properties in a similar way. So we will henceforth calculate on the parallel type only.

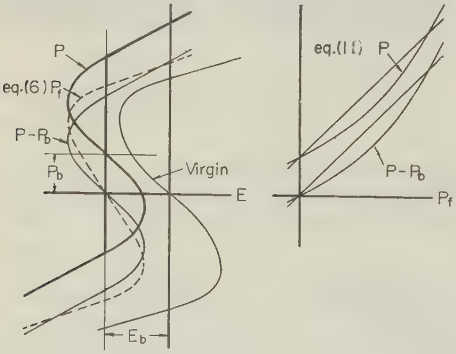


Fig. 14. Theoretical hysteresis loop of damaged single domain crystal. (schematical) E_b is the internal bias. The bias P_b is not observed by the Sawyer-Tower circuit. The coercive field may be reduced largely by the domain wall motion in the experimental result.

(1) *Hysteresis Loop of Single Domain Crystal*

Eq. (6) gives the functional relation between E and P_f. But it is necessary to represent E as a function of P, since observable hysteresis loops are E-P relations. From Eqs. (3) and (4)

$$P=P_f+\frac{\mu}{1+\sigma k}[P_0-(1-\sigma\chi)P_f+\sigma\xi P_f^3]\ . \tag{11}$$

Eqs. (6) and (11) give together the functional relation between E and P, which is illustrated in Fig. 14 schematically. The loop is biased along the E and P axes by E_b and P_b respectively, and its shape is slightly changed, where

$$E_b=-\frac{\mu k}{1+\sigma k}P_0\ , \tag{12}$$

and

$$P_b=\frac{\mu}{1+\sigma k}P_0\ . \tag{13}$$

But the bias P_b is not observed by the Sawyer-Tower circuit[20]. E_b is the internal bias.

(2) *Spontaneous Polarization*

Spontaneous polarization P_s under the external dc field equal to the internal bias of the loop is obtained as below. In Eq. (6) putting $E=E_b$,

$$\xi P_f^2=-\frac{\chi(1+\lambda\sigma k)+\mu k}{1+\lambda\sigma k}\ .$$

Substituting this into Eq. (11),

$$P_s=P-P_b=\lambda\frac{1+\sigma k}{1+\lambda\sigma k}\left[-\frac{\chi}{\xi}-\frac{\mu k}{\xi(1+\lambda\sigma k)}\right]^{1/2}\ . \tag{14}$$

Neglecting the higher order terms of μ, we obtain

$$P_s\simeq\left(-\frac{\chi}{\xi}\right)^{1/2}\left[1-\frac{1-k/(2\chi)}{1+\sigma k}\mu\right]\ . \tag{15}$$

Change of the spontaneous polarization ΔP_s is

$$\Delta P_s\simeq-P_{vs}\frac{1-k/(2\chi)}{1+\sigma k}\mu\ , \tag{16}$$

where $P_{vs}=(-\chi/\xi)^{1/2}$ is the spontaneous polarization of the virgin crystal.

(3) *Reciprocal Susceptibility and Effect of External Dc Biasing Field*

At the Curie point T_c of the virgin crystal where $\chi=0$, from Eq. (5)

$$\frac{1}{\eta}=\frac{3(1+\lambda\sigma k)\xi P_f^2+\mu k}{3\mu\sigma\xi P_f^2+\lambda+\sigma k}>0\ .$$

Therefore, susceptibility stays finite even at T_c.

In order to have infinite dielectric constant it is necessary that $dE/dP=1/\eta=0$ and $d^2E/dP^2=0$. From Eq. (5) the former condition is

$$(1+\lambda\sigma k)(\chi+3\xi P_f{}^2)+\mu k=0\,. \tag{17}$$

Differentiating Eq. (5) with respect to $P=\lambda P_f+\mu P_a$ by the aid of Eq. (11), the latter condition becomes $P_f=0$. Substituting this into Eq. (6),

$$E=-\frac{\mu k}{1+\sigma k}P_0=E_b\,.$$

Therefore, the infinite dielectric constant occurs under the external dc biasing field equal to the internal bias at the temperature satisfying the next equation. Putting $P_f=0$ in Eq. (17)

$$\chi=-\frac{\mu k}{1+\lambda\sigma k}\,. \tag{18}$$

Curie point of the damaged crystal $T=T_c+\varDelta T$ sharpened by the external field is given by means of Eq. (18) and the relation $\chi=(T-T_c)/C$, which is assumed to be satisfied just below the virgin Curie point. T_c and C are the Curie temperature and the Curie-Weiss constant of the virgin crystal respectively. That is,

$$\varDelta T=C\chi=-\frac{\mu k}{1+\lambda\sigma k}C\,. \tag{19}$$

It turns out that the Curie point is lowered by the damage. At this temperature $T_c+\varDelta T$ the spontaneous polarization vanishes from Eqs. (14) and (18). Eliminating μ from Eq. (12) and (19)

$$\frac{\varDelta T}{E_b}=\frac{1+\sigma k}{1+\lambda\sigma k}\frac{C}{P_0}\,. \tag{20}$$

(4) *Curie-Weiss Law*

From the preceding argument $\chi>-\mu k(1+\lambda\sigma k)$ above the Curie point of the damaged crystal. Then, under the external field $E=E_b$, from Eq. (6) $P_f=0$. Eq. (5) becomes

$$\frac{1}{\eta}=\frac{(1+\lambda\sigma k)\chi+\mu k}{\mu\sigma\chi+\lambda+\sigma k}\,.$$

If σ and k are assumed to be temperature independent, temperature dependency of $1/\eta$ is

$$\frac{d}{dT}(1/\eta)=\frac{\lambda}{C}\left(\frac{1+\sigma k}{\mu\sigma\chi+\lambda+\sigma k}\right)^2\,. \tag{21}$$

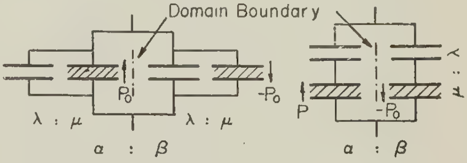
When $\lambda\simeq 1$, it becomes $d/dT(1/\eta)=1/C$ naturally.

(5) *Hysteresis Loops of Multi-domain Crystals*

As depicted in Fig. 15, volume fractions of anti-parallel 180° domians are put α (for positive P_s) and β (for negative P_s). From Eq. (12), each α and β domains have single loops biased by

$$E_b=\mp\frac{\mu k}{1+\sigma k}P_0\,,$$

respectively. Double loop is considered as a superposition of these biased single loops. Since spontaneous polarizations of both domains per unit area at $E=E_b$ are P_s given by Eq. (14), ratio of the loop heights is equal to α/β.



(A) Paraller Type (B) Series Type

Fig. 15. Distributions of polar anisotropy centers in multi-domain crystals.

§ 11. Comparison Between Experimental and Theoretical Results

(1) *Hysteresis Loop and Internal Bias*

The theoretical hysteresis loop Fig. 14 explains qualitatively the experimental result. But the bias P_b can not be observed by the Sawyer-Tower circuit, and owing to the domain wall motion the theoretical hysteresis loop may give a value of the coercive field larger than the experimental value. From Fig. 1, the ratio of heights of the two partial loops of the double loop can be considered to be equal to the ratio of the volumes of the anti-parallel domains. From Eq. (12), if μ is proportional to the X-ray irradiation time, the internal bias E_b must increase linearly with the time. Fig. 11 (A) illustrates this fact. From Eq. (12), assuming that σ and k are temperature independent constants, P_0 may have the same temperature dependency as E_b given in Fig. 9.

(2) *Shift of Curie Point and Estimation of P_0*

Ratio of the shift of Curie point and the internal bias is given by Eq. (20). It depends upon the X-ray dosage through λ. In a slightly damaged crystal $\lambda\simeq 1$, then

$$\frac{\varDelta T}{E_b}=\frac{C}{P_0}$$

at $\lambda\simeq 1$. Fig. 16 shows a relation between the shift of Curie point and the external dc biasing field which gives the sharpest peak in the plot of the dielectric constant *vs.* temperature. Four specimens have been damaged by X-ray dosages of 45 min., 2 hrs., 3 hrs. and 5 hrs. irradiations. E_b in the above equation is the internal bias (shift of the hysteresis loop). This internal bias at the Curie point could be obtained by the exterpolation of the plot of E_b-T, for example Fig. 9. But it is difficult to verify experimentally that the internal bias at the vicinity of the Curie point has the same value as the external dc biasing field which gives the sharpest peak, owing to the fact that the loop becomes slender near the Curie point and E_b is somewhat annealed by the strong ac field. From Fig. 9 the internal bias at about 23°C is suggested to be almost a half of that at 5°C. By the comparison of the external dc biasing field giving the minimum reciprocal susceptibility (shown in Fig. 7) to the internal bias at 5°C plotted in Fig. 11, taking account of the decrease in the internal bias with temperature elevation, these two values may be assumed to be equal.

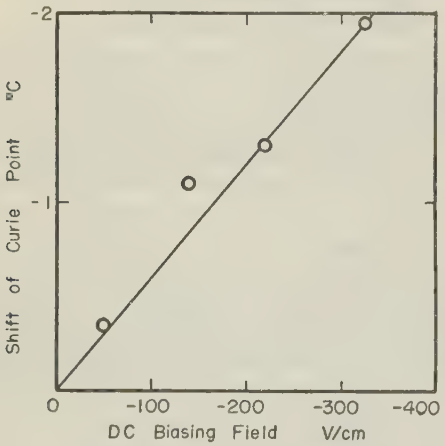


Fig. 16. Relation between the shifts of the Curie point and the external dc biasing fields which give the sharpest transitions in four biased single loop crystals damaged by various X-ray dosages.

$\Delta T/E_b=C/P_0$ is the gradient at the origin of the plot of E_b *vs.* ΔT, and may be approximately 1.8°C/esu from Fig. 16. Putting $C=178$,

$$P_0 \simeq 100 \text{ esu}\ .$$

Dipoles of this magnitude are stabilized by the irradiation, but the value may vary with temperature as mentioned at the end of the preceding subsection.

(3) *Spontaneous Polarization and Coercive Field*

From Eqs. (14), (15) or (16) the spontaneous polarization decreases by increase of μ with irradiation time. Fig. 11 (A) illustrates this fact too. The coercive field increases with the irradiation time. It may be suggested that some lattice imperfections introduced by irradiation prevent the domain wall motion, so that the coercive field is increased.

(4) *On the Quantities μ, σ and k*

In Eq. (21) $\lambda=1-\mu\simeq1$ is necessary for $d/dT(1/\eta)=1/C$ above the Curie point. Curve of $1/\eta$ against temperature under a suitable external dc biasing field is parallel with that of the virgin as shown in Fig. 5. Then, it is suggested that $\lambda\simeq1$ or $\mu\ll1$ in a crystal damaged by such a dosage of irradiation.

From Eqs. (12), (16) and (19) σ and k may be represented by the known quantities and their numerical values may be estimated. Eliminating λ and μ from Eqs. (12) and (19),

$$\frac{1}{\Delta T}=\frac{P_0}{C}\frac{1}{E_b}+\frac{\sigma}{C}\ .$$

From the experiment the linear plot of $1/\Delta T$ *vs.* $1/E_b$ intersects with $1/\Delta T$ axis near the origin, and σ may be considered to be small in comparison with $C=178$. For these estimations a more abundant experimental data are necessary, which are left for the future study.

§ 12. Summary and Discussion

X-ray damage effects in rochelle salt were studied, and a phenomenological theory was developed. Main results are as follows:

(1) X-ray irradiation at the ferroelectric temperature region gives rise to internal bias in the single domain crystal. The hysteresis loop is biased in the E-direction. The ferro-para transition is blurred. These properties resemble those of the externally biased virgin crystal.

(2) This internal bias can be compensated by a suitable external dc biasing field. The dielectric constant is thereby increased and the transition is sharpened again.

(3) There are some effects which are not compensated by the external dc biasing field. The Curie point of the damaged crystal sharpened by the suitable external dc field is lower than that of the virgin crystal. The shift of of the Curie point increases with the irradiation time. The spontaneous polarization is reduced, and the coercive field is increased by the irradiation. Therefore, in comparison with the externally stressed virgin crystal, the ra-

diation damage does not only introduce the internal bias, but also gives rise to a new type of imperfection in the crystal which is treated in the theoretical investigation.

(4) The internal bias increases linearly with irradiation time, and has a weak temperature dependence.

(5) By the irradiation the domain structure is impressed in the initial structure which the crystal possessed before the irradiation. The multi-domain crystal shows double hysteresis loop, which is explained as a superposition of two single loops biased in the opposite directions.

(6) Irradiation under the influences of a strong ac field dose not give rise to any permanent internal bias, but increases in the coercive field occur. Crystals damaged above the Curie point have the same feature.

(7) A phenomenological theory can explain successfully most of the above phenomena. The theory assumes a simple model, that is, some dipoles are stabilized in the direction of the spontaneous polarization by the irradiation, which act as polar anisotropy centers. The region occupied by the centers shows a paraelectric behavior in responce to its external field, and interacts with the other ferroelectric region. The value of this stabilized polarization is estimated to be about 100 esu near the shifted Curie point, and is suggested to have the same weak temperature dependence as that of the internal bias.

The present author wishes to express his sincere thanks to Professor T. Nakamura for the kind guidances and encouragements, to Dr. E. Sawaguchi and Dr. R. Abe for their valuable discussions, and to Mr. K. Toyoda for the helpful informations.

An Effect of Heat Treatment on WO_3 Single Crystal

I. Various Patterns

By Tadao HORIE and Tsuruji IWAI

Faculty of Science, Osaka University

(Received October 31, 1960)

After having been heated in vacuum with or without metallic vapor at a reduced pressure, WO_3 single crystals show various patterns, that is, a pattern composed of green stripes, a bluish splashed pattern, a pattern of dark lines, and so on. Each of them has its own habits of orientation with respect to the crystal axes as well as of color. Which type of these patterns does come out entirely depends on the condition of heat treatment.

§ 1. Introduction

Much attention has recently been payed by many authors to pretty but tiny pieces of WO_3 single crystals, especially because of an expectation for its being a ferroelectric or antiferroelectric substance.[1)-3)] A good many elaborate works have so far been devoted to measurements of a variety of physical properties, including the X-ray analysis of the crystal structure[4)-11)], the dielectric constant,[12)] the electrical resistivity,[2),10),13)] the optical absorption threshold,[14),15)] the indices of refraction,[16)] the heat capacity,[2)] the thermal expansion coefficient,[9),17)] the domain structures,[10),18)-21)] the Hall constant,[13)] the thermoelectromotivity,[2)] and so on.

However, its high electrical conductivity above room temperature and its volatility at still higher temperatures seem to have prevented its various important characteristics from being disclosed. For instance, its semiconductive behavior blinds the intrinsic dielectric property of the crystal. The temperature dependence of the optical property is also obscured by its sublimation character.

In addition to these circumstances, another strange and complicated phenomenon will be presented here in brief. Roughly speaking, the WO_3 single crystal has a perovskite structure modified from the $BaTiO_3$ one, the W ion being put in place of the Ti, and the site of the Ba ion being left unoccupied. The O_6-octahedra, therefore, are sharing corners with one another throughout the crystal. The crystal has several transition points near −40°, 17°, 330°, 740° and 910°C. After having been heated in vacuum or in metallic vapor at least above its monoclinic-orthorhombic transition temperature (330°C), it shows various patterns in dependence on the condition of heat treatment.

After the crystal has been heated in Zn vapor, it exhibits a pattern composed of a lot of obliquely crossed green stripes. When Na vapor is used instead of Zn, a bluish splashed pattern appears. When the crystal is heated high enough in vacuum without metallic vapor, another type of pattern comes out in the crystal. All of them are obviously different from the well known domain structure patterns of WO_3. Which one of these types of pattern does occur entirely depends on the condition of heat treatment. However, the methods of crystallization have no influence upon this phenomenon, so long as the specimens are grown from the vapor phase.

§ 2. Preparation of Specimens

The specimens used were mostly thin plate-like c-crystals, about $500 \times 500 \times 50\,\mu$ in size. They were grown in crystalline form by condensation of the vapor on a comparatively cold surface. The principle of this method has already been described in detail.[14)]

The powder materials of tungsten trioxide were obtained from both American and Japanese chemicals companies. In order to heat the powder above 1000°C, either kryptol furnaces or siliconite ones were utilized. Fused quartz and platinum crucibles were used with success.

Various combinations of the crucibles, the furnaces, and the powders supplied by different makers were tested. The average size of the crystals produced is more or less dependent on the details of the crystallization procedures. However, the phenomenon which will be described in the present paper is entirely independent of them, as far as the condensation methods are concerned.

§ 3. Green Stripes

Either a fused quartz or a hard glass tube of 1 cm diameter and 20 cm length is set horizontally. One end is fused and the other is connected to a pumping system via a stopcock. The tube contains a number of WO_3 single crystals near the closed end, and a small boat made of hard glass with a piece of zinc metal on it, the latter being a few cm apart from the closed end. When the tube is evacuated, and then heated up to near 400°C by an electric heater wound around it, the vapor pressure of Zn is estimated at about 10^{-1} mmHg.

The crystals prepared by the way mentioned in the last section are transparent and yellowish. After they have been heated up to about 400°C in the atmosphere of Zn vapor, and then cooled down to room temperature, microscopic observation reveals that many of them have green patterns as shown in Photo. 1.

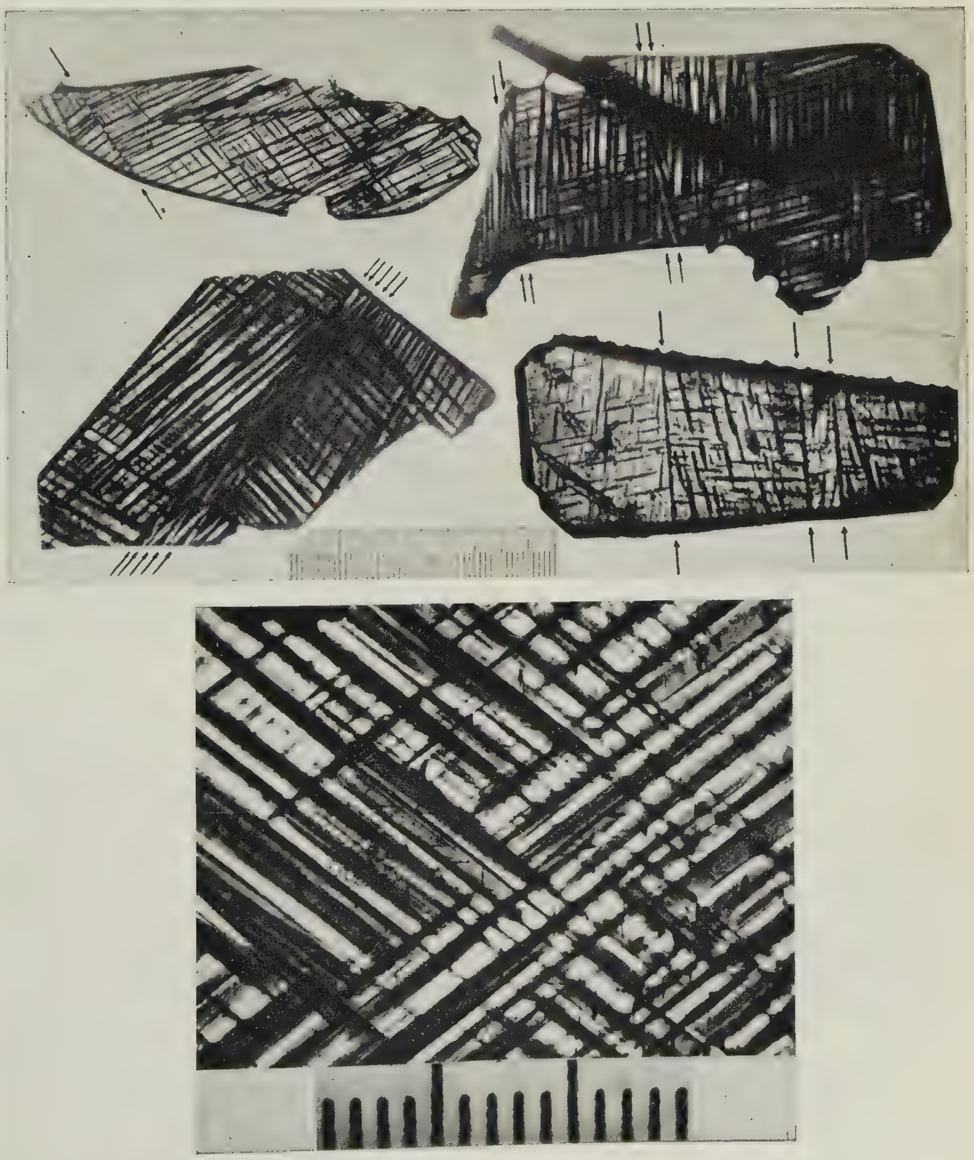

Photo. 1. Patterns of green stripes induced by Zn vapor in thin crystals of WO_3. Arrows indicate *a-b* domain boundaries. (10^{-2} mm/div.)

The pattern is composed of a number of obliquely crossed green stripes against the yellowish background. These stripes appear sometimes thickly and sometimes thinly. The color of the stripes is sometimes dark green and sometimes light green. These variations seem to be due to the experimental conditions, that is to say, the pressure of the metallic vapor, the thickness of the crystal, the duration and the maximum temperature of the heating procedure.

However, several regularities may be pointed out as follows. The pattern is always composed of two groups of green stripes. Each of these groups takes a definite orientation with respect to the crystal axis, or the domain boundary of the monoclinic phase. As depicted in Fig. 1, one encounters the domain boundary at an angle of 8°, and makes an angle of 37.5° with the *a*-axis of the crystal. The other meets the domain boundary at an angle of 83°, and crosses the *a*-axis at an angle of 37.5°. These groups intersect each other at an angle of 75°. So far as these angles are concerned, such patterns in any adjacent domains form mirror images of each other with respect to the boundary wall between them, as shown in Photo. 2.

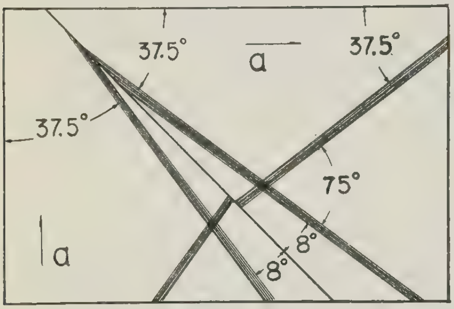

Fig. 1. Schematic drawing of green stripes and a a-b domain boundary in the c-plane.

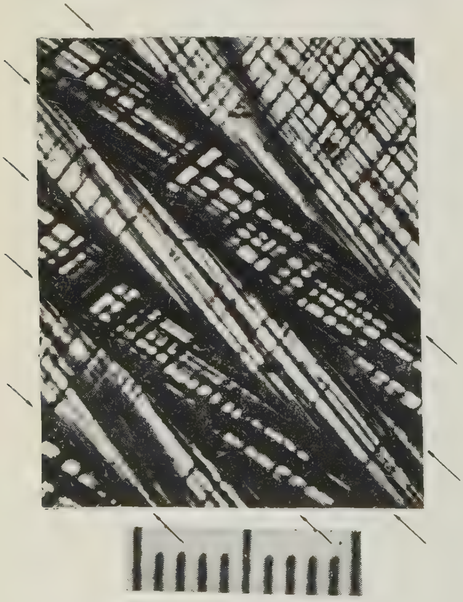

Photo. 2. Green stripes and a-b domain boundaries indicated by arrows in a thin crystal of WO_3. (10^{-2} mm/div.)

Both edges of a stripe are sharply defined, while both ends of the stripe fade out gradually. The stripe seems to be quite a thin band in the interior of the crystal. One of the band edges is located near the top surface of the crystal, while the other near the bottom surface. The inclination of the plane of the band is estimated at about 50° to the crystal surface (c-plane). Furthermore, it has often been recognized that some band has a fine

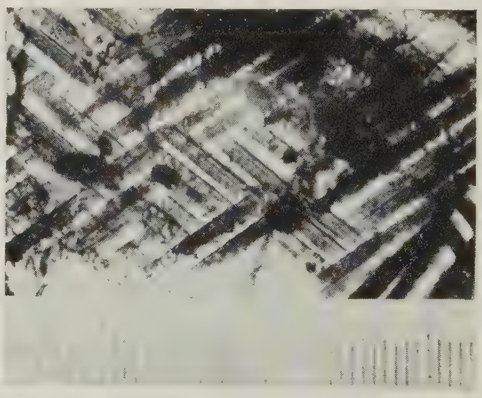

Photo. 3. Fine structure of green stripes in a thin crystal. (10^{-2} mm/div.)

Photo. 4. Green stripes in a thick crystal. (10^{-2} mm/div.)

structure composed of several lines parallel to the band edge, as shown in Photo. 3.

In the previous paper,[14] it has been reported that the same pattern was observed only by heating the crystal in vacuum. At that time, the experiment was done with the aid of a vacuum vessel fitted with a platinum heating coil within it. There was a brass joint connecting the platinum wire with a copper rod in vacuum. Metal vapor which must have had emerged from the joint as a result of current flow was entirely overlooked. According to a series of the later experiments, Zn vapor is essentially necessary for inducing such a pattern of obliquely crossed green stripes in the crystal.

It is, however, too soon to make a plausible decision about the reason why the pattern comes out. Needless to say, any definite conclusion should be preceded by much more detailed studies from all angles on the characteristic property of the pattern. Some informations about its peculiar behavior are being prepared to be published in Part II.

By the way, another type of stripes could occasionally be observed especially when thick crystals were tested. They are quite similar in shape and color to the ordinary ones, as shown in Photo. 4. However, the angle between the stripe of this type and the crystal axis is somewhat different from those mentioned above. Even when there had been no indication directly after the end of heat treatment, some stripes could be detected one or two days later.

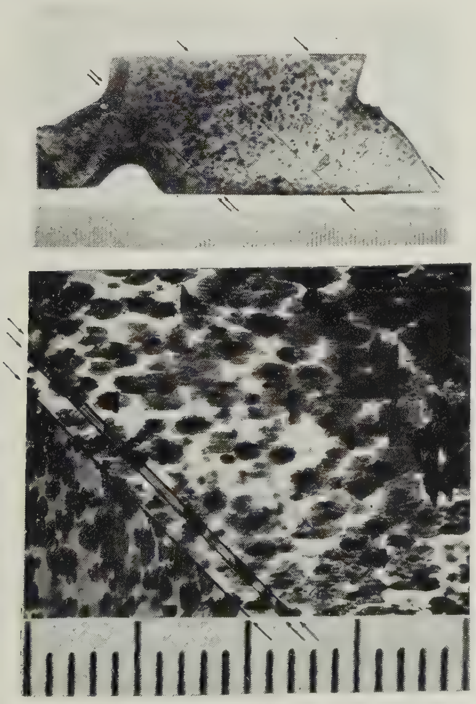

Photo. 5. Splashed patterns induced by Na vapor in WO_3 single crystals. Arrows indicate *a–b* domain boundaries. (10^{-2} mm/div.)

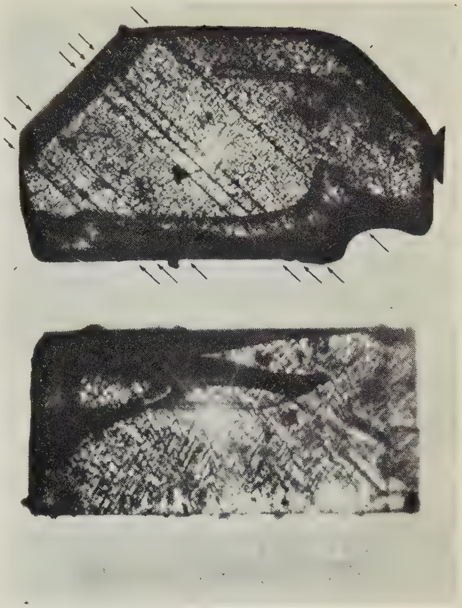

Photo. 6. Dark lines induced in WO_3 single crystals by heating in vacuum at higher temperatures. Arrows indicate *a–b* domain boundaries. (10^{-2} mm/div.)

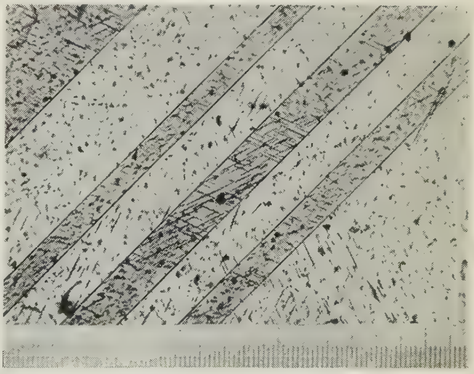

Photo. 7. Dark lines and *a–b* domain boundaries in a specimen placed between Nicols. (10^{-2} mm/div.)

§ 4. Splashed Pattern

If the crystal is treated just in the same way as above in the atmosphere of Na vapor instead of Zn, it shows a complete change in color from yellow to grass green, and besides a quite different kind of pattern is observed in it, as shown in Photo. 5. It resembles a splashed pattern composed of a lot of more or less blurred touches made with a brush in parallel with either the *a*- or *b*-axis of the crystal. These touches are all more or less different in color and in shade both from each other and from the background. Some ones are light greenish blue, and some ones dark blue gray. In addition, the pattern seems to be limited to the crystal surfaces in contrast to the green stripes mentioned in the last section.

Magnéli and others have already performed the X-ray analyses of the structures of the alkali tungsten bronzes Na_xWO_3, where x is larger than 0, and less than 1.[22] The crystal structure is monoclinic for x less than 0.1, tetragonal for $0.1<x<0.3$, and so on. According to many other investigators, WO_3 has also a monoclinic structure at temperatures ranging from 17 to 330°C. On the other hand, according to Straumanis, the color of Na_xWO_3 changes from grass greenish to brighter blue gray, dark blue gray, blue to blue black, violet, red, orange, and yellow, with increasing value of x.[23]

These evidences may lead to an expectation that the splashed pattern might be due to diffusion of a minute amount of Na vapor into the interior of the crystal just near the surfaces. Such an expectation may also be supported by the experiment done by Brown and Banks[24]. They have shown that the alkali tungsten bronzes can be prepared by the powder phase reaction, as a result of heating an evacuated Y-shaped hard glass tube with WO_3 powder in one of the closed ends and with Na metal in the other.

When the crystal with such a pattern in it is heated in the air atmosphere, the crystal turns yellowish, that is, it recovers its original tint, only some traces of the pattern being left visible faintly.

Other metals such as Hg, Cu, and Pb failed to induce any pattern, partly because the equipment used was not suitable for maintaining the vapor of these metals at a desired pressure.

§ 5. Dark Lines

When the crystal is heated as high as about 610°C in a vacuum vessel without any metallic vapor, it turns blue uniformly, and at the same time a number of dark lines crossing obliquely appears in it as shown in Photo. 6. When the crystal is picked out of the vacuum vessel into the air atmosphere, and heated again with a coal gas burner, or a nichrome furnace, it recovers its original tint, while the dark lines remain unchanged against the yellowish background.

These dark lines are rather short compared to the green stripes described above. In addition, these lines seem to be limited to the crystal surface in contrast to the green stripes. As far as a single domain is concerned, they run in the two definite orientations with respect to the crystal axes. They make an angle of either 19° or 71° with the *a*-axis, and intersect each other at an angle of about 52°. Qualitatively speaking, this habit is analogous to that of the green stripes, but they are clearly different from each other as regards the numerical values of their characteristic angles.

In any case, taking a look at Photo. 7, it is readily seen that such a pattern of dark lines in any domain and a similar one in its adjacent domain are symmetric in orientation to each other with respect to the boundary line between the two domains.

When the crystal was heated in vacuum at still higher temperatures than 720°C, dark lines appeared so densely that the crystal turned completely black and no patterns were distinguished.

In conclusion, the authors wish to express their sincere thanks to Professor S. Sawada of Tokyo Institute of Technology for his kind arrangements for the preparation of specimens. The authors are also indebted to the Scientific Research Fund of the Ministry of Education for financial aid.

Magnetic Properties of Intermetallic Compounds in Iron-Germanium System: $Fe_{1.67}Ge$ and $FeGe_2$

By Kō YASUKŌCHI, Kazuo KANEMATSU

Department of Physics, College of Science and Engineering,
Nihon University, Tokyo

and Tetuo OHOYAMA

Department of Physics, Faculty of Science,
Tokyo Metropolitan University

(Received November 5, 1960)

The magnetic properties of the two intermetallic compound β phase ($Fe_{1.67}Ge$) and δ phase ($FeGe_2$), in Fe-Ge system, were investigated. The β phase has $B8_2$ type of crystal structure and is ferromagnetic with the Curie point 485°K, saturation magnetization at 0°K $1.59\,\mu_B$, and paramagnetic moment $3.14\,\mu_B$ per iron atom. The δ phase has C16 type of crystal structure and exhibits a parasitic ferromagnetic behavior in which the Néel point, asymptotic Curie point, saturation magnetization at 0°K, and paramagnetic moment are 190°K, +90°K, $0.11\,\mu_B$, and $2.43\,\mu_B$, per iron atom respectively. Brief discussions on the magnetic structures were given.

§1. Introduction

Recently, we have studied the magnetic properties of intermetallic compounds in the binary systems consisting of iron group transition metals and IVb group elements in the periodic table; Mn-Ge[1], Mn-Sn[2], and Fe-Sn[3]. In the present study, we took up the system of iron-germanium and have carried out some magnetic measurements on the intermetallic compounds of this system. According to the phase diagram adopted by Hansen[4] on the basis of Ruttewit and Masing's work, there are two intermediate phases in the iron-germanium system, i.e. β phase about a composition of 40 at. % Ge and δ phase about a composition of 70 at. % Ge. The crystal structures of these phases have been determined by Laves, Wallbaum[5] and Castelliz[6] to be $B8_2$ (Ni_2In) type for the β phase and C16 ($CuAl_2$) type for the δ phase. No investigations, however, have been made on the magnetic properties of the alloys of this system. According to our investigations[2),3)], the compounds Mn_2Sn and Fe_2Sn, which have the same ($B8_2$) type of structure as the β phase are ferromagnetic, while the compounds $MnSn_2$, $FeSn_2$, and $CoSn_2$, which have the same (C16) type of structure as the δ phase, are not ferromagnetic but antiferromagnetic for the former two and paramagnetic for the last one. Thus, the magnetic properties of the both phases in this system are interesting in relation to those compounds with the same crystal structure. In this paper, will be reported the existence of a ferromagnetism in the β phase and a parasitic ferromagnetism in the δ phase as well as brief discussions on their magnetic structures.

§ 2. Preparation of Specimens and Experimental Method

As seen from the phase diagram, both phases have considerable ranges of homogeneity. To avoid the precipitation of other phases at room temperature, we choose within the homogeneity ranges the compositions Fe_5Ge_3 ($Fe_{1.67}Ge$) and $FeGe_2$ as representatives of β and δ phases respectively. The preparation of the specimens was as follows: Powders of electrolytic iron (99.9%) and pure germanium (seven-nine purity) were mixed at the desired proportions, and the mixtures were charged in alumina crucibles, sealed in evacuated silica tubes, and melted at 1300°C. Finally, after homogenized for several hours at 800°C, they were quenched into water. The specimens thus obtained were examined by an X-ray diffractometer to ascertain their crystal structures. The temperature dependences of the magnetizations of these specimens were measured from the liquid oxygen temperature up to 900°K, under a field of 7.5 kilo-oersteds, by means of a pendulum magnetometer in their ferromagnetic region, and also by means of a magnetic torsion balance in their paramagnetic region. In both apparatus the magnetization was determined by measuring the forces exerted on the specimens placed in an inhomogeneous field.

§ 3. δ phase

For $FeGe_2$ of the δ phase, the temperature dependences of the magnetization σ_g and the reciprocal of the magnetic susceptibility χ_g at higher temperatures are shown in Fig. 1. As seen in the figure, the phase is feebly ferromagnetic at low temperatures. This feeble ferromagnetism appears to be associated with the antiferromagnetism exhibited by the isotypic compounds $FeSn_2$ and $MnSn_2$, and is to be classified under parasitic ferromagnetism. The small value of the saturation magnetization as well as the concavity of the $1/\chi_g - T$ curve of this specimen is in line with this proposal. Further support will be seen below.

The saturation magnetization at absolute zero of temperature is estimated to be 3.15 cgs emu/g, corresponding to $n_f = 0.11$ Bohr magnetons per iron atom. The Néel point was determined to be 190°K by plotting σ_g^2 against T and extrapolating the part with steepest slope to the temperature axis. The asympotic Curie point and the effective Bohr magneton number per ion atom n_p determined from the straight part of $1/\chi_g - T$ curve is 90°K and 2.43, respectively. The X-ray diagram for our specimen could be interpreted by assuming a tetragonal, C16 ($CuAl_2$) type of structure, with the lattice parameters $a = 5.91_1$Å, $c = 4.96_2$Å and $c/a = 0.839$, which is in fair agreement with Wallbaum's results[5)]. The density 7.36 g/cm³ measured by a picnometer gave 3.82 formula weights of $FeGe_2$ per unit cell.

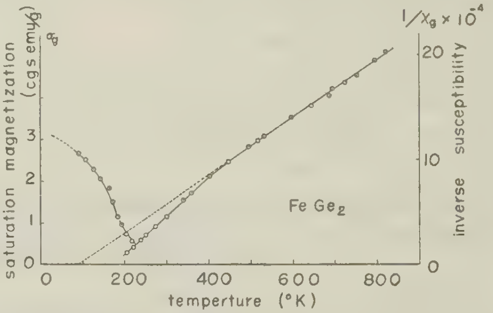

Fig. 1. Magnetic property of $FeGe_2$. Dependences of saturation magnetization and inverse susceptibility on temperature.

Now, we shall give some considerations on the magnetic structure of this compound. As in the case of $MnSn_2$[2)], the whole lattice of the magnetic atom is classified into two crystallographically equivalent sublattices specified by antiparallel spin orientations. Assuming that the spin moments of every iron atom $S = 1$, and Landé factor $g = 2$, n_p is calculated to be 2.82, which may be compared with the experimental value 2.43. Further assumption that the 0.18 vacant sites of iron are distributed only in one of the two sublattices leads to a value $n_f=0.095$, as the uncompensated magnetic moment per iron atom, which is very closed to the experimental value 0.11. Thus the parasitic ferromagnetism of the compound may be considered to come from the destruction of the perfect compensation of spin moments in an otherwise antiferromagnetic substance by vacant sites in the crystal lattice.

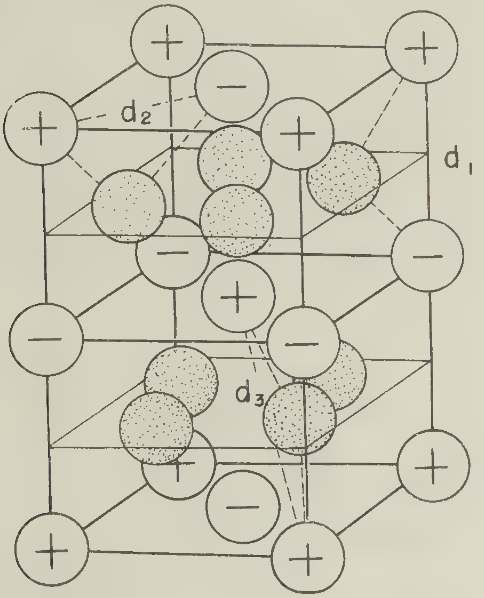

Fig. 2. Crystal structure of δ phase in Fe-Ge system (C16 type) and proposed spin arrangement. Spotted circle: Ge; open circle: Fe. $d_1=2.48$Å, $d_2=4.18$Å, and $d_3=4.86$Å in $FeGe_2$.

Fig. 2 shows the structure of the compound together with the antiferromagnetic spin arrangement which underlies its parasitic ferromagnetism. The nearest neighbor Fe-Fe distances and the angles of Fe-Ge-Fe are 2.48Å and 59° for the pairs of iron atoms along the c axis (first neighbor), 4.18Å and 112° along the face diagonals (second neighbor), and 4.86Å and 148° along the body diagonals (third neighbor).

Now we introduce a positive superexchange interaction between iron atoms through a germanium atom, similar to those proposed by us in manganese-tin alloys[2]. The interaction in the present compound is considered to be stronger than in manganese-tin, because the nature of bonding of germanium is more covalent than that of tin. Then, the magnetic structure may be considered to be as follows: Between the first neighbor iron atoms, the direct interaction may be assumed to be negative and superior to the superexchange interaction through germanium atom, to which the angle of Fe-Ge-Fe may be unfavorable. On the other hand, between the second and the third neighbors, the positive superexchange interaction may be dominant. If the interactions between the first and the third neighbors overshadow that between the second neighbors, the spin arrangement shown in Fig. 2 will be realized in the compound, and, as has been mentioned, the partial failure of this spin arrangement may be localized at the vacant sites in one of the two sublattices, giving rise to the parasitic ferromagnetism of the δ phase.

§ 4. β phase

In the composition of Fe_5Ge_3 ($Fe_{1.67}Ge$) of the β phase, a new ferromagnetic material was found. The saturation magnetization and the reciprocal of the values of the magnetic susceptibility above the Curie point are plotted against temperature in Fig. 3. The σ_g-T curve is similar to that of a typical ferromagnetic substance. It is shown that, near the Curie point, the $1/\chi_g-T$ curve is convex against temperature axis, and that the Curie-Weiss law holds very well at higher temperatures. The saturation magnetization σ_0 at absolute zero of temperature, extrapolated from the σ_g-T curve is 89 cgs emu/g, which corresponds to 1.59 Bohr magnetons per iron atom. The Curie point T_C determined from $\sigma_g{}^2-T$ curve by extrapolation is

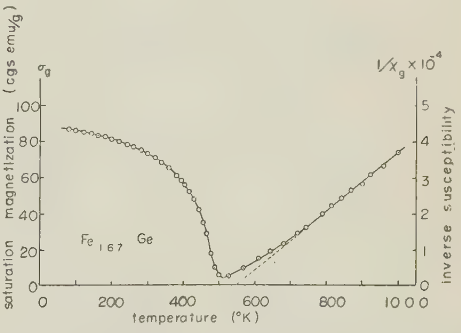

Fig. 3. Magnetic property of $Fe_{1.67}Ge$. Dependences of saturation magnetization and inverse susceptibility on temperature.

485°K. The paramagnetic Curie point θ_p and the effective number of Bohr magnetons per iron atom, which are determined from the linear part of $1/\chi_g - T$ curve, are 540°K and 3.14, respectively.

As examined by an X-ray diffractometer, the specimen of Fe$_{1.67}$Ge used in this study had B8$_2$ type of structure with lattice parameters $a=4.02_1$Å, $c=5.02_7$Å and $c/a=1.25_0$, in accordance with Castelliz, Laves and Wallbaum. And the measured density 7.93 g/cm^3 gives $2.01 \approx 2$ formula weights of Fe$_{1.67}$Ge per unit cell. Then the atomic arrangement in the lattice points is determined by the intensity analysis of the X-ray diagram to have the same feature as that of Mn$_{1.77}$Sn[7], namely,

2 Fe in 2(a) 0, 0, 0; 0, 0, 1/2;
2 Ge in 2(c) 1/3, 2/3, 1/4; 2/3, 1/3, 3/4;
1.33 Fe in 2(d) 1/3, 2/3, 3/4; 2/3, 1/3, 1/4.

It is seen in Table 1 that the intensities of diffraction lines calculated on the basis of this arrangement are consistent with those measured for our specimen. Thus, as shown in Fig. 4, the whole lattice of the compound can be divided into two sublattices; sublattice A consisting of 2(a) (spotted circle), and B consisting of 2(c) and 2(d) (open circle), which are not crystallographically equivalent to each other.

Table I. X-ray diagram of Fe$_{1.67}$Ge

hk. l	observed		calculated	
	$10^3 \sin^2\theta$	I	$10^3 \sin^2\theta$	I
10.0	—		48.92	0.0
10.1	—		72.38	5.7
00.2	93.9	2.5	93.91	3.9
10.2	142.9	34	143.0	63.1
11.0	146.6	26	147.4	71.3
20.0	—		196.4	0.0
20.1	—		219.9	1.1
11.2	—		241.2	0.0
20.2	291.7	7	290.3	21.0
21.0	—		343.7	0.0
21.1	—		367.2	0.5
21.2	439	6	437.6	23.9
30.0			441.9	14.9

Now we assume the magnetic moments of individual iron atom to be those corresponding to the following spin quantum numbers:

$S=1$ for 2 Fe in A sublattice
$S=1/2$ for 1.22 Fe in B sublattice.

Then n_f and n_p^2 may be calculated from these values as the weighted means of gS and $S(S+1)g^2$, giving 1.60 and $(2.45)^2$ respectively, which agree with the experimental values mentioned above.

From a point of view of molecular field theory, the interactions among the magnetic atoms can be described by three coefficients, α, β and γ, which denote the interactions within A sublattice, within B sublattice, and between the two sublattices, respectively. In view of the feature of the $\sigma_g - T$ curve and the convexity of the $1/\chi_g - T$ curve of the β phase, all the interactions α, β and γ may be considered to be positive (ferromagnetic). Assuming the existence of the same kind of indirect interaction as in the case of the δ phase besides the direct one, the three positive coefficients of interaction may be understood as follows: The interaction within A sublatice, α, consists of direct interations between the nearest neighbor iron atoms, which are 2.51Å apart, and of the indirect interactions between second and third neighbors, which are 4.02Å and 4.77Å apart and

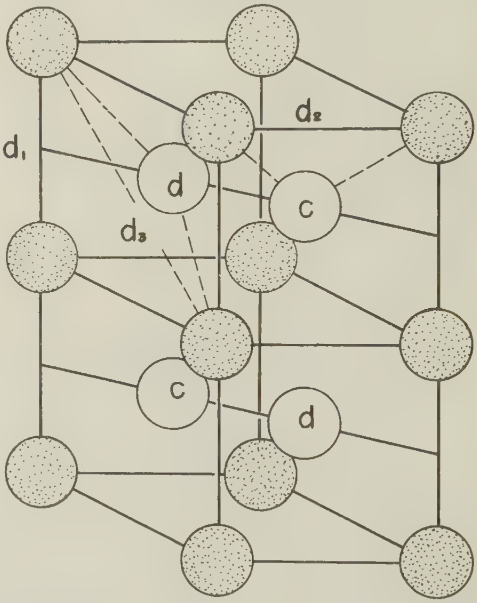

Fig. 4. Crystal structure of β phase in Fe-Ge system (B8$_2$ type). Spotted circle: A sublattice (2(a) site). Open circle: B sublattice (c and d mean 2(c) and 2(d) sites respectively). $d_1=2.51$Å, $d_2=4.02$Å, and $d_3=4.77$Å in Fe$_{1.67}$Ge.

make angles Fe-Ge-Fe of 99° and 128° respectively. Though the Fe-Fe distance which is nearly equal to d_1 in the δ phase (Fig. 2) may lead to a negative direct interaction, it may be probable that, in favor of Fe-Ge-Fe angles, the positive indirect interactions are strong enough to overcome it. Next the interaction within B sublattice, β, is purely due to the superexchange interaction between iron atoms through intervening germanium atom, which is 2.32Å apart from both iron atoms and makes angle of Fe-Ge-Fe 120°. Finally, as to the interaction between the two sublattices, γ, the corresponding Fe-Fe distance is 2.64Å, and it can be considered that the positive superexchange interaction, here again, plays an important role, making the resultant interaction fairly strong positive one.

The authors wish to express their hearty thanks to Prof. S. Iida of Tokyo University and Prof. R. Kimura of Tokyo Metropolitan University who gave them an oppotunity to use the facilites to achieve the work, and are also indebted to Shindengen Electric Manufacturing Co., Ltd. for kindness in supplying germanium metal.

Magnetic Properties of Perovskites Containing Strontium, II. Lanthanum-Strontium Manganites.

By Hiroshi WATANABE

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai.

(Received November 19, 1960)

Magnetic and crystallographic properties have been studied of the system $(La_{1-y}Sr_y)MnO_x$ with varying values of y and x. It is found that the compounds with $y=1$ crystallize in the perovskite-like structures provides that x is lower than a certain limit. Perovskite-like $SrMnO_x$, containing both Mn^{3+} and Mn^{4+} does not show any spontaneous magnetization above the liquid nitrogen temperature, and their paramagnetic Curie temperature is negative, in contrast with the well-known ferromagnetic behavior observed in La-rich manganites. Hence in these compounds no evidence of strong positive $Mn^{3+}-Mn^{4+}$ interaction is obtained. The susceptibility measurements show that $Mn^{3+}-Mn^{3+}$ interaction in Sr-rich cubic perovskite is negative. This fact is consistent with Jonker's results that in cubic perovskite manganites such as $(La, Ca)MnO_3Mn^{3+}-Mn^{3+}$ interaction is positive for large cell dimensions while it is negative for small cell dimensions.

§ 1. Introduction

In the preceding paper[1] we reported magnetic and crystallographic properties of two systems of perovskite-like compounds, $(La, Sr)FeO_x$ and $(La, Sr)CoO_x$. It was found that their crystallographic as well as magnetic properties are greatly influenced by the value of x, or the concentration ratio of tetravalent to trivalent ions. It may be interesting, therefore, to study in a similar way other systems for which properties for "non-correct" samples have not been fully investigated. In this paper we shall report some of the results obtained with respect to the system (La, Sr)-MnO_x.

The properties of La-Sr manganites[2)-4)], as well as analogous manganities[5)-7)] have been the subject of considerable amount of investigation. Strong ferromagnetism has been found in La-rich manganites, and it was ascribed to positive $Mn^{3+}-Mn^{3+}$ and $Mn^{3+}-Mn^{4+}$ interactions. Jonker[4)] points out that these interactions may be of the semicovalent type suggested by Goodenough, and the former interaction is dependent on interatomic distances, being positive for large separations while negative for small separations. But since his conclusion is based on the experimental results on La-rich "correct" perovskites, the range of y is limited, and, moreover, the coexistence of negative $Mn^{4+}-Mn^{4+}$ interaction makes the statement uncertain. We shall show in this paper that evidence for negative $Mn^{3+}-Mn^{3+}$ interaction is fully produced by the experiments on "non-correct" samples.

§ 2. Experimental Procedure

The procedures of preparation of the samples were similar to those in reference 1. Starting materials were pure La_2O_3, $SrCO_3$ and $MnCO_3$. Since higher annealing temperatures, however, were needed for obtaining specimens of low Mn^{4+} ion content, a high-frequency vacuum induction furnace was used; prefired samples, pressed into bricket form, were put in high-alumina crucibles, which were put in graphite crucibles, heated to the scheduled temperatures, maintained about 30 minutes there, and then furnace-cooled.

Each specimen was chemically analyzed for total Mn and Mn^{4+}, following the standard method in the chemical analysis department of our Institute.

X-ray powder patterns were taken of many of the samples in the X-ray research laboratory of our Institute, with 11.46 cm diameter camera and Fe anticathode tube.

Care was taken not to unduly oxidize the pulverized samples before measurement.

Magnetic measurements were made just in the same way as in reference 1.

§ 3. Crystallographic Study

Fig. 1 shows the result of chemical analysis and crystallographic study on a diagram, taking as the abscissa y, Sr concentraction, and as the ordinate Mn^{4+} concentration in total Mn. Samples labeled as A are those heat-treated in the air and have oxygen in excess of correct amount ($x=3$), except for $y=1$, corresponding closely to $SrMnO_3$, which is not perovskite-like. Samples labeled as V are those heat-treated in various temperatures. Roughly estimated phase boundaries are also drawn in the figure.*

One of the striking features of the diagram in Fig. 1 is the appearance of perovskite-like structure at $y=1$; $SrMnO_x$ is cubic when Mn^{4+} concentration is about 25% ($x=2.64$). At higher concentrations of Mn^{4+}, there appears a tetragonal distortion with $c/a>1$, while at lower concentrations (in the presence of Mn^{2+}) there appears a monoclinic distortion with $b/a(=c/a)<1$. The cubic $SrMnO_x$ has the smallest cell volume in the whole system.

Fig. 2 shows the difference in lattice parameter variations with y between A samples and V samples. In the A-preparation, the perovskite-like phase breaks off at $y=0.45$. In the V-preparations, the existence range of the perovskite-like phases is widened, and the cell volume decreases as y increases.

Table I gives the analytical and crystallographical data for several specimens.

The above crystallographical results are consistent with the consideration based on the tolerance factor. Jonker and Van Santen[2)] discussed the stability of the perovskite (ABO_3) compounds in terms of the Goldschmidt tolerance factor

$$t=\frac{r_0+r_A}{\sqrt{2}(r_0+r_B)},$$

where r_A, r_B and r_0 are the radii of the A (large), B (small) and 0 ions, respectively. Using Goldschmidt's values as the radii, they found the maximum possible value of t for the existence of perovskite-type compounds:

$$t_{\max}=0.96_5.$$

If we apply this rule to the system $SrMnO_x$,

---

* The constitution diagram presented here may probably be a very incomplete one, in that the samples are not prepared at the same temperature, nor are they quenched from the preparing temperatures.

† Cub=cubic, Rbh=rhombohedral, Mon=monoclinic, Tet=tetragonal.

* Negative sign represents Mn^{2+} concentration instead of Mn^{4+}.

we find that the maximum possible value of p, Mn^{4+} concentration, for the existence of perovskite-type structure is

$$p_{\max}=0.67 \quad \text{(Point Q in Fig. 1).}$$

In a similar way we find the corresponding value for the system $LaMnO_x$:

$$p_{\max}=0.88 \quad \text{(Point P in Fig. 1).}$$

The values for the system of (La, Sr)MnO_x should lie on a line connecting P and Q, as indicated by the chain line in Fig. 1.

Although the number of specimens in our study is not sufficiently large for the test of such a criterion, qualitative validity of this expectation is borne out, with somewhat lower critical Mn^{4+} concentrations than expected.

Jonker discusses further distortion from cubic to monoclinic symmetry using Megaw's criterion. If we assume that that the structural change takes place at the value of t

$$t=0.9\,,$$

we find that in the system $LaMnO_x$, the critical value of t corresponds to $p=0.13$ (Point R in Fig. 1). Values found experimentally are: $p=0.125$ after Jonker[4], and $p=0.20$ after Wold and Arnott[8]. Our result is also consistent with these values. In the system ($La_{1-y}Sr_y$)-$MnO_{3-y/2}$, corresponding to $p=0$, *viz.*, with no Mn^{4+} and Mn^{2+} ions, monoclinic distortion would be possible for $y<0.6$ whereas the experimental data (*e.g.* $y=0.2$, V_6 or $y=0.5$, V_6) indicate that the cubic phase is more extended than expectation. In the system $y=1$, *viz.* $SrMnO_x$, the criterion predicts the monoclinic distortion when $p<-0.06$, namely when the compound contains 6% Mn^{2+} ions in total Mn ions. The sample $V_{5.5}$ roughly substantiates this prediction.

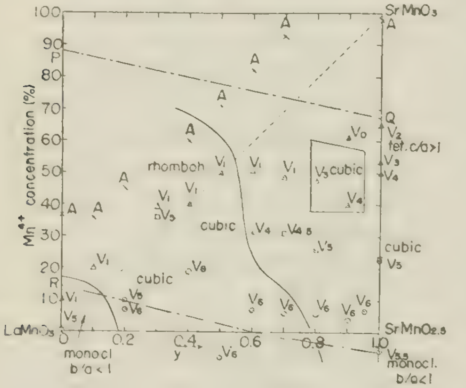

Fig. 1. Mn^{4+} concentration of specimens against y (Sr concentration), as determined by chemical analysis. A: Samples heat-treated in the air at 1300°C. V_i: Samples heat-treated in vacuo at $(1000+i\times100)$°C. The dotted line represents the correct compositions. The upper chain line gives the boundary which separates the perovskite-like phases from others, and the lower chain line gives the boundary between cubic and monoclinic perovskites, as anticipated from the tolerance factor.

§4. Magnetic Study

Measurements of the paramagnetic susceptibility above the Curie temperature have been carried out for all specimens. For samples with compositions $y<0.4$, our results are in qualitative agreement with Jonker's[4]. The significant result in Jonker's measurement that the Curie-Weiss law is obeyed in samples with $0.2<y<0.4$ is also confirmed in our experiment. In the region $y>0.4$ we observed curved $1/\chi-T$ relation. The curvature becomes more and more accentuated as y increases or x decreases (Fig. 3).

$SrMnO_x$ samples with any value of x have no spontaneous magnetization above the liquid nitrogen temperature (Fig. 4), and they have definitely negative Curie temperatures, indicat-

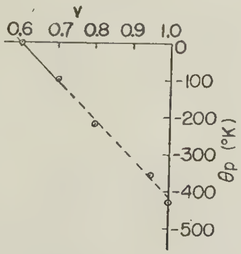

Fig. 5. Paramagnetic Curie temperature (θ_p) vs composition (y) of the V_6-samples ($V_{5.5}$ for $y=1$).

ing predominantly antiferromagnetic interactions between magnetic ions.

$SrMnO_3$, whose crystal structure is different from perovskite[9], is also non-magnetic, and has negative paramagnetic Curie temperature. We may say that in this compond $Mn^{4+}-Mn^{4+}$ interaction is negative.

In Fig. 5 we have plotted the paramagnetic Curie temperature θ_p of Sr-rich specimens with small concentrations of Mn^{4+} ions. θ_p changes its sign near $y\sim0.6$.

Saturation magnetization has been measured of the samples above the liquid nitrogen temperature. Except for details it is similar to Jonker's result (Fig. 6). It is to be noted that the value for $y=0.7$, V_6 is fairly smaller than that for V_1 or $V_{4.5}$.

Temperature dependence of the saturation magnetization of some specimens is given in Fig. 7. It has been found that the reduced saturation magnetization *vs* reduced temperature curves do not agree in general with the usuall Brillouin-type curves.*

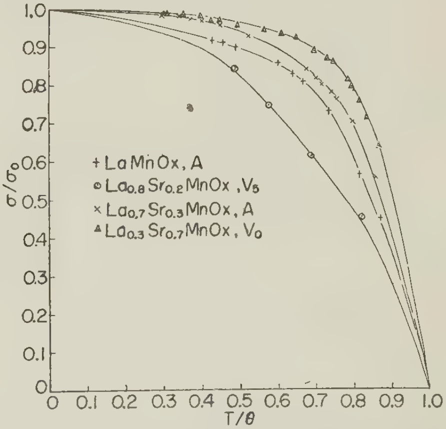

Fig. 7. Reduced magnetization *vs* reduced temperature curves of some of the (La, Sr)MnO_x samples. σ_0 denotes the extrapolated values of magnetization at absolute zero, θ denotes the ferromagnetic Curie temperature obtained by extrapolating the reciprocal susceptibility values to zero.

§ 5. Discussion

Jonker[4] pointed out that $Mn^{3+}-Mn^{3+}$ interaction is positive if the interionic distance is large, while it is negative if this distance is small. This conclusion was drawn from the moment arrangement in $LaMnO_3$, and also from the saturation magnetization in the system $(La, Ca)MnO_3$. Our experiment reveals further evidence of this statement in the system $La_{1-y}Sr_yMnO_x$, since cubic samples with $y>0.6$ have negative $Mn^{3+}-Mn^{3+}$ interaction in increasing amount with decreasing lattice dimension (Fig. 5). Such a dependence on interionic distance may be a result of the combined effect of various types of interaction.

---

* Unusual temperature dependence as was reported in reference 2 for $y=0.6$ has not been found in our experiment.

Goodenough[10)] assumed that $Mn^{3+}-Mn^{3+}$ interaction is antiferromagnetic if cation $d\gamma$ orbitals directed towards the intervening oxygen ion are both occupied or both empty, while it is ferromagnetic if one is occupied and the other is empty. This assumption explains the spin arrangement in $LaMnO_3$. In cubic perovskites the bond ordering as has been suggested by Goodenough is destroyed, both of the degenerate $d\gamma$ orbitals being occupied with equal probability. In such a case the sign of interaction may be determined by the relative magnitude of the various types of interaction. The experimental data suggest that the antiferromagnetic interaction overcomes the ferromagnetic interaction if the interionic distance is small.

In order to estimate the energy of $Mn^{3+}-Mn^{3+}$ interaction as a function of $Mn^{3+}-Mn^{3+}$ interionic distance, the molecular field treatment was applied to the layer-antiferromagnetic spin system as well as to the cubic spin system. In the former system (monoclinic, $b/a<1$), the following equations hold:

$$\theta_{33}(a)+\tfrac{1}{2}\theta_{33}(b)=\tfrac{3}{2}\theta_p$$

and

$$\theta_{33}(a)-\tfrac{1}{2}\theta_{33}(b)=\tfrac{3}{2}T_c,$$

where θ_{33} denotes the energy of $Mn^{3+}-Mn^{3+}$ interaction expressed in degrees Kelvin, θ_p and T_c are the paramagnetic and the Néel temperatures, respectively. As for $LaMnO_3$, V_5 (in the monoclinic range), $\theta_p=65°K$ and $T_c=140°K$ (See the inset in Fig. 3(*a*))*, whence we obtain

$$\theta_{33}(a)=154°K,\quad \theta_{33}(b)=-56°K.$$

On the other hand, the values of θ_{33} for cubic samples with small Mn^{4+} concentrations have been derived by simply equating it to θ_n, neglecting the presence of $Mn^{3+}-Mn^{4+}$ and $Mn^{4+}-Mn^{4+}$ interactions. The result is plotted in Fig. 8. $\theta_{33}(b)$ for $SrMnO_x$, $V_{5.5}$ has been obtained by assuming the value of $\theta_{33}(a)$ for the same specimen to be $-200°K$.

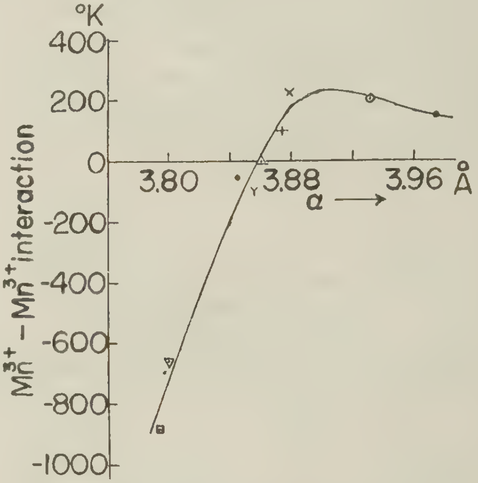

Fig. 8. $Mn^{3+}-Mn^{3+}$ interaction *vs* $Mn^{3+}-Mn^{3+}$ interionic distance, *d*. ● $LaMnO_x$, V_5, low temperature. ∘ $LaMnO_c$, V_5, high temperature. × $La_{0.8}Sr_{0.2}MnO_x$, V_5. + $La_{0.5}Sr_{0.5}MnO_x$, V_6. ⚠ $La_{0.4}Sr_{0.6}MnO_x$, V_6. Fig. 9. Effect of oxygen ion vacancies on the half-filled d_{z^2} orbitals of Mn^{3+} in the $SrMnO_x$ compounds. × represents oxygen vacancies.

$Mn^{4+}-Mn^{4+}$ interaction may be considered to be negative, as is seen from the difference in the paramagnetic Curie temperature of $La_{0.1}Sr_{0.9}MnO_x$, V_0 and V_6. As pointed out by Kanamori[11)], this interaction should be antiferromagnetic according to any mechanism which is considered to play an important role in magnetic interaction.

---

* Here it is assumed that incomplete compensation of the magnetizations of the two antiferromagnetically coupled sublattices produces non-zero net magnitization below T_c.

As for $Mn^{3+}-Mn^{4+}$ interaction, we are not certain of its sign for $y=1$, but the fact that the paramagnetic Curie temperature of V_5 ($\sim$23% Mn^{4+}) is strongly negative suggests that it is not strongly positive.

Although $SrMn^{3+}_{0.75}Mn^{4+}_{0.25}O_{2.625}$ (V_5 is close to this composition) has a negative paramagnetic Curie temperature, antiferromagnetic spin ordering does not seem to develop in it (See the low temperature susceptibility in Fig. 4). Goodenough* interprets this as follows. The half-filled d_{z^2} orbitals of a Mn^{3+} ion adjacent to an oxygen vacancy should be directed towards the vacancy (Fig. 8). Since the oxygen vacancies are distributed at random and there is no magnetic interaction across a vacancy, there may be no magnetic ordering.

Acknowledgements

The author wishes to express his hearty thanks to Professor T. Hirone and to Drs. J. B. Goodenough and J. Kanamori for their valuable disscussions. He is also indebted to the members of the chemical analysis department directed by Professor H. Gotô and to those of X-ray research laboratory directed by Professor S. Ogawa of our Institute. Thanks are also due to Mr. K. Ito for aid with the magnetic measurements. A part of the expenditure of this study has been defrayed from the Scientific Research Funds of the Ministry of Education.

Regrowth of Germanium Single Crystal from Indium Melt

Masami TOMONO

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo

(Received November 28, 1960)

A single crystal of *n*-type germanium was heated with a small piece of indium on it, and subsequently cooled rapidly to cause regrowth of the *p*-type germanium on the substract germanium from the indium melt. After removal of the indium, the growth pattern on the surface of the regrown germanium was observed. In some cases relatively large growth pyramids were observed, while in others flat patterns with threefold or sixfold symmetry were observed. After the detailed examination, it was concluded that the former represents the growth due to the screw dislocations and its center is dislocation array resulting from thermal strain. The shape and size of the growth pyramid vary with the number of screw dislocations which exist at center. The latter seems to be caused by surface nucleation.

§ 1. Introduction

Many studies have been made on the growth of single crystal from germanium melt[1)-5)]. However, because of the difficulty in observing the solid and liquid phases of germanium separately, reports dealing with the growing process of single crystal are relatively few[5)].

Many observation have been made on the regrown germanium produced on the substrate crystal as follows: Contact is made between the substrate germanium and the melt of indium, then germanium is dissolved in the melt. After that the system is slowly cooled so as to cause the regrowth of germanium on the substrate[2),6)-10)]. The author made observations on the *p*-type germanium layer which was regrown on the base single crystal with various cooling speeds of the above-mentioned indium melt, and studied the regrowth of the germanium single crystal from the indium melt. As for the regrowth of single crystal, it is necessary to know which of the screw dislocation or the surface nucleation is responsible for it. In the former, peculiar spiral or concentric curved patterns should be found. While, in the latter, those patterns should not be found. Various growth patterns were observed of germanium single crystal which was regrown on the substrate single crystal from the indium melt.

§ 2. Method of Experiment

A small piece of indium was put on the surface of an *n*-type germanium pellet parallel to (111) plane, and this was heated with a high-frequency furnace in hydrogen atmosphere at about 550°C for 10 minutes. Part of germanium in contact with indium melt is then dissolved into the melt until an approximate saturation is reached. At this time, the high-frequency heating is put off and simultaneously the specimen is cooled rapidly by pouring oil. Fig. 1 shows a resulting *p*-type layer regrown from the indium melt.

This method is convenient because the separate observation of *p*-type and *n*-type germanium layers is possible by the chemical etching and other methods. If this specimen is treated with mercury for amalgamation of indium present over *p*-type regrown layer and this amalgam is dissolved away with nitric acid, then the surface of the *p*-type germanium is exposed[9)]. A smooth surface parallel to (111) plane on the bottom of this exposed pan-shaped regrown layer was observed for the crystal growth pattern by the opical or electron microscope. The observations by the electron microscope were made by replica method using the platinum-palladium shadowing from left to right on the photographs. Then, the *p*-type regrown layer was etched with the dilute CP-4 etchant from the surface and etch patterns were observed successively.

§ 3. Results of the Experiment

3.1 *Abnormal growth pattern*

On the flat and smooth bottom surface of pan-shaped *p*-type regrown germanium layer shown in Fig. 1, the growth pattern of the abnormally large truncated hexagonal pyramid is frequently observed as shown in Fig. 2. Such an abnormal growth pyramid is seen, in most cases, to have nearly flat and smooth top surface as shown in Fig. 3 when magnified observation was made. Each side of the hexagon surrounding the top surface is, of course, parallel to [110] axis. Formation of the apparently large steps on the pyramidal surface by bunching together[11),12)] of a great number of fine growth steps is clearly seen.

The photograph shows in the lower left part how several steps are integrated into one step.

Fig. 4 gives an electron microphotograph of another abnormal growth pyramid with the top surface not flat but slightly inclined. The specimen is applied with shadowing from the left, and the step height can be known from the width of white shadow in the left-hand part of the photograph. It is seen that all the steps except those at the periphery of the top surface hexagon are approximately equal in height. Again each side of the hexagon is parallel to [110] axis, of course. For the slope angle obtained in this way, $\tan\theta \doteqdot 0.12$. The slope of the pyramidal surface obtained by this method on the growth pyramid of Fig. 4 is indicated schematically in Fig. 5.

The slope is small at the skirt of the growth pyramid and gradually increases but at the periphery of the top surface indicated by A, the slope decreases suddenly and discontinuously. Thereafter, the slope decreases at the point B near the center of top surface and in the part between B and C, it is nearly zero.

The point C represents the center of the top surface. An $\angle$-shaped rectilinear groove found near the center of top surface in Fig. 4 is a slip line caused in the course of the crystal growth and the detail will be given in the next report[13)]. Fig. 6 shows a photograph of another abnormal growth pyramid having no flat and smooth part on the top surface.

It is seen that in the neighborhood of the top surface the slope of the pyramidal surface becomes somewhat small but is still considerably large.

Fig. 7 shows the specimen with two abnormal growth pyramids developed one on the top of another. Fig. 8 and Fig. 9 are the growth patterns originating from three vicinal centers: in the neighborhood of these centers each of the three independent groups parallel to the special [110] equivalent direction grows in the corresponding [211] equivalent direction, but with increase of distance from the centers they interact and result in such growth patterns as if they were developed from the same center.

3.2 *Center of the abnormal growth and grain boundary*

This paragraph is devoted to the examination of the center of the abnormal growth

described above. In a photograph of Fig. 10, growth pattern is obviously found also on the flat and smooth top face of the growth pyramid. And in the central part, there exists a pattern which seems to be the center of the growth. In some cases, however, the top surface of the abnormal growth pyramid is truly flat and smooth and free from any recognizable growth pattern, as shown in Fig. 3. Fig. 11 gives an enlarged photograph of such a case.

Fig. 12 shows the results which were obtained by etching the area of the abnormal growth pyramid with dilute CP-4 etchant. In (a) the abnormal growth pyramid after 20-second etching.

Near the center of the flat and smooth top surface, etch pit arrays are present in parallel

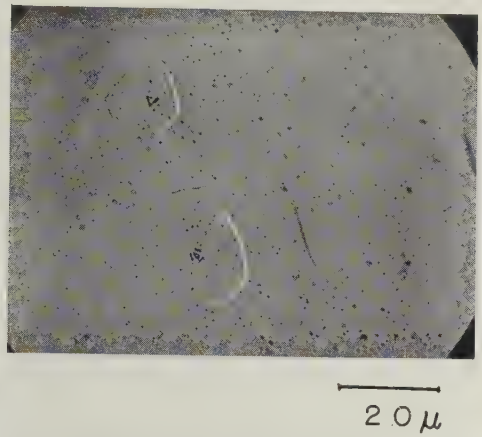
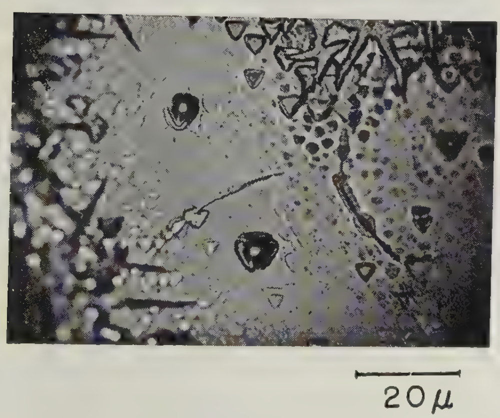
to the alternate three sides of hexagon (to three [110] axes). Grain boundary surrounding the growth pyramid is distinctive in (a). (b) is the case with 15-minute etching. An equilateral triangle of etch pit arrays in the central part of the top face forms a large hole, and the etch pit arrays appears on the grain boundary and indicate that they are caused by misfitting. Fig. 13 shows the results of the etching of the bottom of the regrown p-type layer, and explains the process of the abnormal growth pyramid being attacked. (a) shows the state after 21-minute etching with dilute CP-4 etchant; the portion of the abnormal growth pyramid has been selectively etched away, and the n-type germanium substrate is exposed. (b) shows the state after complete dissolution of the p-type regrown layer by the etching for about 60 minutes. Etch pits corresponding to edge dislocations of n-type germanium have appeared, and it is shown that there is no correlation between the distribution of dislocations in the substrate single crystal and the growth pattern on the regrown layer.

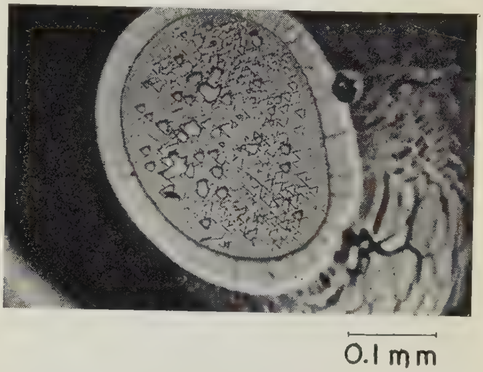


(a) After 20-second etching

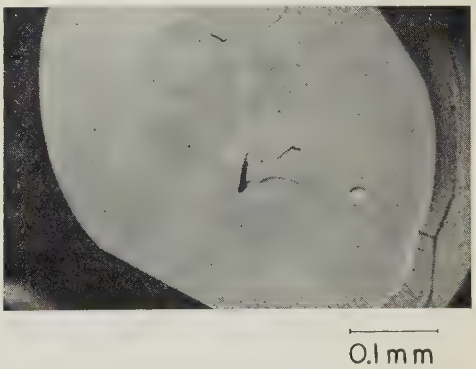


(b) After 15-minute etching

Fig. 12. Etched pattern of abnormal growth pyramids (by optical microscope).



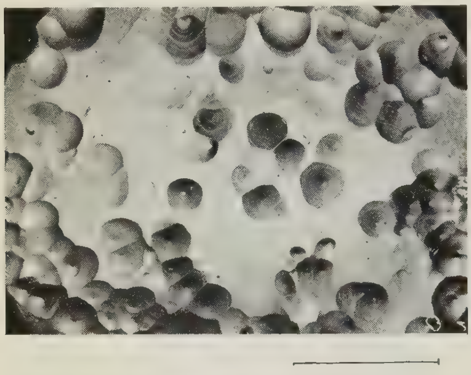
(a) After 21-minute etching



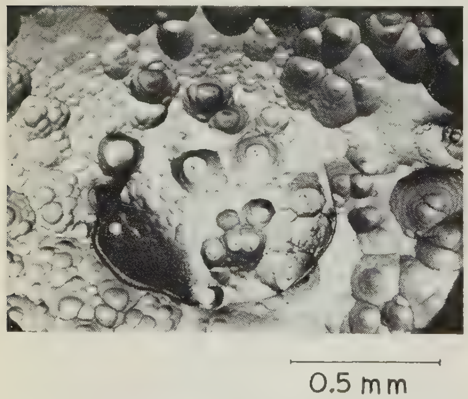
(b) After 60-minute etching

Fig. 13. Etch pattern on the p-type regrown germanium layer (by optical microscope).

As a help to ascertain this fact, photographs are shown in Fig. 14 for an n-type germanium which, while covering the indium alloyed side with wax, has been etched gradually on the reverse side with dilute CP-4 etchant. (a) shows the state of etch pits which appeared after the etching of the reverse side of the n-type germanium. (b) shows the state after further about 1-hour etching; the pointed centers of etch pits appeared on the n-type germanium reached the p-type regrown layer present on the opposite side of the pellet, and the p–n boundary began to appear. Since the etching rate of p-type germanium is smaller than that of n-type, flat and smooth p-type germanium appeared and the etch pits took the truncated cone shape. In the bottom part of each pit, many fine etch pits are recognized. Among them, the etch pit located near the center or the top of the truncated cone is relatively larger than the others. Obviously, it corresponds to the etch pit in the n-type germanium bulk. In other words, it is seen that the dislocations in n-type germanium extend continuously to the p-type regrown layer, and in addition to them, an extraordinarily number of dislocations are present in the p–n junction boundary.

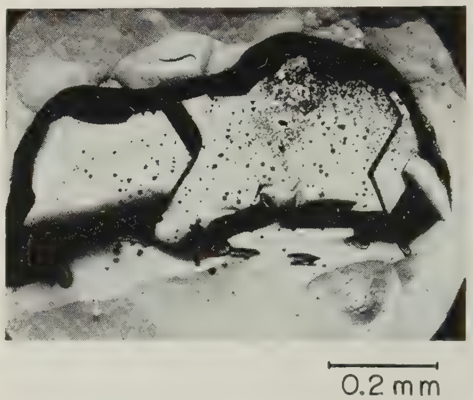


(a) Etch pits on bulk germanium

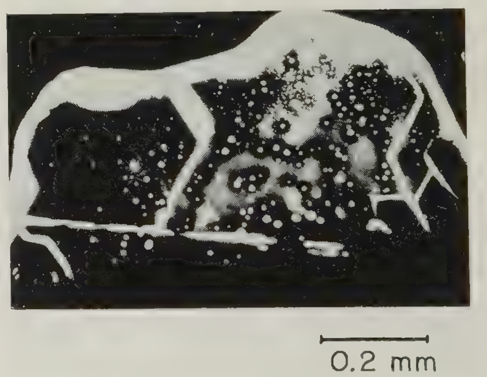


(b) Regrown layer revealed after etching

Fig. 14. Specimen etched on the reverse side of n-type germanium (by optical microscope).



(a) Observation by reflected light



(b) Observation by transmitted light

Fig. 15. Pits which appeared when p-type regrown layer was etched on its reverse side (by optical microscope).

By applying the etching similarly on the reverse side of the n-type germanium neighbouring to the bottom of the pan-shaped p-type regrown layer shown in Fig. 1 was entirely removed away, and the resulting states are shown by the photographs in Fig. 15. The photograph (a) shows the observation of the reverse side of the bottom of such a pan-shaped p-type regrown layer as shown in Fig. 1 by reflected light. This p-type regrown layer was exposed after the n-type germanium layer was removed away by etching. It is seen that the central part of the above mentioned abnormal growth pyramid was easily etched also from the reverse side. In the upper right-hand part of this, ▽-shaped etch pits are seen in a large number, and they indicate that the part corresponding to the center of the abnormal growth pyramid which was visible on the front surface of the regrown layer was easily etched also from the reverse side of the same layer. The star or polygonal shaped pits seen in the other part of the photograph were formed as follows: At first the reverse side of the p-type layer was etched and there appeared ▽-shaped etch pits. With this process wide, curved and dark coloured part seen in the figure was severely attacked by the etchant and penetrated through. Because this part corresponds to the periphery of the regrown layer and here its thickness is remarkably thin as compared to central part. From that part the etchant leaked to the opposite side of the *p*-type layer, thus etch pits appeared also on this side. The triangle of the pits thus formed is rotated by 180° about the first triangle, and these two equilateral triangles overlapped each other to form the star-shaped etch pit. (b) shows the same specimen as (a) but observed by the transmitted light. In this photograph, the part at which the etch pich penetrated through the *p*-type regrown layer looks white. This white etch pit is surrounded by a black area where the transmission of light is not permitted because the abnormally grown layer is thicker than the other part. Another area

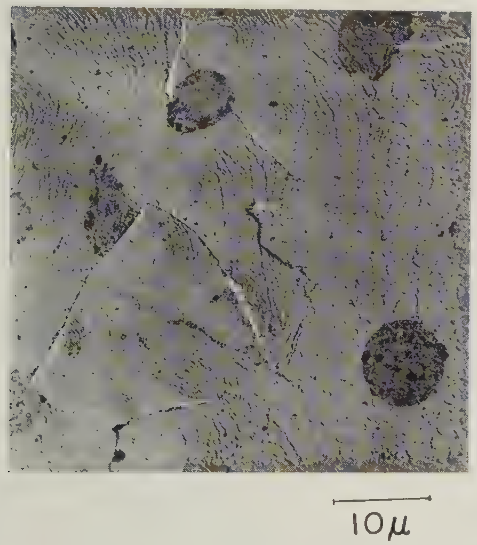


Fig. 16. Small growth pyramid (by electron microscope).

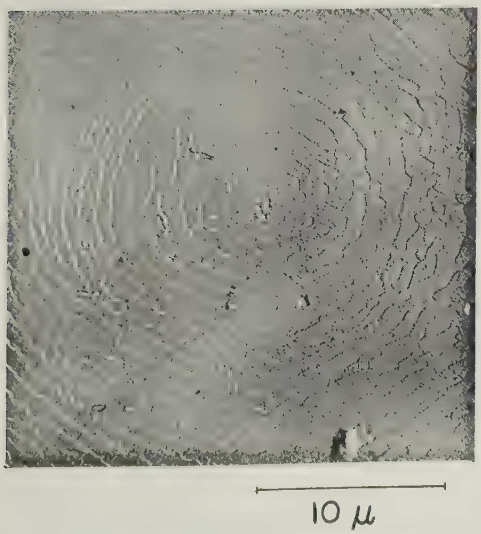

Fig. 17. Pyramidal surface of small growth pyramid (by electron microscope).

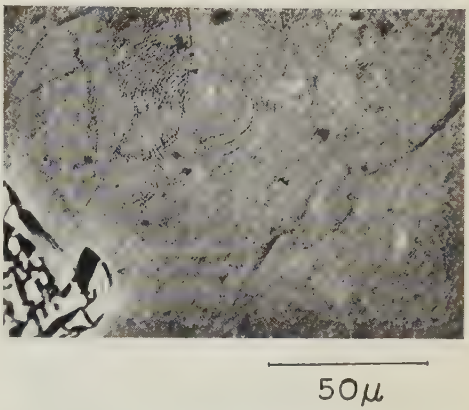
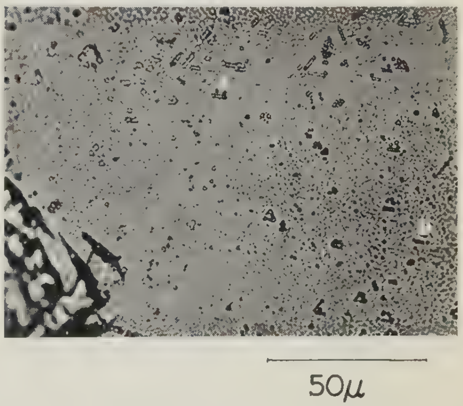


(a) Growth pattern developed by decoration



(b) Etch pattern developed by chemical etching

Fig. 18. Small growth pattern developed by decoration (by optical microscope).

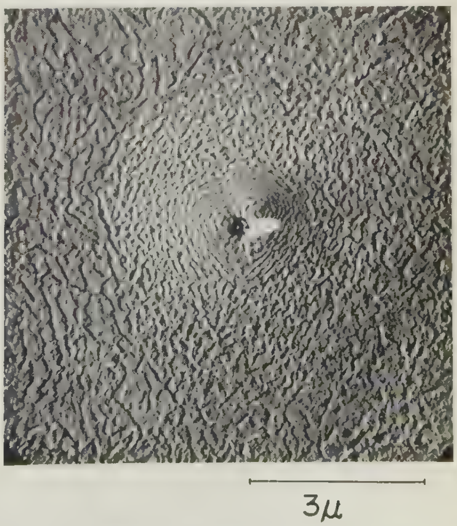


Fig. 19. Three sets of growth patterns developed around the hole (by electron microscope)

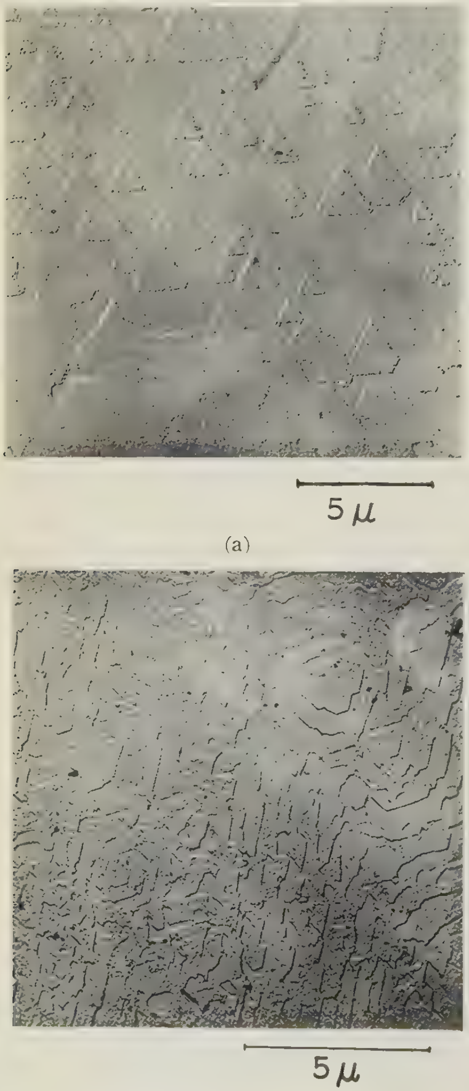
free from the abnormal growth looks gray because the light is partially transmitted due to the thin p-type layer of poor growth. This again shows that the triangle of star-shaped etch pit appears in the central part of the abnormal growth. From the results of the experiments so far described, it is clear that the center of the abnormal growth occurs on the p–n junction boundary irrespective of the lattice defect in the n-type germanium substrate.

3.3 *Small growth pyramid*

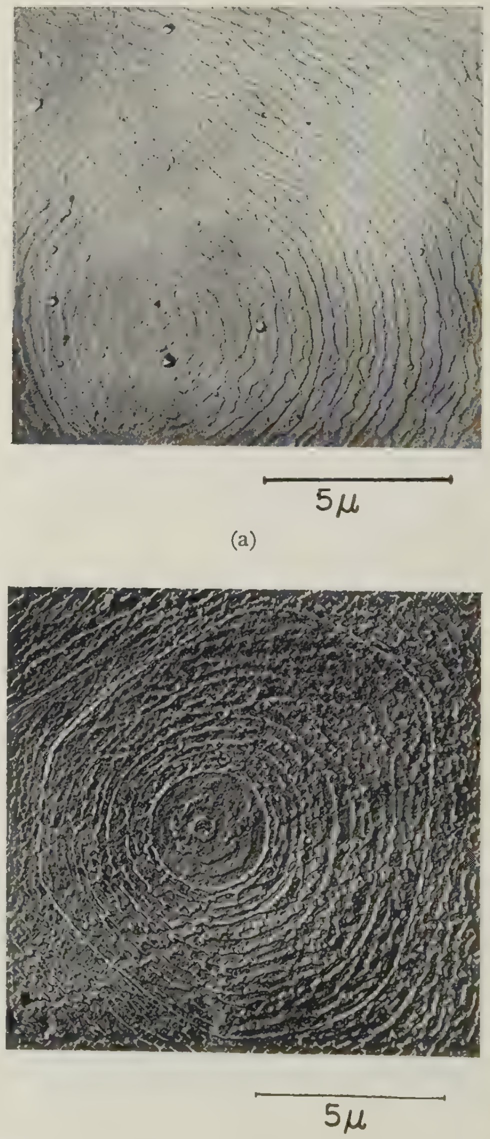
The growth pattern observed on the bottom surface of the pan-shaped regrown layer shown in Fig. 1 reveals not only the abnormal growth pyramid as described in 3.1 but also very small pyramid as shown in Fig. 16 frequently. The pyramid in this case is characterized in that it has uniform slope all over the pyramidal surface and hence free from any flat and smooth top surface seen in the above-mentioned abnormal growth pyramid.

In the photograph, white or black broken line shows the boundary caused in the course of the growth. An enlarged view of such growth pyramid is shown in Fig. 17. In the lower left-hand part of the step shadow is



(a)
(b)

Fig. 20. Planar growth pattern composed of a set of polygons having sides parallel to [110] axis (by electron microscope).



(a)
(b)

Fig. 21. Concentric step pattern compounded with uneven pattern (by electron microscope).

white, while in the upper right-hand part of the step it is black, showing clearly that the pyramidal surface has uniform slope. For the slope angle θ of the pyramidal surface obtained from the width of this shadow, $\tan\theta=0.03$.

In some cases the growth pattern of such a small growth pyramid is not so clearly observed. To obtain the better contrast in such case the author applied the method of decoration. In the first place, a specimen was electrolytically polished anodically in the electrolyte of the composition as shown below. After that, with the polarity inversed, the specimen was applied on its surface with a very thin copper plating, and then it was heat treated in nitrogen atmosphere mixed with a small amount of oxygen at 400°C for 30 minutes. It was known that the growth pattern not so clear at first reveals itself very distinctly by this method.

Composition of the electrolyte:

20% $CuSO_4$ solution	5% (volume)
H_2O_2 (30%)	5% (volume)
HF (48%)	5% (volume)
Deionized water	85% (volume)

The reason for this is probably that copper atoms precipitated at first uniformly on the surface of the specimen moved on the crystal surface by heating and were collected at the growth steps where they were oxidized and fixed. The growth pattern is shown in Fig. 18 (a) which appeared in superior contrast by such decoration on the flat and smooth surface of an abnormal growth pyramid. Before the application of decoration, such pattern was hardly noticeable. It is obvious that this is the growth pattern developed from the central part.

(b) shows the etch pattern developed by 20 minutes etching of this specimen with dilute CP-4 etchant. A large number of etch pit arrays several microns in length parallel to the [110] axis appears, and there is one pit array respectively for each of A and B at the position of major axis of the ellipse which is concentric with the center of the growth pattern as shown in (a). It is remarkable that these pit arrays do not take the complicated triangular shape unlike the case of Fig. 12. Fig. 19 shows the specimen which has three sets of growth centers arround an extremely small hole. At a distance away from the center of the hole, they are integrated into one growth pattern. The depth of the hole is about 0.35 μ as calculated from the shadow.

3.4 *Planar growth pattern*

In the cases described in 3.1 and 3.3, presence of the growth pyramid was recognized, but in some cases, planar pattern is formed by the integration of a number of polygons which have three sides parallel to [110] axis as shown in Fig. 20 (a) and (b).

In Fig. 21 (a) and (b) is shown very slightly sloped concentric step pattern compounded with uneven pattern.

§ 4. Discussion

4.1 *Regrowth of germanium from indium melt*

Consider a system in which (111) plane of a germanium single crystal is, in equilibrium state, in contact with an indium melt. If this system is cooled, germanium precipitates and regrows on the germanium single crystal from the indium melt. As to this regrowth, we may consider it in two cases: in the first case the screw dislocation present on the surface of the substrate single crystal in contact with the melt is responsible for the regrowth, while in the other the surface nucleation is responsible for it. As the supersaturation of germanium in the indium melt becomes remarkable, many critical nuclei are produced on the substrate germanium surface and the regrowth of germanium is caused by them clearly. But in case where the supersaturation is so small, the regrowth is caused, as well known, by the screw dislocation. Now consider the regrowth by the surface nucleation[14)–16)].

Denoting by ρ_c the radius of critical nucleus, we have:

$$\rho_c=\frac{a\phi}{2kT\ln\alpha} \tag{1}$$

where a is the distance between adjacent atoms arround the critical nucleus, ϕ is the bonding energy per bond of the adjacent atoms and α is the saturation ratio of germanium which is related to the supersaturation σ by $(\sigma=\alpha-1)$. Fig. 22 shows the results of calculation of the relationship between σ and ρ_c. The abscissa shows the supercooling temperature ΔT as well as σ.[17)]

Now consider that the step is in the [110] direction on the (111) plane, and one broken bond per atom is present. In this case, the activation energy for nucleation is given by:

$$\varDelta F_c=\frac{\phi^2}{kT\ln\alpha} \tag{2}$$

Further, as to the rate of formation of critical nuclei, I, we have:

$$I=n_0 j\exp(-\varDelta F_c/kT) \tag{3}$$

where n_0 is the number of single atoms which are adsorbed per unit area of the crystal surface, j is the number of atoms which arrive at the surrounding of the critical nucleus per unit time.

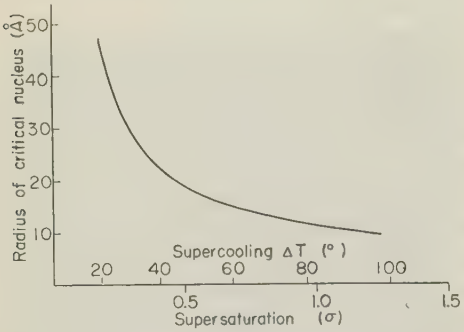


Fig. 22. Relationship between supersaturation and the radius of the critical nucleus ($\varDelta T$ denotes the supercooling assuming that $T_0=773$°K).

The discussion of each constant appearing in Eqs. (2) and (3) is as follows: The heat of melting of germanium into the molten indium, $\varDelta H$, is 11.9 kcal/mol[17], and therefore, $\phi=4.13\times10^{-13}$ erg is obtained as calculated from $\phi=\varDelta H/2N$ (N is Avogadro's constant). As to j, we have:

$$j\approx2\pi\rho_c DN_0 \tag{4}$$

where D is the diffusion coefficient of germanium in the melt, and N_0 is the the concentration of germanium atoms in the indium melt. ρ_c must be calculated with Eq. (1). In Eq. (1), $a=3.97$ Å. According to Y. Sugita $D=5.7\times10^{-5}$ cm²/sec,[18] and by Takabayashi D is estimated to be of the order of 10^{-5} cm²/sec.[19] With reference to the phase diagram of *In—Ge* system at 770K[17),20)], $N_0=3.5\times10^{21}$ cm^{-3}. Thinking from this value of N_0, we may assume $n_0\approx10^{14}$ cm^{-2} in (3) without serious error. Substituting these values into Eq. (4), we have $j\approx10^{11}$ sec^{-1}. With this and the above-shown other values used in Eq. (3), the results as shown in Fig. 23 are derived. As seen from the figure, the error in evaluating n_0 and j does not seriously affect the results, and the order estimation as descrived above is sufficient for the purpose. The abscissa shows the supercooling temperature $\varDelta T$ as well as the supersaturation.

On the assumption that the growth step with sufficiently large radius of curvature exists on the crystal surface and the rate of advance of that step U_∞ is controlled mainly by the diffusion of germanium atom to the step in the melt, the following equation is derived[16),

$$U_\infty=a^2D\pi N_0(\alpha-1)\{\ln(\delta/a)\}^{-1} \tag{5}$$

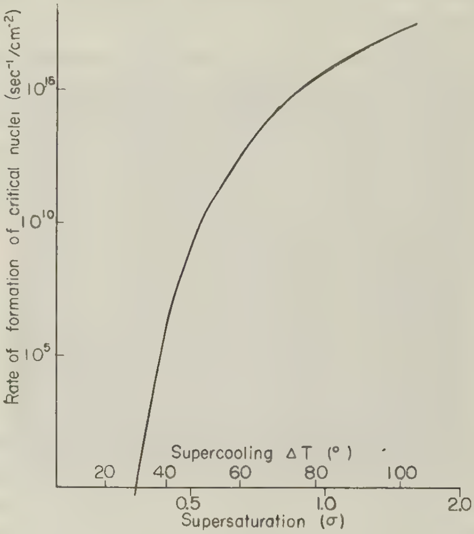

Fig. 23. Rate of formation of critical nuclei.

where δ is the thickness of a molten layer in which the diffusion of solute atom participating in the growth of crystal is carried out, and this layer exists in uniform thickness adjacent to the crystal surface. Now denote the time by t, then δ may be regarded as $\delta\approx\sqrt{Dt}$. If a value $\delta\approx10^{-3}$ cm ($t\approx0.018$ sec) is assumed, Eq. (5) is reduced to:

$$U_\infty\approx97.4\sigma\ \text{cm/sec} \tag{5$'$}$$

Denoting by A the area of the crystal in contact with the indium melt, we have $A\approx1$ mm² for the present case. Thus, the time required for one critical nucleus to grow and cover the entire crystal surface is given roughly by:

$$\frac{\sqrt{A}}{U_\infty}\approx10^{-3}\ \text{sec} \tag{6}$$

Incubation period for the formation of the critical nucleus is expressed as:

$$\tau=\frac{1}{AI} \tag{7}$$

From the value $I \approx 10^5\,\mathrm{cm^{-2}\,sec^{-1}}$ for $\sigma=0.4$ in Fig. 23, $\tau=10^{-3}$ sec follows in this case. Thus, for $\sigma<0.4$ we find $\tau>\sqrt{A}/U_\infty$, and in this case, the growth rate takes the form of:

$$R=\frac{d}{\tau} \tag{8}$$

where d is the spacing of {111} planes, i.e., 3.26 Å which is slightly smaller than the value of earlier-mentioned a. For $\sigma>0.4$, $\tau<\sqrt{A}/U_\infty$ and the surface nucleation becomes remarkable: many steps exist on the crystal surface, and consequently, the growth rate is limited by the diffusion of germanium atom from the indium melt onto the crystal surface. The growth rate R of the crystal in this case is given by[16]

$$R=DN_0\Omega\sigma/\sqrt{Dt} \tag{9}$$

where Ω is the atomic volume of germanium, i.e., $2.25\times10^{-23}\,\mathrm{cm^3}$. For $\sqrt{Dt}=10^{-3}$ cm, the growth rate R was calculated by Eqs. (8) and (9), as a function of the supersaturation σ, and the resnlts are shown by full line in Fig. 24. As σ exceeds 0.4, R increases rapidly according to Eq. (8), but with a little larger value of σ, the growth rate is controlled by the diffusion of germanium atom in the melt, as a result of which R increases linearly with σ according to Eq. (9).

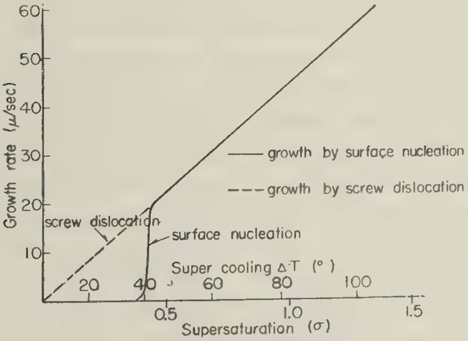

Fig. 24. Relationship between supersaturation and growth rate of the crystal.

For $\sigma<0.4$, the rate of crystal growth due to the surface nucleation is very small, and it can be considered that in this region the screw dislocation is mainly responsible for the crystal growth. After the spiral growth step caused by the screw dislocation is fully developed to cover the entire surface of the crystal and the growth reaches the steady state, the growth rate R is given by Eq. (9). In such case, it varies linearly with the supersaturation σ as shown by the dotted line in Fig. 24. The time required for the growth due to screw dislocation to reach the steady state is roughly of the order of 10^{-3} sec as calculated by Eq. (6). Since this is quite a short time, it may be justified to consider that the rate of growth due to the screw dislocation is represented substantially by the dotted line in Fig. 24. As is commonly known, distance of the growth steps due to a single screw dislocation is $4\pi\rho_c$, but if there exist n screw dislocations of the same sign within the distance of $2\pi\rho_c$, the mean distance of the growth steps is $4\pi\rho_c/n$. In considering that the height d of one step is 3.26 Å, the angle θ between the pyramidal surface of the growth pyramid thus formed and the (111) plane of the crystal surface is expressed by the relation such as:

$$\tan\theta=\frac{nd}{4\pi\rho_c} \tag{10}$$

With the use of Eq. (1), the relationship of the supersaturation σ and $\tan\theta$ was calculated from Eq. (10) for various values of n as a parameter. Fig. 25 gives the results of this calculation.

4.2 *Lattice defects in the regrown layer*

As shown in Fig. 14, the regrown germanium layer has a great number of dislocations independent of the imperfections in the substrate germanium. The mechanism of for-

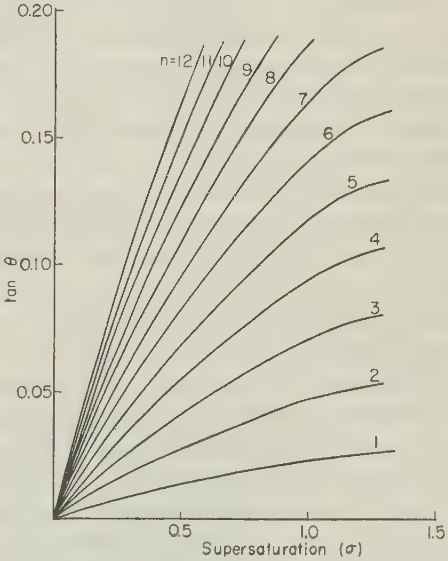

Fig. 25. Relationship between the supersaturation and the slope of the pyramidal surface of the growth pyramid.

mation of these dislocations will be discussed in this paragraph. Consider that an n-type germanium pellet is heated in contact with an indium melt and subsequently cooled rapidly by pouring oil. We consider the state in which indium is in molten state and from this melt, germanium is segregating to form p-type regrown layer. In such condition, the temperature of the upper surface of the regrown layer is raised by the latent heat of solidification of germanium, while the n-type germanium substrate is cooled by pouring of oil. As a consequence, there exists in the p-type regrown layer of Fig. 1 a temperature gradient down from the solid-melt interface towards the substrate germanium. Moreover, the radial temperature gradient exists because of decrease in temperature towards the edge of the regrown layer. Further, in addition to these, local irregularity of temperature is naturally caused when the oil is poured for rapid cooling. Temperature of the thin p-type regrown layer formed in this process is very near to its melting point and so is subject to plastic deformation, but the n-type substrate germanium is difficult to be subject to it at temperatures below 500°C.[21] Thus, at the beginning of the regrowth, many localized slips are caused in the regrown layer, and there is a possibility of generating a great number of dislocations independent of the imperfections in the n-type substrate. For the generation of such many lattice defects, there are other reasons conceivable. That relatively large amount of indium (of the order of 10^{18} cm^{-3})[22] is contained in the p-type layer is, of course, one reason[23]. In some cases, vacancy which is caused in the regrown layer in the solid-melt interface at the beginning of the regrown condenses into a disc form which may collapse and generate dislocation ring.

4.3 *Discussion of the abnormal growth pyramid*

The abnormal growth pyramid mentioned in 3.1 is characterized in that, as seen from Fig. 2, its size is abnormally large compared with the other growth patterns. They can be classified into two cases: first, as shown in Figs. 3, 7 and 11, the top surface of the growth pyramid is flat and smooth, and second, as shown in Figs. 4, 5, 6 and 10, the top surface is inclined a little but its slope is considerably smaller than that of the pyramidal surface. The mechanism of the formation of such abnormal growth pyramid will be discussed in this paragraph. In the centeral part of the top surface of the abnormal growth pyramid of Fig. 12 (a), there exist etch pit arrays parallel to three [110] axes on the (111) surface. Obviously, this is an indication of the existence of the localized slip lines. The reason why such a complicated slip has been created is probably that the area has large localized temperature gradient at the beginning of the regrowth for the reason discussed in 4.2. As to germanium, it has been known that slip is easy to occur in the [110] directions on the {111} planes[21),25),26)]. When the p-type layer is looked down from above in Fig. 1, there are two cases in regard to the orientation of a regular tetrahedron composed of a set of {111} planes. First, the tetrahedron is normal with respect to the (111) plane of the upper surface and the second, it is inverted. For a germanium column with a radial temperature gradient, the slip is possible on either set of {111} planes, but if the column is cooled at its bottom so as to give the axial temperature gradient, the slip is easier to occur on the {111} planes of the inverted regular tetrahedron[27]. If the stress in this case is analyzed into components of the easy-to-slip direction, then both slips, one parallel to [110] axis on the bottom surface (the surface of regrown layer) and the other to [110] axis making an angle of 54°44′ with the bottom surface, should simultaneously occur. The etch pit arrays parallel to [110] axis on the top surface of abnormal growth pyramid in Fig. 12 (a) seem to be the arrays of the edge dislocations caused by the slip of the former direction. The same slip causes also screw dislocations which in the present example do not participate in the growth of crystal. Another screw dislocations from the slip of the latter direction make an angle of 54°44′ with the surface, and coexist with the above-mentioned edge dislocation arrays, and should participate in the subsequent growth of the crystal. The same slip causes also edge dislocation which in the present example is probably invisible because it intersects the surface of the regrown layer at small inclination. It follows from the above that three sets of edge dislocation arrays and screw dislocation arrays, each parallel to [110] axis on the surface of regrown layer but making an angle of 120° with each other, sholud be simultaneously created. In this case, a step whose height inside the three sets of slip lines is larger than that of the outsider is created. In the area with such locally concentrated screw dislocations, regrowth is prominent and hence much heat of solidification is generated, so further formation of screw dislocation is caused enough to form the center of the abnormal regrowth. As to the edge dislocation arrays in the center of the top surface in Fig. 12 (a), the equilateral triangle formed by the arrays is of the same orientation as that of the etch pits present in quantity in the other part of the specimen, and this obviously corresponds to the bottom of the inverted tetrahedron as previously mentioned. Fig. 26 shows a model of the screw dislocation arrays which coexists with the above-mentioned edge dislocation array. Now, considerations are made on the slip line AA' in the figure. Assume that at A n_A screw dislocations of the same sign exist adjacently with one another (or it may be assumed that a single dislocation with a large Burgers vector exists). At A', the existence of the same number n_A of screw dislocations which have the opposite sign is assmed.

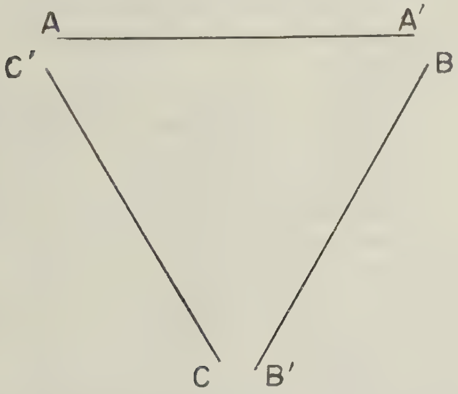

Fig. 26. Model of the dislocation arrays in the central part of the abnormal growth pyramid.

As to B, B' and C, C', existence of concentrated screw dislocations in the respective numbers of n_B and n_C is assumed. With these screw dislocation as centers, growth of crystal takes place. The slip line in Fig. 12 (a) has the length of the order of several microns, so the slip lines $\overline{AA'}$, $\overline{BB'}$ and $\overline{CC'}$ in Fig. 26 may be considered to have nearly the same length. Now assume that $\overline{AC'}$ which indicates the distance between one end of $\overline{AA'}$ and the end of the adjacent slip line is considerably small compared with $\overline{AA'}$, i. e., 0.1 μ or less. Then, for the relatively small supersaturation σ in Fig. 22, the radius of critical nucleus, ρ_c, is relatively large and satisfies the ration $2\rho_c > \overline{AC'}$, and because of the mutually reverse signs, the screw dislocations at A and C' interfere with each other, effecting the growth at the same rate as if there were $|n_A - n_C|$ screw dislocations. While, if σ gradually increases thus resulting in the decrease in ρ_c until the condition $2\rho_c < \overline{AC'}$ is satisfied, the growth will be controlled by the number of screw dislocations, n_A or n_C, namely by larger one of them. For other positions, similar discussion may be applicable. Assume $\overline{AC'} \approx \overline{A'B} \approx \overline{B'C}$, for instance. In the case of $n_A = n_B = n_C$, if σ is small at the beginning of the regrowth, then $2\rho_c > \overline{AC'}$, and the growth due to these screw dislocations does not take place at all. While, if σ gradually increases until $2\rho_c < \overline{AC'}$ is satisfied, then the concentric growth patterns will develop around $\overline{AC'}$, $\overline{A'B}$ and $\overline{B'C}$, from each of the n_A centers and they are integrated in the distance eventually into the concentric growth step around AA', BB' and CC', and the slop increases in proportion to n_A according to Eq. (10). In consideration of $\tan\theta \doteqdot 0.12$ in Fig. 4 as described in 3.1, it follows from Fig. 25 that $n_A \approx 10$ for $\sigma \approx 0.4$. But, towards the end of the regrowth process, the supersaturation σ decreases again resulting in $2\rho_c > \overline{AC'}$, thereby growth by these growth centers is completely stopped. Figs. 3, 7 and 11 seem to represent such case. In general, however, all n_A, n_B and n_C are not necessarily equal. Now, for instance, take up the case of $n_A > n_B > n_C$. For a small σ at the beginning of regrowth, concentric growth patterns are developed from $(n_A - n_C)$ growth centers around $\overline{AA'}$, $\overline{BB'}$ and $\overline{CC'}$, and the pyramid has a small slope. With the gradual increase in σ, concentric growth patterns are developed from n_A centers and the slope of the pyramidal surface is increased in accordance with Eq. (10). Towards the end of the regrowth process concentric growth patterns are developed again from ($n_A - n_C$) growth centers and the slope is made small. This is represented by Figs. 4, 6 and 10 the behavior of the change in the slope is shown by Fig. 5. The possibility of the growth by the screw dislocation arrays as shown in Fig. 26 is clear from Figs. 8 and 9. Either of the figures shows the concentric growth pattern produced around those growth patterns which developed at first from threefold center and subsequently were integrated in the distance away from the center. In Fig. 8, there exist many slip lines of equilateral triangle which are, as previously mentioned, of the same orientation as the etch pits caused by edge dislocation, and in the present example, three centers of growth patterns are also of the same arrangement as above. It is clear that the center of the abnormal growth pyramid has such a complicated structure as mentioned above and a relatively large number of screw dislocations are collected to it.

4.4 *Discussion of small growth pyramid*

In the case of relatively small growth pyramids as shown in Figs. 16 and 17, the slope of the pyramidal surface is nearly unifrom from the skirt to the top. In the central part of the small growth pyramid as seen in Fig. 18 (b), there exists a slip line with a simple structure. This slip line forms one straight line as shown by *A* and *B* in the same figure. As mentioned above, it seems that following this edge dislocation array the screw dislocation array exists. Since the straight lines *A* and *B* are of the order of several microns in length. The distance between the screw dislocations of the different signs may be justifiably considered from Fig. 22 not to become substantially smaller than $2\rho_c$ provided that they exist at a separation of the same order as cited above. It seems from this that the slope of the pyramidal surface of the growth pyramid is constant from the beginning to the end of the regrowth process. Since $\tan\theta \doteqdot 0.03$ from Fig. 17 as discussed in 3.3, the number of the screw dislocations in the present case is about 3 for $\sigma \approx 0.4$ in Fig. 25. It seems that the center of such small growth pyramid has a simple structure compared with that of the abnormal growth pyramid of 4.3, and the number of the screw dislocations existing in that part is relatively small. Fig. 19 shows a specimen which has the growth center of threefold symmetry around a small hole.

4.5 *Discussion of planar growth pattern*

If the rate of growth of the crystal is sufficiently large and exceeds 20 μ/sec in Fig. 24, the growth of the crystal should take place mainly through the surface nucleation. In such case, planar growth pattern should be developed as shown in Fig. 20. Obviously, each of the patterns (a) and (b) has threefold symmetry. Fig. 21 (a) and (b) may be such that the small growth pattern as described in 4.3 appears in good contrast by the oxide decoration.

§ 5. Acknowledgment

The author is indebted to Y. Sugita for his supply of many data and cooperation in experiment, and to T. Mitsuishi and E. Yamada for their discussion about the mechanism of regrowth.

An Electron Diffraction Study on Cu-Sn Alloys

By Tomokuni MITSUISHI

Hitachi Central Res. Lab. Kokubunji, Tokyo

(Received November 30, 1960)

Intermetallic compounds produced by the interdiffusion of Cu and Sn were examined by electron diffraction. In addition to the known phases, a new phase of structure A4 type is found.

§1. Introduction

Cu-Sn alloys were studied by X ray diffraction, and various intermetallic compounds were reported[1]. (Table I). Related to the investigation on the soldering of copper, the boundary layer of Cu_6Sn_5 at low temperature and the additional layer Cu_3Sn between Cu_6Sn_5 and Cu at high temperatures were found by the microscopic observation of Cu-Sn joint[2]. By the electron diffraction method, Tazaki and Kohra[3] confirmed the formation of Cu_6Sn_5 in heat treated double films of Cu and Sn. Recently Y. Fujiki[4] observed electron diffraction patterns of a Cu-Sn compound of NiAs type structure. However, these data on the interdiffusion of Cu-Sn and on the formation of various compounds are not satisfactory. The author examined Cu-Sn compound layers of various stage of interdiffusion, and identified various intermetallic compounds of Cu-Sn reported literatures in various transient states of interdiffusion. In addition, he found a new compound of structure A-4 type.

§ 2. Experimental Procedures

(a) *Foil specimens*

Foil specimens were prepared by vacuum evaporation. Cu and Sn were deposited one after another on resin films which were spread over glass plates. The resin films were then dissolved away with acetone and the specimens were scooped up by a fine mesh. The thickness of foils was measured by a microscopic interferometer using a sodium lamp as the light source. Thickness of Cu was about 700Å and that of Sn 400Å. The specimens were heated in vacum for 1 or 6 min. at each temperature of 200°C and 470°C.

(b) *Block specimens*

The specimens for electron reflection measurements were prepared by evaporating Sn on Cu blocks, $30^{\mathrm{mm}} \times 4^{\mathrm{mm}} \times 3^{\mathrm{mm}}$. They were heated in vacum for one or five minuites at each temperature of 200°C and 400°C.

§ 3. Results and Discussions

(a) *Foil specimens*

Some of the foil specimens, showed diffraction patterns indicating that Cu_6Sn_5 (η) had been formed before any heat treatment, and others those of Cu only. Upon heating both of these specimes changed to a new phase and then to another. Let us call these phases δ' and X respectively. Phase δ' has the lattice constant close to that of δ phase. However δ' phase shows the diffraction pattern corresponding to A-4 type (Fig. 1, Table II), while δ phase has the D-8_{1-3} structure. The δ' phase is a newly found compound. As for the X phase, we were not able to determine its crystal structure. However, it is doubtless that it is different from η, ε or δ phases. It has some variations both in lattice spacing and in intensities of diffraction lines from one specimen to another. Consequently we concluded that this phase was an intermediate one.

Table III. Summary of observed results

Observed phase	η	δ'	X	Sn	η	η	δ'?	$\eta+\varepsilon$	$\eta+\varepsilon$?	η	ε

* T: Transmision R: Reflection Bl.: Block

(b) *Block specimens*

While specimens deposited with thick layer of Sn (70 mμ) showed the diffraction pattern of Sn before the heat treatment, those deposited with thin layer (40 mη) indicated the diffraction pattern likely to be η phase. With the application of the heat treatment to the latter, η phase became distinct and the continuation of heat treatment resulted in the appearence of the pattern like that of δ' phase or ε phase.

ε phase is not observed in foil specimens. This fact indicates that ε phase layer is too thin for transmission experiments, owing to the condition of material supply restricted by foil thickness. Appearance of X phase in foil specimens is also interpreted as a similar phenomenon. It was rare for any specimen to show the typical diffraction pattern of each phase, and even specimens of the same treament showed more or less different diffraction patterns. This is quite conceivable if the specimens did not attain the thermal equilibrium and were in transient states.

In accordance with Fujiki's results, η phase can be easily formed at relatively low temperatures.

Acknowledgement

The author expresses his sincere gratitude to Dr. Ōhara for many helpful discussions. He is indebted to Mr. T. Takagi for assistance with the experiments.

Diffusion of Cobalt into Silver

By Tokutaro HIRONE and Hisao YAMAMOTO

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received December 3, 1960)

The diffusion coefficient of cobalt into silver has been measured as a function of temperature over the range from 745°C to 943°C by the tracer and lathe-sectioning technique. It has been found that the diffusion coefficient can be expressed as follows;

$$D=(104)\exp\frac{59.9}{RT}10^3\ \text{cm}^2/\text{sec}.$$

The value of activation energy, 59.9K cal/mol, obtained by the present experiment is in good agreement with the result of the screening theory of impurity diffusion, but considerable discrepancy is found between the observed and theoretical frequency factor. The amount of diffused cobalt showes an abnormal decrease near the diffusing surface, which may be caused by the low solubility limit of cobalt in silver.

§1. Introduction

Since Lazarus put forward a screening theory of impurity diffusion in metals, various results of calculations based on the Thomas-Fermi method for the diffusibility of impurity atoms in metallic lattices have been reported[1)-3)]. In order to check these theoretical results experimentally, the diffusion coefficients of various impurity atoms into silver as well as copper have been measured. Although results for both these series are qualitatively consistent with the result of the screening theory, quantitative-agreement is less favorable in the case of copper than in the case of silver: The activation energy of solute diffusion into silver increases regularly from Sb to Ru[4),5)], which belongs to the second transition series, but the activation energies for the diffusion of the first transition elements into copper increase in the order Fe, Co, Ni and decrease from Ni to Zn and increase again at Ga[6)-10)]. However it is uncertain whether the activation energy for the diffusion of the first transition metals into silver is similar to the case of the diffusion into copper or not. For the purpose of finding the difference between the both cases, the diffusion coefficient of cobalt into silver was studied. As silver and cobalt had been reported to be insoluble in each other, special precautions were taken in analyzing the results of the experiment.

§ 2. Experimental Method and Results

The specimens were single crystals of silver 99.99%, 1.5 cm in diameter and 15 cm in length, made by means of the Bridman method. A single crytal rod thus prepared was etched, put into a resin mould and, by means of a cut-off wheel, cut into the shape of a short cylinder, 15 mm in length. To avoid the influence of strains due to the cutting process, the surface layer, about 2 mm in thickness, was removed by electropolishing the cut surface. Then the surfaces were smoothed by polishing with emery paper and electropolished again. Each end surface of the specimen was then plated with cobalt containing Co^{60} isotope.

The amount of plated cobalt was calculated from the product of the time and current-density of electroplating. Then its total radioactivity was measured and the ratio of cobalt quantities to the activity was determined. The estimated thickness of the plated layer ranged from 100 to 500Å. The electroplated specimen was sealed in a quartz tube filled with argon gas and was put in a diffusion annealing furnace. The temperature of the specimen was maintained constant within ±1°C. After the annealing was finished, the specimen was quenched, then mounted in a precision lathe and sectioned.

The total depth of sectioning was measured by a dial-gauge. Each slice thickness was determined from the slice mass as well as from the ratio of total masses to total depth. The sum of each slice mass ranged from 99.6% to 99.9% of the total diminution of the specimen weight due to sectioning.

Fig. 1 shows the logarithms of specific activity of each sliced piece plotted against the square of the penetration depth. As is seen from the figure, each curve shows a steep descent of activity near the surfaces, and then decreases linearly with the square of the penetration depth.

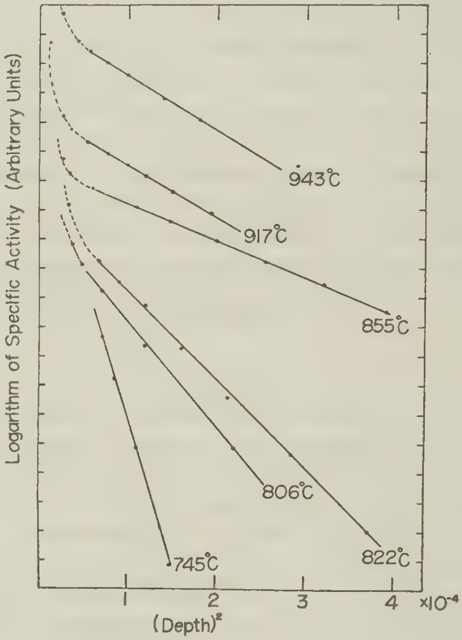

Fig. 1. Penetration curves for the diffusion of Co in Ag.

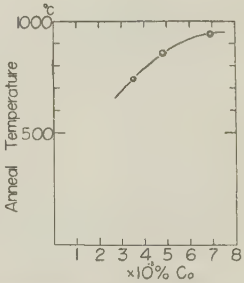

Fig. 2. Co concentrations at the breaking point of the penetration curve versus the annealing temperature.

The analysis of the data was complicated by the existence of the steep descent of the cobalt concentration near the surface. A similar effect has previously been found by Pierce and Lazarus in the case of ruthenium diffusion into silver[5)]. These effects are presumably considered to be caused by the formation of the impermeable intermetallic phase or to the extremely low solubility limit of cobalt or ruthenium in silver. At the present stage it is difficult to give the correct interpretation. However, Tamman proposed previously on the basis of his magnetic measurements that the solubility of cobalt in silver is 0.0007 (at 1000°C) and 0.0004 (at 1200°C) wt. percent respectively.

Fig. 2 shows a temperature dependence of cobalt concentration, which corresponds to the breaking point on the curve of the logarithms of specific activity versus the square of depth where activity ascends sharply. As seen from the curve, these points are roughly in the same order of magnetude as Tamman's result of solubility limit of cobalt in silver.

As in the case of Pierce and Lazarus, the linear part of the x^2-plot of the activity is here assumed to be due to the Fick mechanism of diffusion. Here x means the penetration depth of cobalt into silver. Then the cobalt concentration is expressed by the following equation;

$$c=\frac{c_0}{\sqrt{\pi D t}}\exp\left(-\frac{x^2}{4Dt}\right).$$

In this equation, D represents the diffusion coefficient, t annealing time, c the concentration of diffused atoms and c_0 the concentration of initial solute atom. By comparing the results of the measurements with the above equation, the diffusion coefficient can be obtained as given in the following Table.

Table I. Diffusion of Co in Ag.

Annealing Temperature (deg C)	D (cm²/sec)	Annealing time (sec)
943	2.04×10^{-9}	3.51×10^{4}
917	8.81×10^{-10}	6.57×10^{4}
855	2.78×10^{-10}	26.0×10^{4}
822	1.13×10^{-10}	31.8×10^{4}
806	7.18×10^{-11}	42.5×10^{4}
745	1.50×10^{-11}	59.6×10^{4}

The temperature variation of the diffusion coefficient is shown in Fig. 3.

As can be seen from the curve, the diffusion coefficient can be perfectly expressed by the Arrhenius equation,

$$D=D_0\exp\left(-\frac{Q}{RT}\right).$$

Based on the above results the value of the frequency factor D_0 and the activation energy Q were calculated together with their probable error. The results of the calculations are as follows.

$$Q=(59.9\pm1.2)K\ \text{cal/mol} \qquad (3)$$

$$D_0=(104\pm76)\ \text{cm}^2/\text{sec}. \qquad (4)$$

The present result is shown as one of the points in Fig. 4 together with activation energies obtaineded by other workers versus

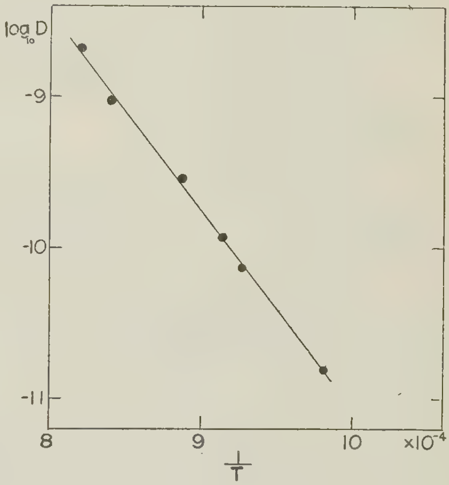

Fig. 3. Diffusion data plotted as log D versus $1/T$.

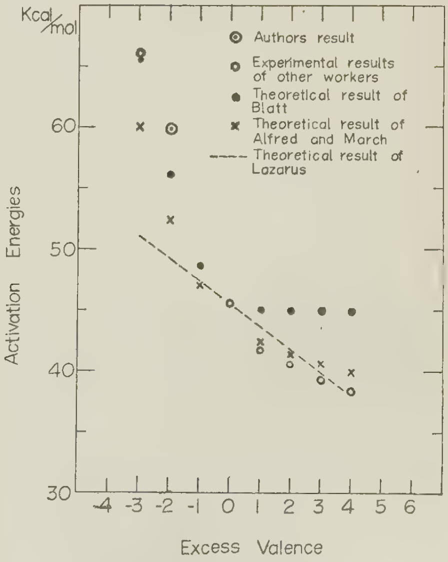

Fig. 4. Calculated and experimental activation energies for the solute diffusion in silver.

the atomic number of diffusing metals. The theoretical results due to Alfred and March, Blatt and Lazarus are also shown in the same figure. As is seen from the figure the present result agrees comparatively well with the result of Blatt[2]. However, the present authors found an unexpected result as for the value of D_0: According to Zener's theory[11], the relation between D_0 and Q is given as follows.

$$D_0=a^2\nu \exp(\lambda\beta Q/RT_m)\,. \tag{5}$$

a: the lattice constant
ν: the Debye frequency
λ: a numerical constant, which should be taken to be 0.55 for diffusion of electronegative impurities in silver[5]
T_m: the melting point.
$\beta=d(\mu/\mu_0)/d(T/T_m)=0.45$[5].
μ: the shear modulus.
μ_0: the shear modulus at absolute zero of temperature.

In very dilute solution all of these quantities except ν and Q are those of the solvent metal. Putting the observed values in Eq. (5), the following result is obtained:

$$D_0=3.5\ \mathrm{cm^2/sec}.$$

Thus the calculated value of D_0 is considerably less than the measured value shown in Eq. (4). The same kind of anomaly in D_0 value was also found by Pierce and Lazarus in the case of ruthenium diffusion into silver. The origin of these large values of D_0 is not known at the present time.

Acknowledgement

The authors wish to express their sincere thanks to Dr. Kunitomi, Prof. H. Watanabe and Mr. T. Suzuoka for their king advice throughout the course of the present investigation. This investigation was supported in part by the Grant-in-Aid of Fundamental Scientific Research of the Ministry of Education.

Orientation Dependent Mechanical Breakdown of a Model High Polymer Solid*

C. C. HSIAO, J. E. OSBORN, and D. B. ROZENDAL

University of Minnesota, Minneapolis, Minnesota

(Received August 16, 1960)

A theory of mechanical breakdown of a model high polymer solid is given. On the basis of considering a static, a quasistatic, or a dynamic system, the orientation dependent mechanical strength of a linear model polymer solid is analyzed. The maximum breaking strength obtainable is six times that of the unoriented strength and is found to occur in the direction of orientation for a fully oriented static system.

§ 1. Introduction

Recently a number of analyses[1)-4)] have been made of the orientation and strength problem of a model solid. On the basis of considering a quasi-static system of oriented microscopic linear elements the stress tensor in the vicinity of a point in an orthogonal coordinate system has been found to be[1)]:

$$\sigma_{ij}^* = \int El^2 \lambda \rho^* f^* \varepsilon_{mn} s_m^* s_n^* s_i^* s_j^* d\omega^* \tag{1}$$

where

E = the spring modulus,
l = the length of any spring,
λ = the number of springs per unit volume,
ρ^* = the probability density function of the orientation of the springs,
f^* = the fraction of unbroken springs,
$\varepsilon_{mn} s_m^* s_n^*$ = The strain along the instantaneous direction of a spring,
s_i^* = instantaneous direction of a spring,
and $d\omega^*$ = the solid angle.

Depending upon the variations of f^* three different cases may be analyzed. If f^* is constant, i.e. $f^* = f_0$, the system is static[3)]. The system becomes quasi-static when

$$\frac{df^*}{dt} = k_r(\varepsilon_{mn} s_m^* s_n^*)\left(\frac{1}{4\pi} - f^*\right) - k_b(\varepsilon_{mn} s_m^* s_n^*) f = 0 \tag{2}$$

and $f^* \cong (1 - K_1 \varepsilon_{mn} s_m^* s_n^*)$ where k_r and k_b are exponential functions of strain and K_1 is a constant[1)]. The system is dynamic when

$$\frac{df^*}{dt} = k_r\left(\frac{1}{4\pi} - f^*\right) - k_b f^* \neq 0\ ; \tag{3}$$

then

$$f^* = \frac{1}{4\pi} \exp\left[-\int (k_r + k_b) dt\right] \left[\int k_r \exp\int (k_r + k_b) dt\ dt + C\right] \tag{4}$$

where C is an integration constant. To a first approximation for small strains, the foregoing expression reduces to

$$f^* \cong f_0[1 - K_2(\varepsilon_{mn} s_m^* s_n^*)^2]$$

if a linear relation between strain and time is considered where $f_0 = 1/8\pi$ and K_2 is a constant. For both the static[3)] and the quasistatic[1)] case the analyses have already been reported. In order to obtain a better understanding of the subject, the following section gives the analysis for the dynamic case.

§ 2. Behavior of Dynamic Model Solid

With $f^* \cong f_0[1 - K_2(\varepsilon_{mn} s_m^* s_n^*)^2]$, the stress tensor becomes

$$\sigma_{ij}^* = El^2 \lambda f \int_0 [\varepsilon_{mn} s_m^* s_n^* - K_2(\varepsilon_{mn} s_m^* s_n^*)^3] s_i^* s_j^* \rho^* d\omega^*\ . \tag{5}$$

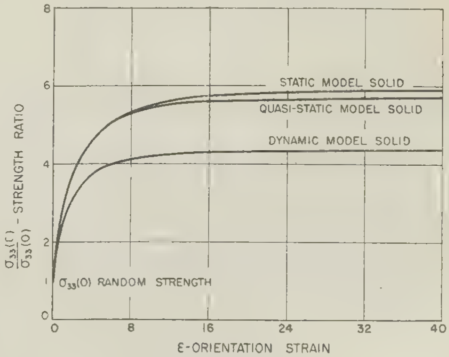

Fig. 1. Fracture strength ratio for three model solids.

---

* Supported in part by the U. S. Atomic Energy commission.

In the case of simple tension in the 33 direction, ε_{mn} has only the principal strain components. Because of symmetry, $\varepsilon_{11}=\varepsilon_{22}=-\nu\varepsilon_{33}$ where ν is the strain ratio. Thus the scalar strain

$$\varepsilon_{mn}s_m{}^*s_n{}^*=\varepsilon_{11}s_1{}^{*2}+\varepsilon_{22}s_2{}^{*2}+\varepsilon_{33}s_3{}^{*2} \tag{6}$$

and

$$s_i{}^*=(\sin\theta^*\cos\varphi^*,\ \sin\theta^*\sin\varphi^*,\ \cos\theta^*)\ .$$

For the uniaxial orientation along the 33 direction, as shown previously[1)], if the orientation strain is ε then the density of the probability distribution function of orientation is

$$\rho^*=\frac{(1+\varepsilon)^3}{[\cos^2\theta^*+(1+\varepsilon)^3\sin^2\theta^*]^{3/2}}\rho \tag{7}$$

where ρ is the density function for the random case. Let $1-(1+\varepsilon)^{-3}=k^2$, then the stress σ_{33}^* may be obtained after integration. The result is

$$\begin{aligned}\sigma_{33}^*=\frac{El^2\lambda\rho\varepsilon_{33}}{8\pi(1+\varepsilon)^{3/2}}\Bigg\{&-\nu\left(\frac{1}{k^2(1-k^2)^{1/2}}-\frac{\sin^{-1}k}{k^3}\right)+(1+\nu)\left(\frac{-1}{2k^2(1-k^2)^{1/2}}+\frac{3}{2k^4(1-k^2)^{1/2}}-\frac{3\sin^{-1}k}{2k^5}\right)\\&-K_2\varepsilon_{33}^2\Bigg[-\nu^3\left(\frac{1}{k^2(1-k^2)^{1/2}}-\frac{\sin^{-1}k}{k^3}\right)+3\nu^2(1+\nu)\left(\frac{-1}{2k^2(1-k^2)^{1/2}}+\frac{3}{2k^4(1-k^2)^{1/2}}-\frac{3\sin^{-1}k}{2k^5}\right)\\&-3\nu(1+\nu)^2\left(\frac{-1}{4k^2(1-k^2)^{1/2}}-\frac{5}{8k^4(1-k^2)^{1/2}}+\frac{15}{8k^6(1-k^2)^{1/2}}-\frac{15\sin^{-1}k}{8k^7}\right)\\&+(1+\nu)^3\left(\frac{-1}{6k^2(1-k^2)^{1/2}}-\frac{7}{24k^4(1-k^2)^{1/2}}-\frac{35}{48k^6(1-k^2)^{1/2}}+\frac{105}{48k^8(1-k^2)^{1/2}}-\frac{105\sin^{-1}k}{48k^9}\right)\Bigg]\Bigg\}\ .\end{aligned} \tag{8}$$

To obtain equilibrium fracture strength, we let $\partial\sigma_{33}^*/\partial\varepsilon_{33}=0$; then

$$\begin{aligned}\varepsilon_{33}^2=\Bigg\{&-\nu\left[\frac{1}{k^2(1-k^2)^{1/2}}-\frac{\sin^{-1}k}{k^3}\right]+(1+\nu)\left[\frac{-1}{2k^2(1-k^2)^{1/2}}+\frac{3}{2k^4(1-k^2)^{1/2}}-\frac{3\sin^{-1}k}{2k^5}\right]\Bigg\}\Bigg/\\3K_2\Bigg\{&-\nu^3\left[\frac{1}{k^2(1-k^2)^{1/2}}-\frac{\sin^{-1}k}{k^3}\right]+3\nu^2(1+\nu)\left[\frac{-1}{2k^2(1-k^2)^{1/2}}+\frac{3}{2k^4(1-k^2)^{1/2}}-\frac{3\sin^{-1}k}{2k^5}\right]\\&-3\nu(1-\nu)^2\left[\frac{-1}{4k^2(1-k^2)^{1/2}}-\frac{5}{8k^4(1-k^2)^{1/2}}+\frac{15}{8k^6(1-k^2)^{1/2}}-\frac{15\sin^{-1}k}{8k^7}\right]\\&+(1+\nu)^3\left[\frac{-1}{6k^2(1-k^2)^{1/2}}-\frac{7}{24k^4(1-k^2)^{1/2}}-\frac{35}{48k^6(1-k^2)^{1/2}}+\frac{105}{48k^8(1-k^2)^{1/2}}-\frac{105\sin^{-1}k}{48k^9}\right]\Bigg\}\ .\end{aligned} \tag{9}$$

Thus the fracture stress as a function of ε is given by

$$\begin{aligned}\sigma_{33}(\varepsilon)=\frac{E\lambda\rho l^2}{(3k_2)^{1/2}12\pi(1+3)^{3/2}}\Bigg\{&-\nu\left[\frac{1}{k^2(1-k^2)^{1/2}}-\frac{\sin^{-1}k}{k^3}\right]+(1+\nu)\left[\frac{-1}{2k^2(1-k^2)^{1/2}}+\frac{3}{2k^4(1-k^2)^{1/2}}\right.\\&\left.-\frac{3\sin^{-1}k}{2k^5}\right]\Bigg\}^{3/2}\Bigg/\Bigg\{-\nu^3\left[\frac{1}{k^2(1-k^2)^{1/2}}-\frac{\sin^{-1}k}{k^3}\right]+3\nu^2(1+\nu)\left[\frac{-1}{2k^2(1-k^2)^{1/2}}+\frac{3}{2k^4(1-k^2)^{1/2}}\right.\\&\left.-\frac{3\sin^{-1}k}{2k^5}\right]-3\nu(1+\nu)^2\left[\frac{-1}{4k^2(1-k^2)^{1/2}}-\frac{5}{8k^4(1-k^2)^{1/2}}+\frac{15}{8k^6(1-k^2)^{1/2}}-\frac{15\sin^{-1}k}{8k^7}\right]\\&+(1+\nu)^3\left[\frac{-1}{6k^2(1-k^2)^{1/2}}-\frac{7}{24k^4(1-k^2)^{1/2}}-\frac{35}{48k^6(1-k^2)^{1/2}}+\frac{195}{48k^8(1-k^2)^{1/2}}-\frac{105\sin^{-1}k}{48k^9}\right]\Bigg\}^{1/2}\ .\end{aligned} \tag{10}$$

§ 3. Generalized Fracture Theory and Stress-Strain Law

An interesting inter-relation common to all the three analyses[1)-3)] has been observed. For clarity the following table is given to bring out the common nature for the three different cases of equilibrium fracture:

In the foregoing table all C's are proportional to $El^2\lambda f_0$;

$$\varphi(\varepsilon)=\left[\frac{3-k^2}{4^4}-\frac{3(1-k^2)^{1/2}}{k^5}\sin^{-1}k\right]-\nu\left[\frac{-3+3k^2}{k^4}+\frac{3-2k^2}{k^5}\sin^{-1}k\right]$$

which varies from 1/3 for $\varepsilon=0$ to 2 for $\varepsilon=\infty$, with

Table II. Comparison of Different Models.

Model	Static	Quasi-Static	Dynamic
f^*	$f_0=\frac{1}{8\pi}$	$f_0[1-K_1(\varepsilon_{mn}s_m s_n)]$	$f_0[1-K_2(\varepsilon_{mn}s_m s_n)^2]$
$\sigma_{33}(\varepsilon)$	$C_0\varphi(\varepsilon)\varepsilon_{33}(\varepsilon)$	$C_1\varphi(\varepsilon)_{33}(\varepsilon)$	$C_2\varphi(\varepsilon)\varepsilon_{33}(\varepsilon)$
$\sigma_{33}(0)$	$\frac{1}{3}C_0\varepsilon_{33}(\varepsilon)$	$\frac{1}{3}C_1\varepsilon_{33}(\varepsilon)$	$\frac{1}{3}C_2\varepsilon_{33}(\varepsilon)$
$\frac{\sigma_{33}(\varepsilon)}{\sigma_{33}(0)}$	$3\varphi(\varepsilon)\frac{\varepsilon_{33}(\varepsilon)}{\varepsilon_{33}(0)}$		

$$k^2=-1(1+\varepsilon)^{-3}$$

and

$$\nu=-\frac{\varepsilon_{11}}{\varepsilon_{33}}=\frac{\left[1-\frac{(1-k^2)^{1/2}}{k}\sin^{-1}k\right]-\frac{1}{2k^2}\left[3-k^2-\frac{3(1-k^2)^{1/2}}{k}\sin^{-1}k\right]}{k^2-2\left[1-\frac{(1-k^2)^{1/2}}{k}\sin^{-1}k\right]+\frac{1}{2k^2}\left[3-k^2-\frac{3(1-k^2)^{1/2}}{k}\sin^{-1}k\right]}$$

which varies from 1/4 for $\varepsilon=0$ to 1 for $\varepsilon=\infty$. The difference between the three analyses is seen to lie wholly in the ratio $\varepsilon_{33}(\varepsilon)/\varepsilon_{33}(0)$. For fracture the numerator is the fracture strain when orientation is present and the denominator is the fracture strain when orientation does not exist. It is reasonable to believe that the fracture process is essentially a brittle one and a linear relation between the stress and the small fracture strain holds while the orientation strain is nearly the total strain and is only associated with the directions of the basic components of the model solid. For any state before fracture the foregoing relations seem to hold. Thus, we have a stress-strain relation which for simple tension is capable of specifying the strength for any particular state of orientation. Mathematically the general linear stress-strain relation is

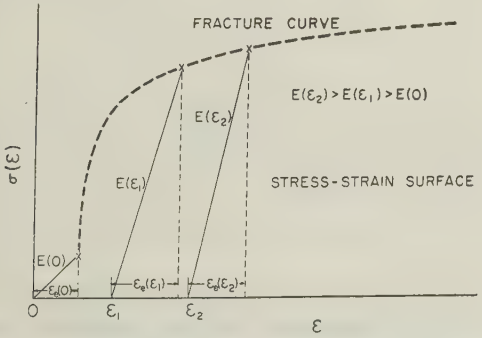

Fig. 2. Schematic stress-strain surface of oriented model solid.

$$\sigma(\varepsilon)=E(\varepsilon)\varepsilon_e(\varepsilon) \tag{13}$$

where ε_e is the elastic strain, and $E(\varepsilon)=C\varphi(\varepsilon)$ is a modulus as a function of orientation strain $\varphi(\varepsilon)$ and C is the material constant depending upon the microscopic model chosen. If we plot this out we obtain an area in the $\sigma(\varepsilon)-\varepsilon$ plane describing the linear and non-linear behavior of the solid as shown in Fig. 2. For oriented solids when the fracture strain is constant it is seen that the modulus increases as the degree of orientation increases. This is quite true in reality. When $\varepsilon=0$ the modulus reduces to the elastic modulus $E(0)$ of the solid.

In spite of the difference in models used if the elastic fracture strain is considered independent of orientation then the strength ratio reduces to the same expression for all the models

$$\frac{\sigma(\varepsilon)}{\sigma(0)}=\frac{E(\varepsilon)\varepsilon_e(\varepsilon)}{E(0)\varepsilon_e(0)}=\frac{E(\varepsilon)}{E(0)}=3\varphi(\varepsilon) \tag{14}$$

which approaches to 6 as ε goes to ∞. By varying the fracture strain ratio we can easily widen the applicability of the general orientation-strength relation.

Furthermore, it seems possible to generalize the stress-strain relations for a model solid with uniaxial orientation strain ε along one of the principal directions in the following form:

$$\sigma_{ij}(\varepsilon)=E_{ij}(\varepsilon)\varepsilon_{ij}(\varepsilon)\ . \tag{15}$$

For biaxial orientation,[4] if ε_x and ε_y are the orientation strains along two mutually perpendicular principal directions then

$$\sigma_{ij}(\varepsilon_x, \varepsilon_y)=E_{ij}(\varepsilon_x, \varepsilon_y)\varepsilon_{ij}(\varepsilon_x, \varepsilon_y)\,. \qquad (16)$$

It is hoped that these relations will be investigated in the future.

X-Ray Line Broadening in Polyethylene Filaments

By Ken-ichi KATAYAMA

Textile Research Laboratory, Asahi Chemical Industry Company, Ltd.
Takatsuki, Japan

(Received August 5, 1960)

The precise methods of obtaining X-ray line profile and broadening in crystalline high polymer using X-ray diffractometer are discussed in detail, and the causes of X-ray line broadening in highly oriented linear polyethylene 'Marlex 50' are investigated. It is found that the main causes are crystallite size effect and lattice-distortion, and the strain distribution function is approximated by Cauchy-form $1/(1+k^2x^2)$. Therefore, the separation of two effects can be made by means of Hall's equation. Using 110 and 220 reflections on the equator, recrystallization of crystallite by annealing, break-up of crystallite with elongation and change in lattice-distortion are observed.

The obtained values of strain (1~2%) are larger by one order of magnitude than those of cold-worked metals, and not changed so greatly by annealing and deformation, whereas crystallite size varies widely (100Å~larger than 700Å).

§ 1. Introduction

It is well known that the X-ray diffraction lines from crystalline high polymers are somewhat broadened as compared with those given by large perfect crystals of inorganic substances.

The X-ray line broadening may be due to several cause; (i) small size effect of crystallite; (ii) distortions in crystal-lattice or other imperfections, and (iii) thermal vibration of high polymer chains. In high polymers, measurements of line profiles of diffracted X-rays contain many difficulties, and the causes of line broadening have not been studied. With recent advances in measuring technique by X-ray diffractometer, it is possible to overcome experimental difficulties and distinguish between probable causes of broadening in some way.

Highly oriented filament of linear polyethylene 'Marlex 50' was chosen as specimen for the following reasons:

(i) Lattice imperfections due to irregularities in chain structure have little effect on broadening, since molecular chains of this type of polyethylene are regular and have few branches.

(ii) The crystal structure was fully analysed by Bunn[1].

(iii) Two orders of reflection, 110 and 220, from the same planes can be observed with intensities enough to measure diffraction profile correctly.

In the present paper, discussions on the causes of broadening and strain distribution function will be given. The thermal and load-induced changes of crystallite size and distortion will also be investigated.

§ 2. Theory of Line Profile and Broadening

The methods of separating lattice-distortion and size effects on broadening in X-ray pattern have been discussed by means of Fourier analysis of powder diffraction line profiles[2,3], and were successfully applied to cold-worked metals by many authors[4]. Some remarkes on using the important results of broadening theory are summarized here.

The profile of the diffraction peak of l-th order from certain set of planes can be represented by a Fourier series:

$$P(h,l)=K\sum_{-\infty}^{\infty}A_n(l)\cos 2\pi nh\,, \tag{1}$$

where $h=(2a\sin\vartheta/\lambda)-l$, a is interplanar spacing, ϑ the Bragg angle, λ the X-ray wave length, and K a proportionality factor involving some slowly varying functions of ϑ. If two types of broadening are present, $A_n(l)$ is represented by the product of small particle size coefficient A_n^P which is independent of l, and distortion coefficient $A_n^D(l)$ which is dependent on l. That is, observed profile is obtained by convolution process on two profiles which would be obtained if two causes were present separately.

If we have a number of orders of reflection from the same planes, it is possible to separate the two effects with complete accuracy. When only one or two orders of reflection are available the following approximation methods[3] can be used.

(1) n small

When n is small,

$$-\frac{\log A_n}{n}=\frac{1}{\bar{N}}+2\pi^2l^2\overline{e^2}n\,, \tag{2}$$

where Na is the thickness of the crystal normal to the reflecting planes, and e is the local strain. $\bar{N}$ value determined from this formula is largely influenced by the tail of the line profile, so the measurements of the tail must be made with great accuracy.

(2) n large

If the displacements of widely separated planes are independent, the line profile due to lattice-distortion will be of the Cauchy-type $1/(1+k^2x^2)$ for small h, and

$$-\frac{\log A_n^D}{n}=f(l)\,. \tag{3}$$

The functional form of $f(l)$ depends on the strain distribution function. For example, $f(l)$ is equal to αl for the Cauchy distribution and αl^2 for the Gaussian distribution, where α is a constant relating to the magnitude of strain. Therefore, we can find the strain distribution function if we know the form of $f(l)$.

Instead of the methods based on the Fourier analysis of line profile, Hall has suggested a simple method[5], which is rather recommended when the intensity measurement of the tail is ambiguous. According to his suggestion, integral line breadth β is expressed by

$$\frac{\beta\cos\vartheta}{\lambda}=\frac{1}{t}+2\xi\frac{\sin\vartheta}{\lambda}\,, \tag{4}$$

where t is 'apparent size' which is equal to $aN^2/\bar{N}$[6], and ξ the integral breadth of the strain distribution function. Eq. (4) is valid if both line profiles are always of the exact Cauchy-form and the breadth due to distortion effect is proportional to the order of reflection, because the convolution of two Cauchy-forms is also of the same form and integral breadths are additive. The line profile due to small size effect is closely approximated by Cauchy-form provided that specimen contains a fairly wide distribution of crystallite size. In fact, exponential distribution of size gives the exact Cauchy-form. Therefore, the applicability of Eq. (4) depends on the nature of the line broadening generated by pure distortion effect.

§ 3. Experimental Procedure and Correction

Difficulties of the measurement of line broadening in high polymer are as follows:

(i) Since scattered X-rays from high polymer contain amorphous scattering besides temperature and incoherent scatterings, the base line of crystalline peak cannot be drawn with certainty.

(ii) For measurement of pure line profile, we must know the instrumental profile[7], but in the present case we cannot consider the line profile of well-annealed sample as instrumental, because the strain in high polymer crystallite does never disappear entirely by annealing.

(iii) Since the intensities of reflections of higher order are weak, we seldom have two or more reflections from the same planes with intensities enough to measure the profiles accurately.

In the present experiment, a highly stabilized X-ray source[8] with Cu target was used, and the monochromatization was achieved by means of balanced filters[9] (Ni and Co foils) which were balanced within 1% at K_β wave length. Highly oriented monofilaments with 0.16 mm diameter were arranged side by side on a flat sample-holder parallel to the line focus of X-ray tube, and the profiles of diffraction peak were obtained by usual spectrometric powder technique.

The general methods of obtaining the true profile and line breadth from observed data have been discussed in detail[10], so only the special aspects in the present experiment are described below.

(1) *Correction of observed intensities*

By transmission technique, the sum of amorphous and incoherent scatterings was measured previously along the meridian of fiber diagram.

On the assumption that this diffuse scattering on the meridian is equal to that on the equator, the background of crystalline peak 110 can be corrected. The error due to this assumption may be small because the peak intensity of amorphous halo is about 0.5% of that of 110 reflection.

Proportionality factor in the formula (1) involves the influence of absorption of X-ray by the sample, geometrical factors (polarization and Lorentz factors*), and the modulation by structure factor which can be calculated from crystal structure data. These corrections are necessary when the lines are fairly broadened.

(2) *Correction of Fourier coefficients*

The Fourier coefficients of true profile are given by Stokes' method[7] using observed profile when instrumental profile is known. Though the profile of well-annealed sample is considered as the instrumental profile in the case of cold-worked metals, we cannot use this simple procedure in the case of high polymers. Therefore the line profile from perfect crystal powder with high absorption coefficient for Cu K_α (for example, KI) is measured near the Bragg angle of high polymer reflection, and the convolution of this profile and the calculated weight function due to finite thickness of high polymer sample is used as the instrumental profile. The measured instrumental profiles were appreciably asymmetrical. Though observed profiles of polyethylene samples were also asymmetrical, this asymmetry could be explained by that of the instrumental profiles.

(3) *Correction of integral breadth*

Simplified correction of observed integral breadth based on Stokes' method has been given by Rudman[11], but it is still troublesome without suitable computer. If we can assume adequate functional forms for the true and instrumental profiles, simpler method[12] may be used. As a matter of fact, the observed profile, which is widely broadened than the instrumental profile, is closely approximated by Cauchy-form, so we can assume that true profile has Cauchy-form. The measured instrumental profiles are asymmetrical, but they can be approximated by Gaussian form so far as they are used for the correction of the integral breadth. Thus, it is written as:

$$\text{true profile:}\quad \frac{1}{\beta}\frac{1}{1+\dfrac{\pi^2}{\beta^2}x^2}\,,$$

$$\text{instrumental profile:}\quad \frac{1}{b}\exp\left(-\frac{\pi}{b^2}x^2\right),$$

and by convolution operation, one finds that the observed integral breadth is

$$B=\frac{b\exp\left(-\dfrac{\beta^2}{\pi b^2}\right)}{1-2\Phi\left(\sqrt{\dfrac{2}{\pi}}\dfrac{\beta}{b}\right)}\,, \tag{5}$$

where

$$\Phi(t)=\frac{1}{\sqrt{2\pi}}\int_0^t \exp\left(-\frac{u^2}{2}\right)du\,.$$

From Fig. 1, we can find β, when B and b are known. The curve in Fig. 1 is somewhat different from Alexander's[12] which was obtained by numerical integration.

§ 4. Strain Distribution

Among many reflections from polyethylene filament, 110 and 220 are only one pair of reflections from the same planes that have appreciable intensities. For this reason, attention was confined to the profiles of 110 and 220 peaks. This would have the generality, for the changes of broadening of reflections on the equator have the same tendency. To obtain a sample which has as large crystallite size as possible, sample filament was annealed for 30 minutes allowing free shrinkage at 110°C and further for an hour at 130°C maintaining constant length. Then, the line profiles of 110 and 220 were measured at 20°C and $-196°C$. Low temperature was attained by cooling the sample-holder by liquid nitrogen. Observed values of A_n and $-\log A_n/n$ are plotted against n in Fig. 2 and Fig. 3 respectively.

---

* Though the theory in § 2 was first obtained for the powder diffraction line profile, it can be applied to highly oriented filaments if we use the Lorenz factor for rotating-crystal method instead of that for powder method.

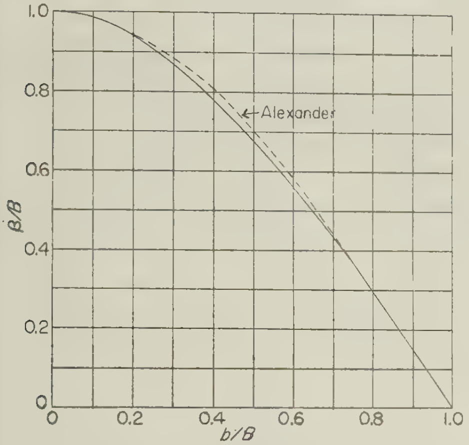

Fig. 1. Curves for correcting X-ray integral line broadening for instrumental broadening. Full-line was obtained from Eq. (5), and dotted-line by Alexander.

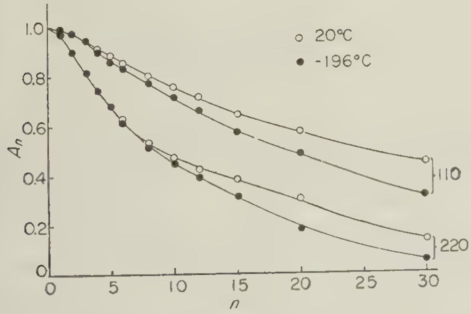

Fig. 2. Fourier coefficients A_n for annealed specimen measured at 20°C and $-196°C$.

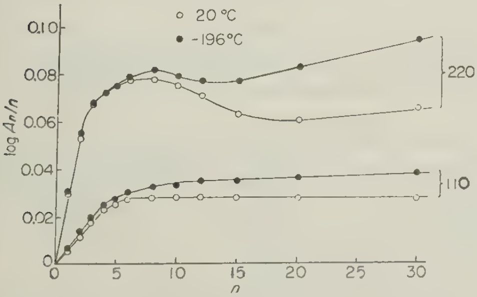

Fig. 3. $-\log A_n/n$ for annealed specimen measured at 20°C and $-196°C$.

In Fig. 3, the curves are straight lines passing through the origin for small n, and therefore, the crystallite size must be very large as seen from Eq. (2), even though measured crystallite size is affected by tail error. Consequently, the line broadening of this sample may be ascribed to pure lattice-distortion. As for the temperature scatterings at 20°C and $-196°C$, it is found that two shapes of tails of line profiles differ little from one another though the background level decreases a little by cooling. Thus it is concluded that the temperature scattering is so diffuse that it has little effect upon the shape of tail. On the other hand, the central part of line profile becomes broader by cooling contrary to the thermal effect in which the line profile becomes usually sharper by cooling. Moreover, this change is reversible, so the increase in line broadening at low temperature can be ascribed to that in elastic strain.

For large n, $-\log A_n/n$ tends to become a constant value. This fact indicates that the displacements of planes far apart become independent. The ratio of saturated value for the second order to that for the first order is about 2, so the strain distribution function for large n is expected to take Cauchy-form[3], but this result is not conclusive unless we have more reflections from the same planes. At any rate, the line profile due to pure distortion effect is nearly described by Cauchy-form, and its integral breadth is proportional to the order of reflection so far as 110 and 220 reflections are concerned. Therefore, Hall's equation (4) may be used hereafter with confidence.

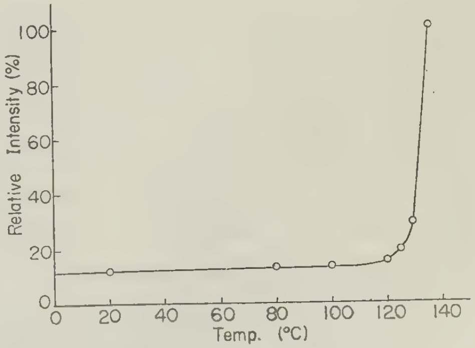

Fig. 4. Change of relative intensity under amorphous peak with temperature.

§ 5. Thermal Changes

The thermal changes of filaments at constant length were followed above room temperature. In highly oriented polyethylene, the crystallinity is not obtained so precisely as in powder specimen by X-ray method[13]. For simplicity, the integrated intensity of amorphous scattering along the meridian obtained by transmission technique was conveniently considered as the measure of the crystallinity*. The ratio of the integrated intensity to that of completely molten sample is plotted against temperature in Fig. 4.

Bragg distance corresponding to amorphous peak is also plotted against temperature in Fig. 5. Beyond 100°C, the coefficient of linear expansion of amorphous region increases and returns to the initial value after melting, but in crystalline region this phenomenon[14] cannot be seen as far as highly oriented filaments are maintained at constant length. From these facts, the thermal motion of chains in amorphous region seems to become more active above 100°C.

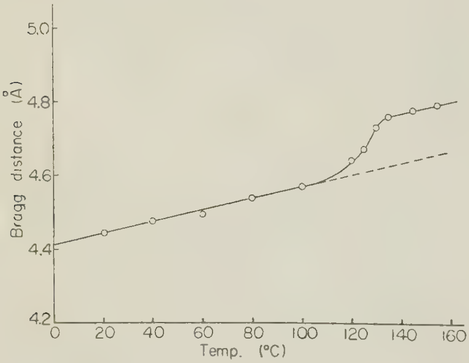

Fig. 5. Change of Bragg distance for amorphous peak with temperature.

To investigate changes in crystallites with annealing temperature, the integral breadths of 110 and 220 reflections were measured by the use of Fig. 1, and β *versus* temperature curve was plotted in Fig. 6. The values of 'apparent size' t and integral breadth of strain distribution function, ξ, were calculated using Hall's equation (4) and are shown in Fig. 7. From the two curves obtained from measurements at annealing temperature, it is seen that the strain decreases rapidly and the crystallite size increases appreciably above 100°C. This implies that the small imperfect crystallites melt and large ones recrystallize, because the crystallinity does not decrease so rapidly with rising temperature as seen from Fig. 4. In cooling process after annealing, as seen from other two curves in Fig. 7, the crystallite size increases further and strain also increases to the value before annealing.

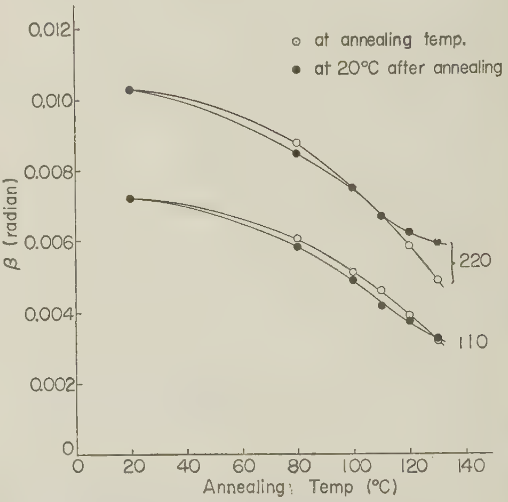

Fig. 6. Change of integral breadth with annealing temperature.

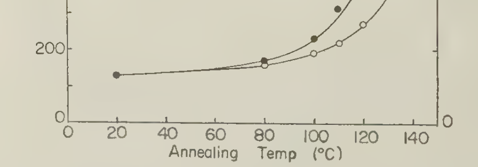

Fig. 7. Change of apparent size, t, and integral breadth of strain distribution function, ξ, with annealing temperature.

These data indicate, therefore, that the distortion or imperfection in crystalline region generates in the course of crystallization by cooling.

§ 6. Load-induced Changes

For the understanding of the mechanical

---

* These values do not express exactly true crystallinity, because the intensity of amorphous halo is not uniform but rather influenced by preferred orientation of chains in amorphous region.

behavior of crystalline high polymer, it is very important to know how microscopic structure changes with microscopic deformation. Therefore, the load-induced changes in crystallites were examined by following changes in line broadening by focusing our attention on crystallite size and distortion. Before loading, the specimens were annealed at 110°C for 30 minutes allowing free shrinkage, and then deformed in tension in a Instron Tensile Testing Instrument at constant rate of deformation of 0.2% per second. The load-elongation curve is shown in Fig. 8 with full-line, the dotted-lines representing 'load-elongation cycles', in which a specimen is elongated to a certain value and contracted till the load drops off to zero. The maximum elongation used in this experiment was almost the elongation at rupture, 40%.

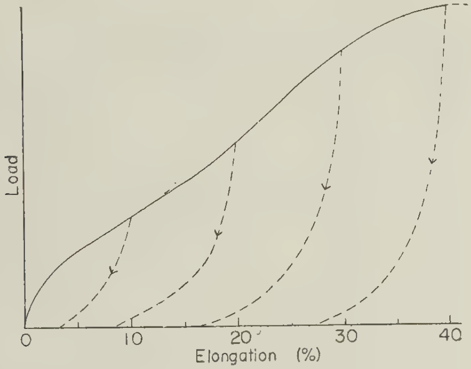

Fig. 8. Load-elongation curve and cycles.

The specimens were clamped on specimen-holders immediately after deformation, and the measurements of line broadening were made after 12 hours. Repeated measurements on the same specimen gave the same results, so the specimen did not change during measurement.

In Fig. 9, t and ξ obtained from integral breadths of 110 and 220 are plotted against elongation*. The changes in t and ξ become large beyond 25% elongation which corresponds to the inflection point on the load-elongation curve in Fig. 8. This results agree with that of Nylon filaments[15].

The difference in apparent size for elongated specimen and contracted one after the same elongation is very little, so break-up of crystallite by elongation is not recovered by contraction after elongation and seems to give rise to the permanent change in microscopic structure. On the other hand the strain decreases a little with contraction, and this is due to the elastic part of strain induced by elongation. Thus, it is worth noticing that the load-induced microscopic structural changes are mainly the break-up of crystallites and the increase in lattice-distortion is unexpectedly small.

The reflections on the first layer line which are expected to be sensitively broadened by the slip occurred among chains were recorded on a photographic film, because the precise method using diffractometer are only applicable for the reflections on the equator. By visual inspection, it is found that the change in broadening of the reflections on the first layer line with elongation has the same tendency as that on the equator.

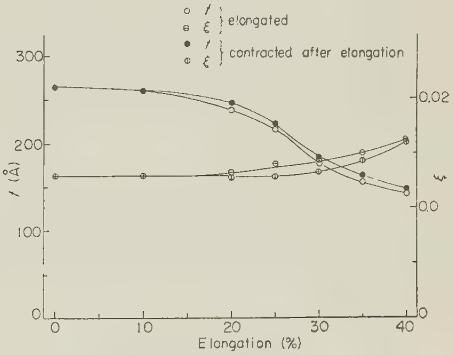

Fig. 9. Changes of apparent size, t, and integral breadth of strain distribution function, ξ, with elongation.

The angular broadening in fiber pattern, which is defined as the width of diffraction arc at half-maximum intensity taken along the arc, is about 7° for 110 reflection and slightly decreases with elongation. So the disorientation of crystallites at large elongation which was found in Nylon filaments[15] are not observed in polyethylene.

New crystalline phase[16] has been reported in polyethylene film extremely deformed by rolling or drawing. In the present work, however, reflections which could not be indexed on the orthorhombic cell were not observed.

---

* In the case of load-elongation cycle, the maximum elongation in the cycle is used as the parameter.

§ 7. Conclusion

There are many difficulties in measuring X-ray line broadening in crystalline high polymers, but careful intensity measurements and appropriate correction methods make it possible to obtain true values of Fourier coefficients or integral breadth of diffraction line with sufficient accuracy.

By analysing line broadening of 110 and 220 reflections from highly oriented linear polyethylene 'Marlex 50', it was found that important causes of broadening are crystallite size effect and lattice-distortion. Fourier analysis of line profiles shows that the strain distribution function is well approximated by Cauchy-form*. Therefore, the simple method suggested by Hall can be used. The crystallite changes widely in its size with annealing (100Å∼larger than 700Å) and breaks up with elongation, whereas the strain does not change so greatly. However, the amount of strain is larger by one order of magnitude even in the case of minimum strain (about 1% in integral breadth) than that in cold-worked metals. Large amount of strain contained in crystallite may be one of the reasons why rather large temperature factors should be used in the crystal structure analysis of polyethylene1) and other high polymers17).

The origin of the distortion is not clear at present, but the Cauchy-type strain distribution suggests that large distortions are localized somewhere in crystallite.

Acknowledgments

The author wishes to express his sincere thanks to Prof. K. Tanaka of Kyoto University for his continued encouragement and Mr. T. Amano for his assistance during the course of this experiment.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 3, MARCH, 1961

Study on the Ordered Alloys of Gold-Manganese System by Electron Diffraction, III. Lattice Modulation in the Ordered Au_3Mn.

By Denjiro WATANABE

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received August 5, 1960)

In the present paper, some discussion is given of the nature of the lattice modulation which is believed to cause the satellites to flank main reflections in electron diffraction patterns of the ordered Au_3Mn alloy and also in the case of CuAu (II) as well as of Cu_3Pd. Two types of modulation, i.e. a periodic change of lattice spacing and of scattering factor, are considered. It is pointed out that the valence electron may play an important rôle for the lattice modulation. In order to clarify this problem, a detailed X-ray study will be necessary.

§ 1. Introduction

In Part I of the present study[1], the structure of the ordered Au_3Mn alloy was investigated by electron diffraction, using thin single-crystalline films prepared by evaporation, and it was shown that this alloy possesses a two-dimensional anti-phase domain structure of a new kind, whose fundamental lattice consists of a face-centred orthorhombic cell with the atomic arrangement similar to Cu_3Au. In that case, satellites flanking intense main reflections were observed, as seen in Photo. 1 of Part I, but their intensities could not be derived from the proposed structure model. Such satellites as above have also been observed in other ordered alloys with anti-phase domain structure such as CuAu (II)[2], Cu_3Pd[3], and Cu-Au-Zn ternary ordered alloys[4], and it has been believed that some kind of periodic modulation with the same periods as anti-phase domain size does exist in the ordered lattice. In the case of Au_3Mn, five kinds of satellites were seen in photographic plates, their separations from the relevant main reflections being $m_1=a_1^*/M_1$, $2m_1$, $m_2=a_2^*/M_2$, $2m_2$ and $3m_2$ in reciprocal space respectively. Among these satellites only those with the separations of m_1, m_2 and $3m_2$ were represented in Figs. 2 and 3 of Part I by small open circles.†

For the origin of the satellites, on the other hand, Glossop and Pashley suggested that they are entirely caused by double diffraction of split superlattice-reflections[5]. This explanation is based on the fact that the distances of the satellites from the relevant main reflections are integer times the separations of the splits of the superlattice reflections. Carrying out the same experimental procedure as in cases of CuAu (II)[6] and a Cu-Au-Zn ternary ordered alloy[4], however, the present author confirmed also in the Au_3Mn alloy that the periodic modulation of the lattice plays an important rôle. Photo. 1 shows a pattern obtained from an ordered Au_3Mn film tilted by 45° around the principal axis lying in the film plane. The superlattice reflections seen at normal incidence disappear here, since there is no superlattice reflection in the {110} plane of reciprocal lattice as described in Part I.

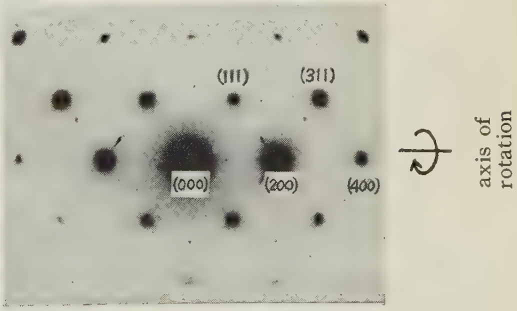

Photo. 1. Electron diffraction pattern of the ordered Au_3Mn film: [110] incidence.

Nevertheless, the satellites remain fairly strong. This fact shows that a greater part of intensity of the satellites is not caused by double diffraction but due to a periodic lattice modulatoin. Recently, we observed, in addition, the satellites flanking the superlattice reflections, {001}, in electron diffraction patterns of the ordered Cu_3Pd (α'') alloy mixed with one-dimensional anti-phase domains[7]. These satellites are also considered to be caused by the periodic lattice modulation.

---

† All the notations, m_1, m_2, a_1^*, a_2^*, M_1 and M_2, have the same significance as in Part I.

In general, either or both of two kinds of modulation in a crystal lattice are conceivable as the cause of the satellites, i.e. a periodic change of lattice spacing, and of scattering factor[8]. For CuAu (II), Ogawa and the present author[2] proposed some explanation about the origin of the satellites, by considering a definite amount of expansion of lattice spacing at each anti-phase domain boundary, but it seems that this explanation is difficult to apply to all cases so far examined, because there are some cases in which contraction takes place along the alignment direction of anti-phase domains.

In the present paper, contribution of a periodic lattice modulation accompanying anti-phase domains to the diffraction pattern will be reconsidered, and some discussion will be given of the origin of the satellites, on the basis of observed intensities.

§ 2. Models of Lattice Modulation and Comparison with the Experimental Facts

First, we shall consider for simplicity the case of one-dimensional anti-phase domains, the fundamental lattice of which is of ordered A_3B type with the first kind of out-of-step having the period of Ma along the x direction, and calculate the structure amplitudes of the satellites for some possible models of lattice modulation.

(1) *Periodic change of lattice spacing*

Let us assume a periodic modulation of the spacing as shown by arrows in Fig. 1 (a), with the period of modulation Ma and with the shifts of lattice planes expressed by a sinusoidal function as shown in Fig. 1 (b). Positions, x_p^1 and x_p^2, of the two kinds of lattice plane, which are parallel to the boundary plane and belong to the p-th fundamental cell, will be given by the following equations, by assuming that the lattice position on the boundary plane as indicated by arrow (↟) is taken as the origin of the crystal lattice:

$$x_p^1 = pa + \delta a \cdot \sin 2\pi \frac{p+(1/4)}{M} \tag{1-1}$$

$$x_p^2 = \left(p+\frac{1}{2}\right)a + \delta a \cdot \sin 2\pi \frac{p+(3/4)}{M} \tag{1-2}$$

The structure amplitude for this crystal is

$$\begin{aligned} S = \sum_{q=0}^{N-1} \exp 2\pi i q(2M)A_1 \times \Biggl[\Psi_1 \sum_{p=0}^{M-1} \exp 2\pi i p A_1 \cdot \exp\left(2\pi i A_1 \delta \cdot \sin 2\pi \frac{p+(1/4)}{M}\right) \\ + \Psi_2 \sum_{p=0}^{M-1} \exp 2\pi i p A_1 \cdot \exp\left(2\pi i A_1 \delta \cdot \sin 2\pi \frac{p+(3/4)}{M}\right) \Biggr], \end{aligned} \tag{2}$$

where N is half the number of anti-phase domain along the x direction, and

$$\Psi_1 = E_B + E_A \exp \pi i(A_2+A_3) + \{E_A + E_B \exp \pi i(A_2+A_3)\} \exp 2\pi i M A_1, \tag{3-1}$$

$$\Psi_2 = E_A\{\exp \pi i(A_1+A_2) + \exp \pi i(A_3+A_1)\} \cdot (1+\exp 2\pi i M A_1), \tag{3-2}$$

in which E_A and E_B are the atomic scattering factor for electron of A-and B-atom respectively, and A_1, A_2 and A_3 are continuous variables in reciprocal space. By expanding $\exp\left(2\pi i A_1 \delta \cdot \sin 2\pi \frac{p+(1/4)}{M}\right)$ and $\exp\left(2\pi i A_1 \delta \cdot \sin 2\pi \frac{p+(3/4)}{M}\right)$ by Bessel functions, we obtain

$$\begin{aligned} S = \sum_{q=0}^{N-1} \exp 2\pi i q(2M)A_1 \times \Psi_1 \times \\ \Biggl[J_0(2\pi A_1 \delta) \cdot \sum_{p=0}^{M-1} \exp 2\pi i p A_1 \\ + J_2(2\pi A_1 \delta) \cdot \left\{ \exp \frac{\pi i}{2M} \cdot \sum_{p=0}^{M-1} \exp 2\pi i p\left(A_1 + \frac{1}{M}\right) - \exp\left(\frac{-\pi i}{2M}\right) \cdot \sum_{p=0}^{M-1} \exp 2\pi i p\left(A_1 - \frac{1}{M}\right) \right\} \\ + J_2(2\pi A_1 \delta) \cdot \left\{ \exp \frac{\pi i}{M} \cdot \sum_{p=0}^{M-1} \exp 2\pi i p\left(A_1 + \frac{2}{M}\right) + \exp\left(\frac{-\pi i}{M}\right) \cdot \sum_{p=0}^{M-1} \exp 2\pi i p\left(A_1 - \frac{2}{M}\right) \right\} \end{aligned}$$

$$+J_3(2\pi A_1\delta)\cdot\left\{\exp\frac{3\pi i}{2M}\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1+\frac{3}{M}\right)-\exp\left(\frac{-3\pi i}{2M}\right)\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1-\frac{3}{M}\right)\right\}+\cdots\Bigg]$$

$$+\sum_{q=0}^{N-1}\exp 2\pi iq(2M)A_1\times\Psi_2\times$$

$$\Bigg[J_0(2\pi A_1\delta)\cdot\sum_{p=0}^{M-1}\exp 2\pi ipA_1$$

$$+J_1(2\pi A_1\delta)\cdot\left\{\exp\frac{3\pi i}{2M}\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1+\frac{1}{M}\right)-\exp\left(\frac{-3\pi i}{2M}\right)\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1-\frac{1}{M}\right)\right\}$$

$$+J_2(2\pi A_1\delta)\cdot\left\{\exp\frac{3\pi i}{M}\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1+\frac{2}{M}\right)+\exp\left(\frac{-3\pi i}{M}\right)\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1-\frac{2}{M}\right)\right\}$$

$$+J_3(2\pi A_1\delta)\cdot\left\{\exp\frac{9\pi i}{2M}\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1+\frac{3}{M}\right)-\exp\left(\frac{-9\pi i}{2M}\right)\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1-\frac{3}{M}\right)\right\}+\cdots\Bigg] \tag{4}$$

for $A_1>0$. The structure amplitudes of the satellites flanking the main reflections and those flanking the superlattice reflections are given respectively as follows:

(i) Satellites flanking the main reflections ($A_1=h_1\pm(n/M)$, $A_2=h_2$, $A_3=h_3$, where h_1, h_2 and h_3 are unmixed and n=integer.)

$$\begin{aligned}|S_m|&=2N\cdot M\cdot J_n(2\pi\cdot h_1\pm(n/M)\cdot\delta)\cdot|E_B+3E_A|, && \text{for } M>2\\ &=5.656\,N\cdot J_1(2\pi\cdot h_1\pm(1/2)\cdot\delta)\cdot\sqrt{E_B^2+5E_A^2+2E_BE_A}, && \text{for } M=2\end{aligned} \tag{5-1}$$

(ii) Satellites flanking the superlattice reflections undergoing no splitting ($A_1=h_1\pm(n/M)$, $A_2=h_2$, $A_3=h_3$, where h_2+h_3=even and n=integer).

$$\begin{aligned}|S_s|&=2N\cdot M\cdot J_n(2\pi\cdot h_1\pm(n/M)\cdot\delta)\cdot|E_B-E_A| && \text{for } M>2\\ &=|S_m| && \text{for } M=2\end{aligned} \tag{5-2}$$

It is readily known from the above result that the intensities of the satellites increase with the order of reflection and the satellites flanking the main reflections with $h_1=0$ must have the smallest intensity. The circumstances remain the same even when a definite spacing change, i.e. an expansion or a contraction of the lattice, exists periodically only at each domain boundary, as already proposed by Ogawa and the present author for CuAu (II)[2].

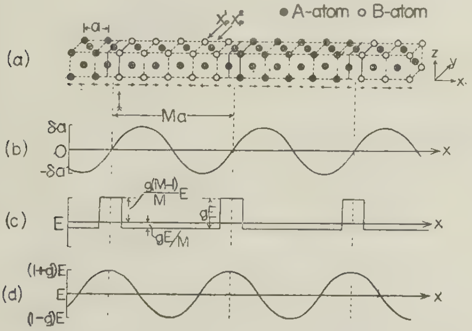

Fig. 1. Some models of periodic lattice modulation.
(a) and (b); Periodic change of lattice spacing. Small arrows in (a) represent the displacements of lattice planes.
(c) and (d); Periodic change of scattering factor.

Experimentally, however, the satellites flanking the direct spot is most pronounced in all cases so far examined, and the higher the order of main reflection, the smaller the intensity of the satellites becomes. Therefore, it becomes clear that the observed satellites are hard to be explained by the periodic change of lattice spacing alone, unless an anomalous value of atomic scattering factor for electron at the lowest scattering angle such as previously proposed[2] is assumed.

2) *Periodic change of scattering factor*

If the scattering factor at each domain boundary is different on the average from that inside each domain, satellites should also arise. Here we shall consider the following two simplified models.

(a) First, let us examine the model as shown in Fig. 1(c), in which the change of scattering factor is gE, that is to say, the scattering factors of atoms on domain boundary and inside domain are given by $\left(1+\frac{g(M-1)}{M}\right)E$ and $\left(1-\frac{g}{M}\right)E$ respectively, where E is the scattering factor for the structure without modulation. The structure amplitude for such a crystal is given by

$$\begin{aligned} S=&\left(1-\frac{g}{M}\right)\cdot\sum_{q=0}^{N-1}\exp 2\pi iq(2M)A_1\cdot\sum_{p=0}^{M-1}\exp 2\pi ipA_1\cdot(\Phi_1+\Phi_2\exp 2\pi iMA_1) \\ &+g\cdot\sum_{q=0}^{N-1}\exp 2\pi iq(2M)A_1\cdot\{\Psi_1+\Psi_2\cdot\exp 2\pi i(M-1)A_1\}\ , \end{aligned} \tag{6}$$

where

$$\Phi_1=E_A\{\exp\pi i(A_1+A_2)+\exp\pi i(A_2+A_3)+\exp\pi i(A_3+A_1)\}+E_B \tag{7-1}$$

and

$$\Phi_2=E_A\{1+\exp\pi i(A_1+A_2)+\exp\pi i(A_3+A_1)\}+E_B\cdot\exp\pi i(A_2+A_3)\ , \tag{7-2}$$

and Ψ_1 and Ψ_2 have the same significance as in Eq. (3). The structure amplitudes of the satellites flanking main reflections and those flanking superlattice reflections become respectively as follows:

$$|S_m|=2g\cdot N\cdot\left|E_B+E_A+2E_A\exp\left(\mp\frac{n\pi i}{M}\right)\right|\ , \tag{8-1}$$

and

$$|S_s|=2g\cdot N\cdot\left|E_B+E_A-2E_A\exp\left(\mp\frac{n\pi i}{M}\right)\right|\ . \tag{8-2}$$

(b) Next, we shall consider a structure in which the scattering factor varies sinusoidally as shown in Fig. 1 (d), where the scattering factors of atoms on the two kinds of lattice plane in the p-th fundamental cell are given by

$$E_p^1=E\left(1+g'\cos 2\pi\frac{p+(1/4)}{M}\right) \tag{9-1}$$

and

$$E_p^2=E\left(1+g'\cos 2\pi\frac{p+(3/4)}{M}\right)\ , \tag{9-2}$$

and g' represents a parameter of the sinusoidal variation. The structure amplitude for such a crystal is given by

$$\begin{aligned} S=\sum_{q=0}^{N-1}\exp 2\pi iq(2M)A_1\Bigg[&\Psi_1\Bigg\{\sum_{p=0}^{M-1}\exp 2\pi ipA_1+\frac{g'}{2}\exp\frac{\pi i}{2M}\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1+\frac{1}{M}\right) \\ &+\frac{g'}{2}\exp\left(\frac{-\pi i}{2M}\right)\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1-\frac{1}{M}\right)\Bigg\} \\ &+\Psi_2\Bigg\{\sum_{p=0}^{M-1}\exp 2\pi ip\,A_1+\frac{g'}{2}\exp\frac{3\pi i}{2M}\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1+\frac{1}{M}\right) \\ &+\frac{g'}{2}\exp\left(\frac{-3\pi i}{2M}\right)\cdot\sum_{p=0}^{M-1}\exp 2\pi ip\left(A_1-\frac{1}{M}\right)\Bigg\}\Bigg]\ , \end{aligned} \tag{10}$$

$$\begin{aligned} |S_m|&=g'NM\cdot|E_B+3E_A| && \text{for}\quad n=1,\quad M>2\ , \\ &=0 && \text{for}\quad n\geq 2,\quad M>2\ , \\ &=2\sqrt{2}\,g'N\cdot|E_B+E_A\mp 2iE_A| && \text{for}\quad M=2, \end{aligned} \tag{11-1}$$

and

$$\begin{aligned} |S_s|&=g'NM\cdot|E_B-E_A| && \text{for}\quad n=1,\quad M>2\ , \\ &=0 && \text{for}\quad n\geq 2,\quad M>2\ , \\ &=2\sqrt{2}\,g'N\cdot|E_B+E_A\pm 2iE_A| && \text{for}\quad M=2. \end{aligned} \tag{11-2}$$

From these calculations it is seen that the ratio of intensity of satellites to that of the relevant main or superlattice reflection is independent of the reflection order, and therefore satellites flanking the direct spot are expected to be most strong if the dependence of scattering factor upon scattering angle is taken into account. Since, however, the result of the model (d) contradicts the experimental fact that the second and the third order satellites ($n=2$, 3) are clearly observed in many cases including Au_3Mn, the observed amplitudes of satellites from the Au_3Mn alloy is now compared with the calculated values based on the more favourable model (c). The calculation for the two-dimensional anti-phase domain structure of Au_3Mn is similar as in the above one-dimensional case, and the structure amplitude of the first order satellites due to the modulation with $M_2=2$ along the y-direction is shown to be

$$|S_m|=2\sqrt{2}\,g\cdot N\cdot|E_{\text{Mn}}+3E_{\text{Au}}|\equiv N\cdot F. \quad (12)$$

In the second column of Table I* the values of the structure amplitude obtained from the square root of the observed intensities of satellites, which have been already given in Table II of Part I, are tabulated again, and these values and the values of $|F|/g$ calculated from Eq. (12) are shown against the change of scattering angle in Fig. 2, where the observed value of (12, 2, 0) reflection is normalized with the calculated one. It is to be noted that the observed values decrease more slowly than the calculated one. If intensities

* In this table, the index, $(H_1H_2H_3)$, refers to the large orthorhombic cell $2\times4\times1$ times as large as the fundamental cell. The relation between the indices, $(h_1h_2h_3)$ and $(H_1H_2H_3)$, is given as follows: $h_1=(H_1/2)$, $h_2=(H_2/4)$, $h_3=H_3$.

of the satellites be somewhat strengthened by double diffraction, this tendency should be more pronounced, because such an effect is expected to be conspicuous at small scattering angle. If a fraction of the modulation, g, is assumed to be about 1/8.5, the intensity of the satellites flanking the main reflections of lower order may be explained by the present model (c), but the satellites with large scattering angle seem not to be fully elucidated. These circumstances seem to suggest that the scattering factor variation mainly contributes to the lower angle satellites, while part of the intensity of the higher angle satellites is ascribed to the lattice spacing variation.

Here, the order of magnitude of the spacing variation, if any, can be estimated in the following way: The values of structure amplitudes of satellites are calculated, by assuming various values for the displacements of atoms at the domain boundaries along the x and y directions. In this case, we assumed that along both directions the lattice constant is slightly expanded at domain boundaries. Comparing the observed structure amplitudes with the calculated ones, the most appropriate values of the displacements were so selected that the coincidence between both values might be best for the higher angle satellites. In this way, the displacements of atoms at domain boundaries were estimated to be about 0.01 Å along the x and 0.02 Å along the y direction. It is readily shown that such an order of displacements has little effect on the structure amplitudes of main and superlattice reflections but exerts a large influence upon the structure amplitudes of satellites. In the third column of Table I the structure amplitudes of satellites calculated by taking only the above displacements into account are also tabulated. In this table we see that for the satellites with small H_1 or H_2 value, i.e. $(2H_20)$ and $(6H_20)$,

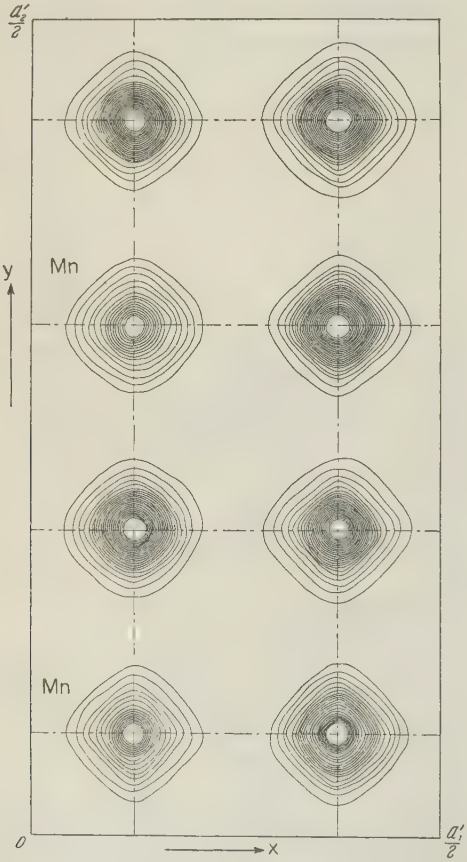

Fig. 3. (a); Two-dimensional Fourier map obtained from reflections except satellites.

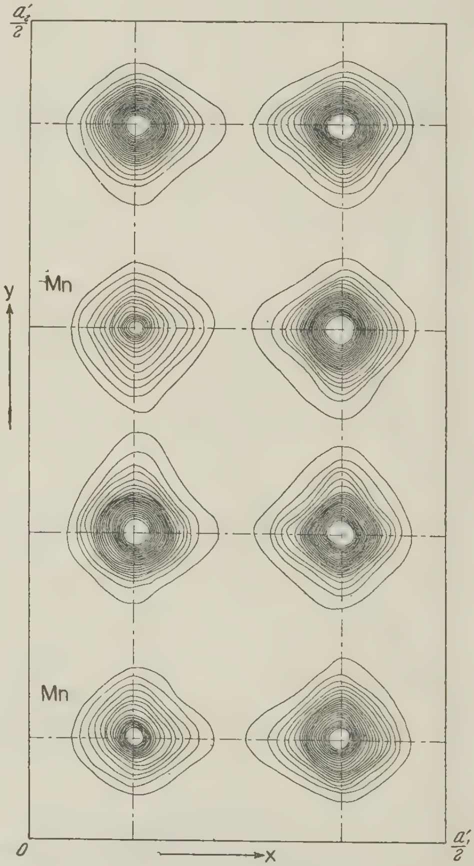

Fig. 3. (b); Two-dimensional Fourier map obtained from all the reflections including satellites.

In (a) and (b), the full lines represent the places where out-of-steps occur, i.e. the domain boundaries.

The contours are drawn at arbitrary unit.

$(H_1 20)$ and $(H_1 60)$, the calculated structure amplitudes are smaller than the observed ones, while for the satellites with relatively large H_1 or H_2 value the agreement is good.

In order to investigate the nature origin of the of the satellites with small H_1 or H_2 value, Fourier synthesis for the potential distribution was tentatively undertaken, using the measured structure amplitudes given in Table II of Part I. The potential distribution estimated from reflections not including the satellites is shown in Fig. 3 (a). In this figure, which is a projection on (001) plane of a quarter of a large orthorhombic unit cell ($a'_1=2a_1$, $a'_2=4a_2$, $a'_3=a_3$), the positions of gold and manganese atoms, showing the potential distribution of nearly spherical symmetry, are clearly distinguished. Fig. 3 (b) is the result obtained by taking account of all the observed reflections including the satellites, with the following assumption regarding the determination of the phase of the structure amplitudes for the satellites:

(i) Along the x direction the lattice constant at every boundary between the domains is assumed to be elongated slightly. The periodic change of the scattering factor is forbidden due to the symmetry operation of the present space group, P_{nnm}-D^{12}_{2h}.

(ii) Along the y direction the modulation of the scattering factor may be present, but in the present case we only assume also for this direction that the lattice constant at every boundary is slightly elongated.

It is remarkable that in Fig. 3 (b) the potential distribution around gold and manganess atoms is fairly distorted in comparison with Fig. 3 (a). The displacements of potential peaks at domain boundaries, however, can not be detected in this figure, because their magnitudes are very small, as mentioned above. Moreover, from the detailed analysis of Fig. 3 (b) we see that the height of potential peaks at the boundaries of domains along the y direction decreases slightly in comparison with Fig. 3 (a).* This fact means that the modulation of the scattering factor also occurs along the y direction, though this has not been assumed beforehand. It was known in the course of Fourier synthesis that the distortion of the potential distribution around each atom is attributable to the satellites with small H_1 or H_2 value. That is to say, this distortion causes the abnormally intense satellites in question, especially those flanking the direct spot.

(3) *Combination of both types of lattice modulation*

In view of the above result that neither the lattice spacing variation alone nor the scattering factor variation alone explains the intensities of the satellites satisfactorily, we shall tentatively consider a two-dimensional antiphase domain structure of Au$_3$Mn type in which both the variations given by Figs. 1 (a) and (c) occur simultaneously along the y direction. In this case we assume that no variation occurs along the x direction. The structure amplitude is given by

$$\begin{aligned}S=\sum_{q=0}^{N-1}\exp 2\pi iq(2M_2)A_2\cdot\Bigg[\,&G_1\Bigg\{\left(1-\frac{g}{M_2}\right)\cdot\sum_{p=0}^{M_2-1}\exp\, 2\pi iA_2\left(p+\delta\cdot\sin 2\pi\frac{p+(1/4)}{M_2}\right)\\&\qquad+g\cdot\exp\left(2\pi iA_2\delta\cdot\sin 2\pi\frac{1}{4M_2}\right)\Bigg\}\\&+G_2\Bigg[\left(1-\frac{g}{M_2}\right)\cdot\sum_{p=0}^{M_2-1}\exp\, 2\pi iA_2\left(p+\delta\cdot\sin 2\pi\frac{p+(3/4)}{M_2}\right)\\&\qquad+g\cdot\exp\left\{2\pi iA_2\left(M-1+\delta\cdot\sin 2\pi\frac{M_2-(1/4)}{M_2}\right)\right\}\Bigg]\Bigg],\end{aligned}\tag{13}$$

where

$$\begin{aligned}G_1=E_{\mathrm{Mn}}+E_{\mathrm{Au}}\exp\pi i(A_3+A_1)+\{E_{\mathrm{Au}}+E_{\mathrm{Mn}}\exp\pi i(A_3+A_1)\}\exp 2\pi iM_2A_2\\+E_{\mathrm{Au}}\{1+\exp\pi i(A_3+A_1)\}\cdot\{1+\exp 2\pi iM_2A_3\}\exp 2\pi iA_1\end{aligned}$$

and

---

* Such a change of peak height, however, can not be detected in Fig. 3.

$$
\begin{aligned}
G_2=E_{\mathrm{Au}}\{&\exp\pi i(A_1+A_2)+\exp\pi i(A_2+A_3)\}\cdot\{1+\exp 2\pi iM_2A_2\}\\
&+\{E_{\mathrm{Au}}\cdot\exp\pi i(A_1+A_2)+E_{\mathrm{Mn}}\exp\pi i(A_2+A_2)\}\cdot\exp 2\pi iA_1\\
&+\{E_{\mathrm{Mn}}\cdot\exp\pi i(A_1+A_2)+E_{\mathrm{Au}}\exp\pi i(A_2+A_3)\}\cdot\exp 2\pi i(A_1+M_2A_2)\ ,
\end{aligned}
$$

and the domain size along the x direction, M_1a_1, is considered to be a_1 ($M_1=1$). Assuming $M_2=2$, we have

$$
\begin{aligned}
|S|\doteqdot N\cdot\Bigg|\,&G_1\Bigg[J_0(2\pi A_2\delta)\cdot\left\{\left(1-\frac{g}{2}\right)(1+\exp 2\pi iA_2)+g\right\}\\
&\qquad+J_1(2\pi A_2\delta)\cdot\left\{\left(1-\frac{g}{2}\right)(1-\exp 2\pi iA_2)+g\right\}\cdot\sqrt{2}\,i\Bigg]\\
&+G_2\cdot\Bigg[J_0(2\pi A_2\delta)\cdot\left\{\left(1-\frac{g}{2}\right)(1+\exp 2\pi iA_2)+g\cdot\exp 2\pi iA_2\right\}\\
&\qquad+J_1(2\pi A_2\delta)\cdot\left\{\left(1-\frac{g}{2}\right)(1-\exp 2\pi iA_2)-g\cdot\exp 2\pi iA_2\right\}\cdot\sqrt{2}\,i\Bigg]\Bigg|\ . \qquad (14)
\end{aligned}
$$

The structure amplitude of satellites located at $A_1=h_1$, $A_2=h_2\pm 1/M_2$), $A_3=h_3$, is given by

$$|S_m|\doteqdot 2\sqrt{2}\,N\cdot|(E_{\mathrm{Mn}}+3E_{\mathrm{Au}})\cdot(gJ_0\mp 2.828J_1)|\ . \qquad (15)$$

It is clear from this equation that for the positive value of g the calculated intensity of the inner satellites ($A_2=h_2-(1/M_2)$) becomes exceedingly larger than that of the outer ones ($A_2=h_2+1/M_2$), provided that g and δ are of the same order of magnitudes as those already estimated. Table II shows some examples of the intensity asymmetry.* If g-value is negative, the asymmetry is reversed.

Furthermore, Eq. (14) predicts that the intensity asymmetry should appear also in a pair of split superlattice reflections, but such an order of magnitude of g and δ as above is so small that the asymmetry does not appear in the superlattice reflections in the present case. The derivation of such an asymmetry of intensity in a pair of satellites is characteristic for the model in which both types of lattice modulation are combined[8]. The circumstances are of course much the same for the one-dimensional domain structure.

Since such an intensity asymmetry in satellites could not actually be observed in all cases so far examined by electron diffraction, the model taking account of both modulations as considered here seems to be not satisfactory in explaining the origin of the satellites. In this connection, it is worth mentioning that in the Au_4Zn alloy which exhibits the two-dimensional anti-phase domain structure of Cu_3Pd type, the intensity asymmetries in both satellites and split superlattice reflections have been observed by X-rays[9).]** In this case, it is reasonable to assume that the scattering factor variation due to a composition change inside each anti-phase domain coexists with the lattice spacing variation.

(4) *On the satellites flanking the superlattice reflections*

As was described in §1, the satellites flank-

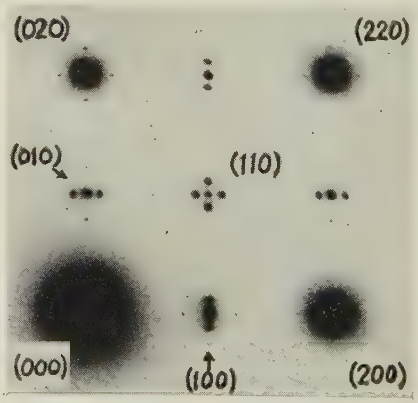

Photo. 2. Electron diffraction pattern of the ordered Cu_3Pd (α'') film mixed with the one-dimensional anti-phase domain structure; normal incidence. Indices refer to the disordered cubic lattice.

---

* Such an asymmetry appears also in the model ($a-b$), in which lattice spacing variation only is considered, as readily known from equation (5).

** However, the satellites flanking the direct spot were hardly detected by X-rays, while they were observed by electron diffraction. This ordered alloy was named $Au_{3+}Zn$ instead of Au_4Zn by Iwasaki *et al*[9). following Wilkens and Schubert[11), ing the {001} superlattice reflections were observed besides those flanking the main reflections in the ordered Cu_3Pd alloy, in which the one-dimensional anti-phase domain structure lined-up along the *z*-direction are mixed with a little amount of the two-dimensional structure[7]. In Photo. 2 is reproduced an electron diffraction pattern taken from this alloy. The intensity distribution in reciprocal space derived from Photo. 2 is shown in Fig. 4, where superlattice reflections and satellites are represented by the small closed and open circles respectively.* As already shown in the preceding calculations and pointed out by Okuzumi, Perio and Tournarie[10], the satellites flanking the superlattice reflections are also expected to appear by the periodic lattice modulation.

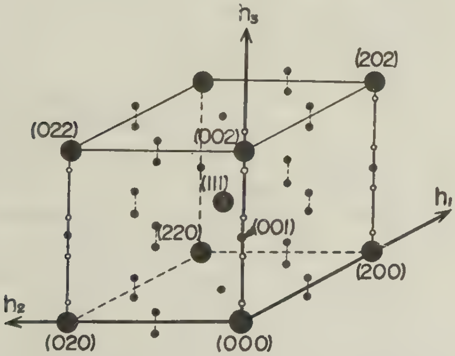

Fig. 4. Fundamental intensity distribution in reciprocal space induced from Photo. 2.

Table III. Structure amplitudes of the satellites flanking (001) and (002) reflections calculated for the Cu_3Pd alloy.

Index	$\|S\|/N$
$0,\ 0,\ 1-(1/M)$,	$24\,g$
$0,\ 0,\ 1+(1/M)$,	$18\,g$
$0,\ 0,\ 2-(1/M)$,	$30\,g$
$0,\ 0,\ 2+(1/M)$,	$24\,g$

In the present Cu_3Pd alloy, the intensity of the satellites in question seems to be explained by the periodic change of scattering factor (model (c)). In Table III, for example, are shown the structure amplitudes of the satellites flanking (001) superlattice reflection and of those flanking (002) main reflection calculated from Eq. (8–2) and (8–1), respectively, for the Cu_3Pd alloy, where *M* was estimated to be about 4. As the observed intensity distribution well coincides with that given in this table, it is supposed that the satellites flanking the superlattice reflections are caused by the same origin as those flanking the main reflections. In the Au_3Mn alloy, however, we could not detect any satellite around superlattice reflection.

§ 3. Further Considerations

Although we can not draw after all a decisive conclusion about the nature of the lattice modulation from the above considerations, it is suggested that the lattice spacing variation is required to be assumed for the satellites with large scattering angle and some kind of the scattering factor variation for those with small H_1 or H_2 values, though the magnitude of these modulations may somewhat be diminished if the effect of double diffraction exists.

If the periodic change of scattering factor, say in the model depicted in Fig. 1 (c), is caused by the difference in degree of ionization between the boundary atoms and inside ones, the appearance of the satellites flanking the direct spot may be explained, and the intensity asymmetry in a pair of satellites may not be expected to occur at $\sin\theta/\lambda$ larger than 0.2 even when the lattice spacing variation co-exists, because the effect of ionization on the atomic scattering factor for electron is negligible except at small values of $\sin\theta/\lambda$ less than 0.2. But, appreciable intensity of the satellites may not be expected for small H_1 and H_2 values, although those for large H_1 and H_2 values may be attributable to the lattice spacing variation. The present difficulty can not be overcome even if we take account of secondary diffraction of the satellites flanking the direct spot[2], because the actual intensity distribution in a pair of the satellites flanking other main reflections, especially of those flanking $\{220\}_{\text{cub.}}$ reflection, remains unexplained. That is to say, the inner satellite flanking $\{220\}_{\text{cub.}}$ reflection has obviously larger intensity than that of the outer, whereas these satellites should have at least the same order of intensity in order to be explained by secondary diffraction. Thus, it seems that the actual nature of the scattering factor variation is more complicated than the above model of ionized atom.

---

* In this figure, the superlattice reflections due to the two-dimensional structure were neglected.

Here, it must be noted that up to the present the satellites flanking the direct spot are hardly observed by X-rays except the only one case. Wilkens and Schubert[11] observed a very weak diffraction line at the satellite position around the direct spot using a polycrystalline specimen of $Cu_5Au_2Zn_8$. In the case of electron diffraction, the distortion of the potential distribution around each atom has a large influence on the satellites with small H_1 or H_2 value including those flanking the direct spot, as already mentioned. From this fact, it is suggested that such a distortion in the distribution of valence electron as ellipsoidal distribution considered in zinc oxide by Johnson[12] exists at each domain boundary and causes the satellites in question to arise. If these satellites are caused by such an effect, they will hardly be observable in an X-ray diffraction pattern, for the abnormality of valence electron distribution seems not so to affect X-ray diffraction as to affect electron diffraction. In this connection, Schubert *et al*[13]. proposed that the valence electron plays an important rôle in the formation of anti-phase domain structure. They found a definite relation between the valence electron density and the domain size in many ordered alloys with stable anti-phase domain structure, and assumed that excess or deficiency of valence electrons to unity is located with the definite period and gives rise to out-of-step of ordering. According to this idea, the distortion of valence electron distribution at domain boundary and also the lattice spacing variation may occur, if the spatial change of valence electron number causes a periodic variation in the cohesive force of the lattice. Accordingly, the idea given by Schubert *et al.* seems to be closely connected with the origin of the satellites. However, a more concrete theoretical foundation might be desired for this idea, and at the same time a more detailed X-ray study about the satellites should be carried out.

The present author wishes to express his sincere thanks to Professor S. Ogawa for the kind guidance and encouragement.

The present investigation has partly been supported by the fund of the Ministry of Education in Aid of Scientific Researches.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 3, MARCH, 1961

The Ferroelectric Phase Transition in $(\text{Glycine})_3 \cdot H_2SO_4$ and Critical X-Ray Scattering

By Iwao SHIBUYA* and Toshio MITSUI**

Crystal Research Laboratory, The Pennsylvania State University,
University Park, Pennsylvania, U.S.A.

(Received October 3, 1960)

On the assumption that the ferroelectric phase transition in $(\text{Glycine})_3 \cdot H_2SO_4$ is of the order-disorder type, expressions for Bragg reflections and critical scattering of X-rays are given in terms of a long-range order parameter and pair correlation functions. Temperature dependence of the critical scattering is discussed on the basis of the Bragg-Williams approximation and of a modified Fröhlich theory. Experimental observations agree with theoretical predictions, and prove that the phase transition is of the order-disorder type. The observed critical scattering exhibits a pronounced peak at the Curie point, suggesting that the local field theory is not a good approximation. The shape of the peak appears to be quite different from that in the ferromagnetic case. It has been found that the sulfur atoms do not shift appreciably when the glycine groups rotate. A method for evaluating the pair correlation function is proposed.

§1. Introduction

Critical scattering is one of the effects associated with a condensed material in the vicinity of a phase transition. It may be expected to occur in crystals where there are, under appropriate conditions, atoms of more than one type or atoms existing in more than one state in the lattice. An example of the former case is an order-disorder transition in alloys[1], and the latter a ferromagnetic transition[2]. As has been shown in these cases[1)-3)], investigation of critical scattering provides very valuable information about the mechanism of a phase transition. The purpose of the present paper is to show how critical scattering of X-rays takes place in the ferroelectric transition of $(\text{Glycine})_3 \cdot H_2SO_4$, and to give a foundation for more detailed studies of this phenomenon. (For simplicity, $(\text{Glycine})_3 \cdot H_2SO_4$, triglycine sulfate, will be abbreviated as TGS below). The reasons why we chose TGS as the first sample in our studies of critical scattering by ferroelectrics are as follows: (1) the transition is of second order[4], (2) the transition seems to be of the order-disorder type (see Sec. 2), (3) the crystal structure at room temperature has been analyzed[5], and (4) the unit cell has only two molecular units and the crystal structure is relatively simple.

One can find a general theory on diffuse X-ray scattering by partially ordered crystal in Zachariasen's book[6] and, in more detail, in Matsubara's articles[7]. Our present theory described in Sec. 2 will be based on their formulations. The long-range order parameter and pair correlation function will be defined in an analogous way to the alloy case, and intensities of Bragg reflections and critical scattering will be expressed in terms of them. A method to evaluate the pair correlation function will be proposed in Sec. 2. With the help of statistical mechanics, the pair correlation function will provide information on the interaction between atoms or molecules in the crystal, and thus on the origin of ferroelectricity. Estimation of pair correlation will be made in a later paper. Experimental observations of Bragg spots and critical scatterings will be reported in Sec. 3. Discussions on obtained results will be given in Sec. 4.

§2. Theory

A. *Fundamental assumptions*

Ferroelectricity in TGS was fonnd by Matthias, Remeika, and Miller in 1956[8]. The crystal is ferroelectric along the *b*-axis below 47°C[4], and the transition is of second order[4]. Usually ferroelectric phase transitions are classified into two types[9]; one is the $BaTiO_3$ type sometimes called a displacive type, and the other is the KDP type usually called an order-disorder type. The type of a transition can be decided by examining the order of magnitude of the Curie-Weiss constant or of the transition entropy as has been demonstrated clearly by Anderson[10]. The Curie-Weiss constant of TGS is 3,280°K[4] compared to 3,260°K for KDP[11] and to 170,000°K for $BaTiO_3$[12]. The transition entropy of TGS is 0.48 cal./mol. deg.[4] compared to 0.47[11] or 0.72[13] for KDP and to 0.12 for $BaTiO_3$[12]. These values suggest that the transition of TGS is of the order-disorder type.

---

* Now at the Institute for Solid State Physics, University of Tokyo, Tokyo, Japan.

** Now at Laboratory for Insulation Research, Massachusetts Institute of Technology, Combridge, Massachusetts, U.S.A. On leave from Hokkaido University, Sapporo, Japan.

The crystal structure of TGS has been analyzed recently by Hoshino, Okaya and Pepinsky[5]. The space group is $P2_1/m$ above the Curie point and $P2_1$ in the ferroelectric phase. The *c*-projection of the structure at room temperature is shown in Fig. 1. The figure corresponds to a structure of negative polarity[15]. The structure of positive polarity is a mirror image of Fig. 1, putting the mirror perpendicular to the *b*-axis. A molecular unit is enclosed by the dashed lines. The unit cell has two molecular units, which are related with each other by the twofold screw axis 2_1. Coupling between atoms seems to be strong within this molecular unit and it may be considered a statistical unit. However, for simplicity, the crystallographic unit cell will be assumed to be a statistical unit below. There is some evidence suggesting that this is not a very bad assumption. We get a transition entropy of $R\ln 2 = 1.38$ cal./mol. deg., where R is the gas constant, if we assume that the molecular unit is a statistical unit with two positions of equilibrium, and if we use the Bragg-Williams approximation[16] (for this terminology, see Sec. 4). On the other hand, if we assume that the crystallographic unit cell is a statistical unit, we get a transition entropy of $\frac{1}{2}R\ln 2 = 0.69$ cal./mol. deg., which is close to the observed value of 0.48. Further, existence of the twofold screw axis results in zero Bragg reflection and zero diffuse coherent scattering at (0*k*0), where *k* is odd, due to the extinction

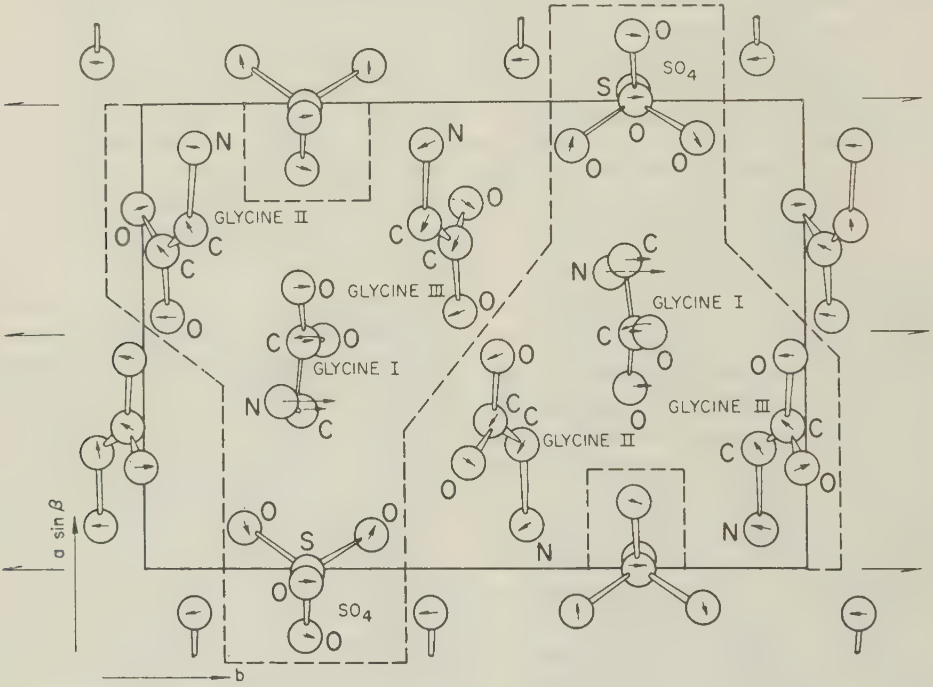

Fig. 1. Projection of the structure of TGS along the *c*-axis (after Hoshino, Okaya and Pepinsky[5]). This structure corresponds to negative polarity. Arrows show displacements of atoms during a reversal of polarity. The molecular unit is enclosed by dashed lines.

law[17)] and to the reasons described below. However, if coupling between the two molecular units in the unit cell is weak, the two molecules could have opposite polarity and destroy 2_1 symmetry frequently due to the thermal agitation at elevated temperatures, and a diffuse peak should be observed also around (0*k*0), where *k* is odd. No well defined peaks, however, have been observed, suggesting that coupling along the *b*-axis is strong.

The phase transition at 47°C will be assumed to be of the order-disorder type, and the actual crystal structure to be a statistical mixture of two basic structures, one of which has positive polarity and the other negative polarity, and which are mirror images of each other. Above the Curie point, the basic structures exist in the same proportion, and the unit cell has a center of symmetry on the time average. Below the Curie point, the ratio of the two structures deviates from $\frac{1}{2}$, and spontaneous polarization appears. The basic structure with negative polarity is assumed to be the same as that determined by Hoshino, Okaya and Pepinsky[5)]. The structure factor which they calculated by placing the sulfur atom at $y=\frac{1}{4}$ will be written as

$$F'=A'+iB' . \qquad (1)$$

For the space group $P2_1$, the origin of the unit cell cannot be determined uniquely along the *b*-axis. If the origin is defined by referring to a special atom which shifts during a reversal of polarity, the origin has to be shifted according to the reversal. This procedure is not convenient for handling the problem, since we cannot superpose origins of two unit cells by the lattice translation when they have different polarities. Suppose that a part of the crystal (or of the domain below the Curie point) has positive polarity, and another part negative polarity simultaneously, and that the two parts were superposed by the lattice translations. The resultant structure should have a center of symmetry. In the present treatment, the origin of the unit cell is put at one of these centers of symmetry which is closest to the origin chosen by Hoshino *et al*. For this new choice of the unit cell, the origin of Hoshino *et al.* is at $(0\delta 0)$; and δ should be added to all *y* coordinates in order to adjust to the new origin. We can now treat the two basic structures in a symmetrical way by this choice of the unit cell. Structure factors F_+ and F_-, which correspond to positive and negative polarity, can be written for the new origin as

$$F_+=A-iB \qquad (2a)$$

and

$$F_-=A+iB . \qquad (2b)$$

By the definition of structure factors[17)], A and B are related to A' and B' by equations

$$A=A'\cos 2\pi k\delta-B'\sin 2\pi k\delta , \qquad (3a)$$

$$B=A'\sin 2\pi k\delta+B'\cos 2\pi k\delta . \qquad (3b)$$

In Sec. 3 it will be found that δ is nearly equal to zero.

Hoshino *et al.* took the effect of the thermal vibration of the atoms into account by isotropic temperature factors when they calculated the structure factor F'. Therefore, in reciprocal space, the weight J for the diffracted coherent X-rays may be written as

$$J=\sum_s \sum_{s'} \langle F^*_{s'}F_s\rangle e^{2\pi i(\boldsymbol{H}\cdot\boldsymbol{r}_{ss'})}+J_T . \qquad (4)$$

Here F_s and $F_{s'}$ are the scattering amplitude of the *s*th and the *s'*th unit cells, $\langle\ \rangle$ is the time average, $\boldsymbol{H}$ a position vector in reciprocal space, $\boldsymbol{r}_{ss'}$ the vector from the *s'*th to the *s*th unit cell, and J_T is the thermal diffuse scattering due to the lattice vibration. The summation should be carried out for all unit cells in the crystal bathed in the incident X-rays. The above expression can be rewritten as

$$J=J_B+J_C+J_T , \qquad (5)$$

where

$$J_B=|\langle F_s\rangle|^2 \sum_s \sum_{s'} e^{2\pi i(\boldsymbol{H}\cdot\boldsymbol{r}_{ss'})} \qquad (6a)$$

and

$$J_C=\sum_s \sum_{s'}\{\langle F^*_{s'}F_s\rangle-|\langle F_s\rangle|^2\}e^{2\pi i(\boldsymbol{H}\cdot\boldsymbol{r}_{ss'})} . \qquad (6b)$$

$\sum_s \sum_{s'} e^{2\pi i(\boldsymbol{H}\cdot\boldsymbol{r}_{ss'})}$ gives the Laue interference function, and J_B represents Bragg spots when the unit cell is defined independent of atomic shift as in our case. J_C gives the critical scattering which is caused by disorder configuration of molecules in the crystal.

B. *Effect of long range order on J_B*

Suppose that the unit volume of TGS has N unit cells, of which N_+ have positive polarity and N_- negative. Then $x_+\equiv N_+/N$ and $x_-\equiv N_-/N$ are the probabilities that a unit cell has positive and negative polarity, respectively. Naturally $x_+ + x_- = 1$.

A long-range order parameter S is defined by

$$S = x_+ - x_- \,. \tag{7}$$

$x_+ = x_- = \frac{1}{2}$ and thus $S=0$ in the paraelectric phase, and $x_+=1$, $x_-=0$, and thus $S=1$ at very low temperatures if a domain of positive polarization is considered. S is related to the spontaneous polarization P_{Ss} by the equation

$$S = \frac{N_+}{N} - \frac{N_-}{N} = \frac{(N_+ - N_-)\mu}{N\mu} = \frac{P_s}{N\mu} \,, \tag{8}$$

where P_s is the spontaneous polarization and μ is the dipole moment of the unit cell. x_+ and x_- are given in terms of S by the equations

$$x_+ = \tfrac{1}{2}(1+S) \quad \text{and} \quad x_- = \tfrac{1}{2}(1-S) \,. \tag{9}$$

Thus we have

$$\langle F_s \rangle = x_+ F_+ + x_- F_- = A - iSB \,, \tag{10}$$

where Eqs. 2 and 9 were used. Therefore, by Eq. 6a, we have

$$J_B \propto |\langle F_s \rangle|^2 = A^2 + S^2 B^2 \,. \tag{11}$$

Here it should be mentioned that B is not the imaginary part of the structure factor of the actual crystal, but that of the basic structure. B has a finite value also above the Curie point, while an imaginary part of the structure factor of the actual crystal disappears above the Curie point as S becomes zero. Measurements of P_s were made from -100°C to the Curie point and values of S have been calculated by Eq. 8 assuming that $S=1$ at -100°C. The result is shown in Fig. 2. $S=0.77$ at about 22°C, and therefore, the room temperature structure is a superposition of 11.5% of one of the basic structure and 88.5% of the other according to Eq. 9.

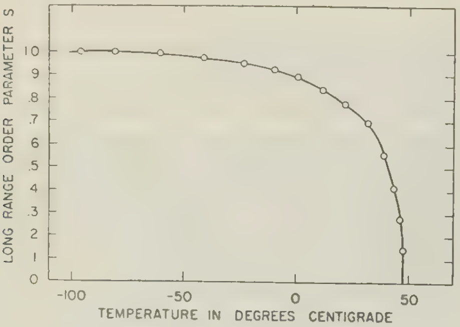

Fig. 2. Long-range order parameter S as a function of temperature. Perfectly ordered structure was assumed and S was put equal to one at -100°C, where $P_S = 3.6$ microcoulombs/cm².

One can easily show that Eq. 11 can be derived also on the assumption that the molecular unit is a statistical unit. In this sense, this equation is free from the assumption made for the derivation described above.

C. *Expression for J_C in terms of pair correlation functions*

A pair correlation function, $g_{ss'}(++)$, is defined as the probability that the sth and the s'th unit cells have positive polarity at the same moment. $g_{ss'}(+-)$, $g_{ss'}(-+)$ and $g_{ss'}(--)$ are defined in analogous ways. Then we have

$$g_{ss'}(++) + g_{ss'}(+-) = x_+ = \tfrac{1}{2}(1+S) \,,$$

$$g_{ss'}(++) + g_{ss'}(-+) = x_+ = \tfrac{1}{2}(1+S) \,,$$

$$g_{ss'}(--) + g_{ss'}(-+) = x_- = \tfrac{1}{2}(1-S) \,,$$

and

$$g_{ss'}(--) + g_{ss'}(+-) = x_- = \tfrac{1}{2}(1-S) \,.$$

For simplicity $g_{ss'}(++)$ will be written as $g_{ss'}$, below. From the above equations we have

$$\left.\begin{aligned} &g_{ss'}(++) \equiv g_{ss'} \,, \\ &g_{ss'}(+-) = \tfrac{1}{2}(1+S) - g_{ss'} \,, \\ &g_{ss'}(-+) = \tfrac{1}{2}(1+S) - g_{ss'} \,, \\ \text{and}\quad & \\ &g_{ss'}(--) = g_{ss'} - S \,. \end{aligned}\right\} \tag{12}$$

$\langle F_{s'}^* F_s \rangle$ and $|\langle F_s \rangle|^2$ are given by

$$\begin{aligned} \langle F_{s'}^* F_s \rangle = {} & g_{ss'}(++)F_+^*F_+ + g_{ss'}(+-)F_+^*F_- \\ & + g_{ss'}(-+)F_-^*F_+ + g_{ss'}(--)F_-^*F_- \end{aligned} \tag{13}$$

and

$$|\langle F_s \rangle|^2 = (x_+ F_+^* + x_- F_-^*)(x_+ F_+ + x_- F_-) \,. \tag{14}$$

Therefore, using Eqs. 2, 9 and 12, we have

$$\langle F_{s'}^* F_s \rangle - |\langle F_s \rangle|^2 = 4\varDelta_{ss'} B^2 \,, \tag{15}$$

where $\varDelta_{ss'}$ is defined by

$$\varDelta_{ss'} \equiv g_{ss'} - \tfrac{1}{4}(1+S)^2 \,. \tag{16}$$

Therefore, J_C given by Eq. 6b becomes

$$J_C = 4B^2 \sum_s \sum_{s'} \varDelta_{ss'} e^{2\pi i (\boldsymbol{H} \cdot \boldsymbol{r}_{ss'})} \,. \tag{17}$$

$g_{ss'}$ has the following tendency:

$$\lim_{r_{ss}\to\infty} g_{ss'} = x_+ x_+ = \tfrac{1}{4}(1+S)^2 \,. \tag{18}$$

Therefore, by Eq. 16, $\lim\limits_{r_{ss'}\to\infty} \varDelta_{ss'} = 0$, and J_C can be written as

$$J_C = 4NvB^2 \sum_s \varDelta_s e^{2\pi i (\boldsymbol{H} \cdot \boldsymbol{r}_s)} \,, \tag{19}$$

where v is the volume of the crystal bathed in the incident X-ray beam, and Δ_s and r_s are $\Delta_{ss'}$ and $r_{ss'}$, respectively, when the origin of the coordinate system is put at the origin of the s'th unit cell. Putting

$$G \equiv J_C/(4NvB^2)\ ,$$

we can rewrite Eq. 19 as

$$G = \sum_s \Delta_s e^{2\pi i(\boldsymbol{H}\cdot\boldsymbol{r}_s)}\ . \qquad (21)$$

$\boldsymbol{H}$ and $\boldsymbol{r}_s$ can be written as

$$\boldsymbol{H} = h\boldsymbol{a}^* + k\boldsymbol{b}^* + l\boldsymbol{c}^* \qquad (22)$$

and

$$\boldsymbol{r}_s = n_1\boldsymbol{a} + n_2\boldsymbol{b} + n_3\boldsymbol{c}\ . \qquad (23)$$

Here $\boldsymbol{a}^*$, $\boldsymbol{b}^*$ and $\boldsymbol{c}^*$ are the reciprocal lattice vectors, $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ the unit cell vectors, and n_1, n_2 and n_3 are integers. G is a periodic function in the reciprocal space with periods of $h=1$, $k=1$ and $l=1$. By Fourier's theorem, Δ_s is given by

$$\Delta_s = \iiint G e^{-2\pi i(\boldsymbol{H}\cdot\boldsymbol{r}_s)} dh dk dl\ . \qquad (24)$$

Here the integration should be carried out in a unit cell of reciprocal space, say, in the region determined by $m_1 - \frac{1}{2} \leqslant h \leqslant m_1 + \frac{1}{2}$, $m_2 - \frac{1}{2} \leqslant k \leqslant m_2 + \frac{1}{2}$ and $m_3 - \frac{1}{2} \leqslant l \leqslant m_3 + \frac{1}{2}$, where m_1, m_2 and m_3 are integers. It should be noticed that for $\boldsymbol{r}_s = 0$,

$$g_{ss'} = g_{00} = x_+ = \tfrac{1}{2}(1+S)\ , \qquad (25)$$

and

$$\Delta_0 = \tfrac{1}{2}(1+S) - \tfrac{1}{4}(1+S)^2 = \tfrac{1}{4}(1-S^2)\ . \qquad (26)$$

Therefore, Eq. 24 becomes

$$\tfrac{1}{4}(1-S^2) = \iiint G dh dk dl\ . \qquad (27)$$

This relation may be used for the normalization of experimental data, when Δ_s is evaluated experimentally using Eq. 24. The above discussion holds for both the ferroelectric and the paraelectric phases. S should be put equal to zero for the paraelectric phase.

D. *Temperature dependency of J_C*

It is very difficult to predict the temperature dependence of the critical scattering, especially since one does not have any quantitative knowledge about interaction forces between dipoles. If we use the Bragg-Williams approximation (see Sec. 4), however, we have $g_{ss'} = x_+x_+$ except for g_{00} and we may put Δ_s $(s \neq 0)$ equal to zero by Eqs. 9 and 16, and thus Eq. 19 becomes

$$J_C = NvB^2(1-S^2)\ . \qquad (28)$$

Here use was made of Eq. 26. The Curve 1 in Fig. 3 shows values of $J_C/(NvB^2)$ calculated with Eq. 28. The calculation was made using data shown in Fig. 2. A somewhat similar argument has been made for the ferromagnetic case by van Hove[18].

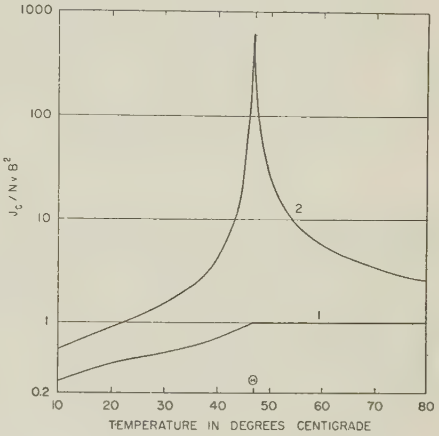

Fig. 3. $J_C/(NvB^2)$ as functions of temperature. The Curve 1 was calculated by Eq. 28, and the Curve 2 by Eq. 33. Experimental observations are expected to be an intermediate of the two curves.

Another approach to this problem may be made by relating the critical scattering to the dielectric constant. Fröhlich[19] developed a general theory of isotropic dielectrics and gave an expression for the dielectric constant in terms of thermal fluctuation of polarization. He considered a macroscopic spherical region of volume V in an infinite homogeneous specimen of which the dielectric constant is ε. The expression he derived is

$$\varepsilon - 1 = \frac{4\pi}{V}\,\frac{\varepsilon}{2\varepsilon+1}\,\frac{\langle M^2\rangle}{kT}\ . \qquad (29)$$

Here k is Boltzmann constant, T temperature in degrees Kelvin, and $\langle M^2\rangle$ the time average of the square of the dipole moment $\boldsymbol{M}$ of the spherical region in the absence of an applied field. The origin of $\boldsymbol{M}$ is in the thermal fluctuation of dipoles. To derive the above equation, however, the specimen was assumed not to have spontaneous polarization, and use was made of the cavity field of isotropic dielectrics. Therefore, the above expression is not directly applicable to TGS. However, the basic idea of Fröhlich's theory can be applied to any dielectric, and below his theory will be applied to our case of TGS with the fictitious assumption that both the ferroelectric and the paraelectric phases are dielectrically isotropic.

To derive an expression for the ferroelectric phase, we consider a single domain crystal of positive polarity, and put the probability that $\boldsymbol{M}$ is in a negative direction equal to zero. Following Fröhlich's procedure and having in mind that $\langle \boldsymbol{M} \rangle$ is not zero in the ferroelectric phase, we obtain the expression,

$$\varepsilon - 1 = \frac{4\pi}{V}\,\frac{3\varepsilon}{2\varepsilon+1}\,\frac{\langle (\boldsymbol{M}-\langle \boldsymbol{M} \rangle)^2 \rangle}{kT}\,. \tag{30}$$

This equation holds for both ferroelectric and paraelectric phases. For the paraelectric phase $\langle \boldsymbol{M} \rangle = 0$, and Eq. 30 is identical with Eq. 29 except for the coefficient 3. This difference comes from the fact that the dipoles can have any direction in Fröhlich's theory while they should be parallel or antiparallel to the b-axis in our model of TGS. If the dipole moment vector of the sth unit cell is denoted as $\boldsymbol{\mu}_s$ and its absolute value as μ_s, naturally μ_s is equal to μ and $\langle \boldsymbol{\mu}_s \rangle$ is a vector parallel to the b-axis with magnitude $S\mu$. Thus, using Eqs. 12 and 16, we have

$$\begin{aligned}
&\langle (\boldsymbol{M}-\langle \boldsymbol{M} \rangle)^2 \rangle \\
&\quad = \Big\langle \sum_s \sum_s (\boldsymbol{\mu}_{s'} - \langle \boldsymbol{\mu}_{s'} \rangle)(\boldsymbol{\mu}_s - \langle \boldsymbol{\mu}_s \rangle) \Big\rangle \\
&\quad = \sum_s \sum_{s'} (\mu_{s'} - S\mu)(\mu_s - S\mu) g_{ss'}(++) \\
&\qquad + (-\mu_{s'} - S\mu)(\mu_s - S\mu) g_{ss'}(+-) \\
&\qquad + (\mu_{s'} - S\mu)(-\mu_s - S\mu) g_{ss'}(-+) \\
&\qquad + (-\mu_{s'} - S\mu)(-\mu_s - S\mu) g_{ss'}(--) \\
&\quad = 4\mu^2 NV \sum_s \Delta_s\,.
\end{aligned}$$

Therefore, for a large value of ε, Eq. 30 becomes

$$\varepsilon \approx \frac{24\pi N\mu^2}{kT} \sum_s \Delta_s\,. \tag{31}$$

If we write G at a lattice point in the reciprocal space as G_0 and put h, k and l equal to integers in Eq. 22, Eq. 21 becomes

$$G_0 = \sum_s \Delta_s\,.$$

Therefore, using Eq. 31, we have

$$G_0 \approx \frac{kT}{24\pi N\mu^2}\,\varepsilon\,. \tag{32}$$

Using Eq. 20, J_C at a lattice point in the reciprocal space is given by

$$J_C \approx \frac{kNvB^2}{6\pi N\mu^2} \cdot \varepsilon T\,. \tag{33}$$

That is, critical scattering at each lattice point in reciprocal space is proportional to εT, and thus should have a distinct peak at the Curie point. The Curve 2 in Fig. 3 shows $J_C/(NvB^2)$ calculated with Eq. 33. The calculation was made by putting ε equal to the dielectric constant measured along the b-axis[4]. N and μ were determined using the known cell dimensions[5], and the spontaneous polarization measured at −100°C (3.6 $\mu Q/\text{cm}^2$); $N = 1/(\text{unit cell volume})$ and $\mu = 3.6/N$ μQ cm. J_C at non-integer values of (kkl) also seem to exhibt a peak at the Curie point, which is an intermediate of the two curves shown in Fig. 3.

§ 3. Experiments

The intensity of diffracted X-rays was measured with a General Electric X-ray unit. CoKα radiation was used with the help of iron filter and a discriminator put in the electronic circuit. An iron filter serves to cut the Kβ radiation and a part of the white radiation with short wavelength. The discriminator sends signals to the scaler only when photons having energy close to that of CoKα radiation come into the counter tube. The applied voltage to excite the CoKα radiation was 45 kv and the current used was 6 ma. A receiving slit with a small pin hole was used for studies of diffuse scattering. Slits wide enough to get proper integrated intensity were used for studies of Bragg reflection. Small cylindrical specimens were used for all experiments.

TGS is a monoclinic crystal and its cell dimensions and monoclinic angle vary with varying temperature due to thermal expansion and to the spontaneous strains. Great care was taken to eliminate the effect of these variations when intensities were measured as function of temperature. The azimuthal and the longitudinal angles of crystal setting were readjusted at each temperature by making the intensity of a Bragg reflection a maximum. The proper angles for the diffuse scattering measurements were determined at each temperature by referring to near-by Bragg points. For example, the diffraction angle for the (0 8.1 0) measurements was determined by referring to the (0 8 0) and (0 10 0) peak positions at each temperature.

In order to check the validity of Eq. 11, several Bragg reflections were measured as functions of temperature. B is zero for $(h0l)$ reflections due to the twofold screw axis existing along the b-axis[17]. Fig. 4 shows temperature dependence of (100), (001) and (004) reflections. These are relatively weak reflections and seem to be free from the extinction effect. Measured intensities were reduced to electron units using calculated F values of Hoshino *et al.*[5] According to Eq. 11, since $B=0$ for these reflections, the curves show the temperature dependence of A^2 of the basic structure. The figure shows that a slight change takes place in A^2, and thus, in the basic structure near the Curie point. However, since (100), (001) and (004) are weak reflections, the curves suggest that the change of the basic structure during the phase transition is very small.

Fig. 5 shows the temperature dependence of Bragg reflections (0 8 0) and (0 6 1). According to Hoshino *et al.*, $A=40.26$ and $B=-19.11$ for (0 8 0), and $A=2.42$ and $B=15.06$ for (0 6 1) in electron units. The dashed curves in the figure show the values calculated using Eq. 11. That calculation was made with the assumption that $\delta=0$ in Eq. 3b, and that A and B are independent of temperature. The first assumption that $\delta=0$ is supported also by the measurement of critical scattering as will be described below. Fig. 4 seems to suggest that the second assumption on the temperature dependence of A and B is not very far from reality.

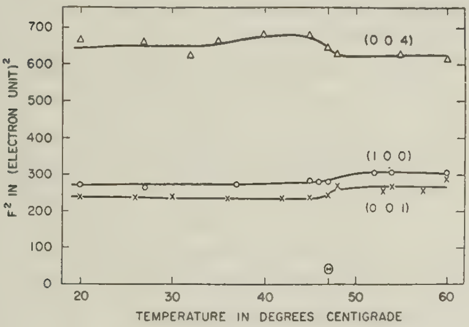

Fig. 4. F^2 of Bragg reflections $(h0l)$ as functions of temperature. Measured integrated intensities were reduced to F^2 by putting their room temperature values equal to F^2 calculated by Hoshino *et al*[5].

The calculated curves agree reasonably well with the observations. The small discrepancy seems to be attributed partly, as has been observed by Lowde in the ferromagnetic case[2], to the fact that the measured intensity of the Bragg reflection includes a contribution from the critical scattering which has a peak at the same place as the Bragg reflection. If the peak height of a proper Bragg reflection is divided by integrated intensity, the quotient is determined only by the divergent angle of the incident X-ray beam and by the mosaic spread of the crystal, and is, therefore, independent of temperature insofar as the mosaic structure remains unchanged*. The peak of diffuse scattering seems to have a flatter shape than that of a Bragg reflection, as seen in other cases.[1),2),20)] Therefore, if the measured Bragg intensity includes a contribution from the diffuse scattering, the above quotient of the measured quantities decreases with increasing contribution from the diffuse scatterings. Fig. 6 shows the peak height of the

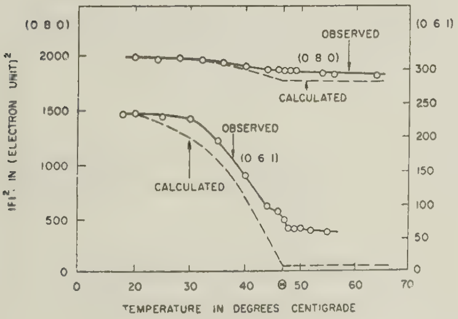

Fig. 5. F^2 of Bragg reflections (080) and (061) as functions of temperature. See the text for the calculated values. Scales of the ordinate were determined so that the room temperature values agree with the square of the structure factor $|F|$ calculated by Hoshino *et al*[5].

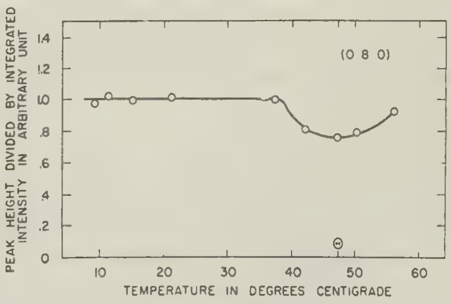

Fig. 6. Temperature dependency of a peak height of (080) Bragg reflection divided by its integrated intensity.

---

* The authors owe this argument to Dr. B. C. Frazer.

(0 8 0) Bragg reflection divided by its integrated intensity as a function of temperature. The curve deviates from a straight line with increasing temperature and reaches its minimum value at the Curie point, suggesting that there is a very definite contribution from the critical scattering to the measured Bragg reflection.

A part of the discrepancy in Fig. 5 could be due to an error in B' of Hoshino *et al.*[5]. They analyzed the crystal structure by putting $S=1$ in Eq. 11, while the actually observed S is 0.77 at room temperature. Therefore, the B' of Hoshino *et al.* could be subject to some errors.

As seen in the curve for (0 6 1) in Fig. 5, the discrepancy between observed and calculated values becomes large at about 30°C. Similar bumps were observed also in some of the other Bragg reflections. At this time no explanation can be presented for these bumps.

The observed total background consists of a critical scattering, thermal diffuse scattering, an incoherent scattering due to the Compton effect, and the natural background counts of the counter tube. We have to subtract the latter three from the observed background, in order to compare the experimental observations with the discussion on the critical scattering given in Sec. 2.

For simple cubic crystals in which lattice points are occupied by identical atoms of scattering factor f_0, the thermal diffuse scattering J_T is given by[21]

$$J_T=|f_0|^2e^{-2M}\sigma ,$$

where M is the Debye-Waller factor and σ is a function of the temperature, of the position vector $\boldsymbol{H}$ in reciprocal space, and of the elastic stiffness c_{ij}. In analogy to this equation, thermal diffuse scattering by TGS is assumed to be expressed by

$$J_T=|F|^2\sigma , \tag{34}$$

where σ is a function of temperature, $\boldsymbol{H}$ and c_{ij} as above, but its functional form must be somewhat different from that in the simple case. The temperature factor e^{-2M} is implicitly included in Eq. 34, since Hoshino *et al.*[5] calculated F by assigning the Debye-Waller factor to each atom.

There are two kinds of elastic stiffnesses, usually written as c_{ij}^E and c_{ij}^D. c_{ij}^E is the elastic stiffness of the electrically shorted crystal and c_{ij}^D is that of the crystal with no electrodes on its surfaces. Some of the c_{ij}^E's could have an anomaly at the Curie point, while there is no reason to expect sharp anomalies in the c_{ij}^D at the Curie point[22]. The crystals used in our measurements had no electrodes on their surfaces. Therefore, the elastic stiffness in our case is c_{ij}^D and we can reasonably assume that σ and thus J_T have no anomaly at the Curie point. This assumption is supported by the experimental observations shown in Figs. 7 and 10, as described below.

$A=B=F=0$ for $(0k0)$ where k is odd, due to the existence of the twofold screw axis[17]. Therefore, $J_B=J_C=J_T=0$ at these points, according to Eqs. 11, 19 and 34, and thus the diffuse background at these points is a sum of an incoherent scattering and the natural background counts. This fact was used to determine the intensity of the incoherent scattering and natural background counts at any (hkl) by assuming that these contributions be the same as for an $(0k0)$ point for which k is odd and which is closest in angle to the relevant (hkl). For instance, J_C+J_T at (0 8±0.1 0) is determined as a total background at (0 8±0.1 0) minus a background at (0 7 0). Here a background at (0 8±0.1 0) means an average value of background at (0 8.1 0) and that at (0 7.9 0). The same notation will be used also for other (hkl)'s below.

Fig. 7 shows diffuse background at $(h0l)$, where B is zero[17] and thus no critical scat-

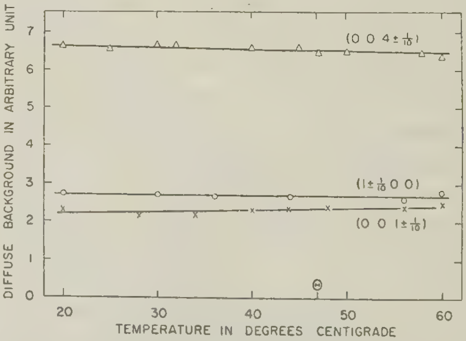

Fig. 7. Temperature dependency of the diffuse background around $(h0l)$. Incoherent scattering and natural background counts have been subtracted and the polarization correction has been made. The plotted values represent the thermal diffuse scattering J_T (see the text).

tering is expected according to Eq. 19. For the data shown in Fig. 7, the incoherent scattering and natural background counts have been already subtracted in the above manner and the polarization correction has been made. Therefore, Fig. 7 shows J_T around (004), (100) and (001). The curves show no anomaly at the Curie point and support our assumption discussed above. Fig. 7 shows also that the J_T around (004), (001) and (100) are almost exactly proportional to F^2 of those Bragg reflections shown in Fig. 4, a fact suggesting that Eq. 34 is not a bad assumption. The agreement of relative intensities at room temperature seems, however, to be too good and probably somewhat accidental, if we consider experimental errors and the H dependence of σ in Eq. 34.

Fig. 8 shows J_C+J_T at (0 8±0.1 0). According to Hoshino *et al.*, $A=40.28$ and $B=-19.11$ for (0 8 0) and the figure shows a peak at the Curie point as discussed in Sec. 2D. In the figure, J_C is separated from J_T by the dashed line, which was drawn using Eqs. 11 and 34 on the assumptions that J_C is negligible at room temperature and that A, B and σ are independent of temperature as suggested by the curves in Figs. 4 and 7.

Fig. 9 shows J_C separated in the above manner for (0 8±0.1 0) and (0 8±0.2 0). The closer to the Bragg reflection (0 8 0), the more pronouced the anomaly.

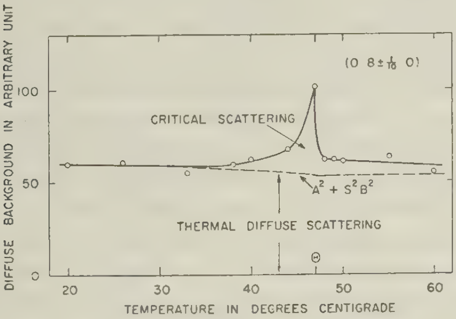

Fig. 8. Temperature dependency of diffuse background at (0 8±0.1 0). Incoherent scattering and natural counts have been subtracted, and the polarization correction has been made. See the text for the separation of the critical scattering from the thermal diffuse scattering.

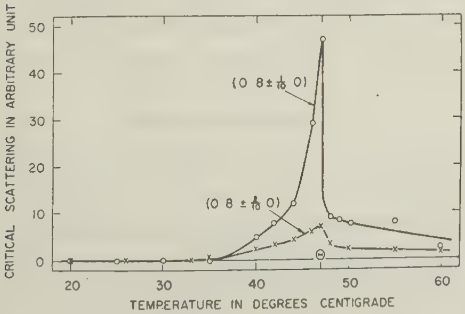

Fig. 9. Critical scatterings at (0 8±0.1 0) and at (0 8±0.2 0) as functions of temperature.

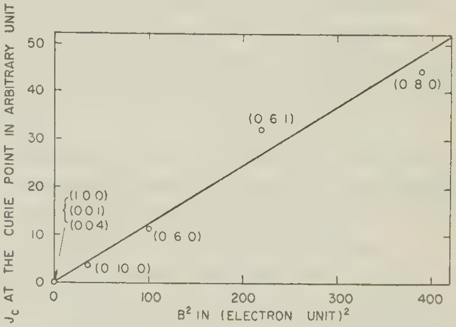

Fig. 10. Relation between the critical scattering J_C at the Curie point and B^2 calculated by Hoshino *et al*[5]. (*hkl*) on the figure shows that the measurements were made at (h k±0.1 l) except for the cases of $B=0$. The data were obtained with the same specimen and measured intensities were corrected by the polarization factor, except for the cases of $B=0$.

Eq. 19 shows that J_C should be proportional to B^2 times a periodic function G in reciprocal space. To examine this relation, J_C was measured at several points corresponding to (h k±0.1 l), where h, k and l are integers, and plotted as a function of B^2 at the (h k l) calculated by Hoshino *et al.*[5] The periodic function G has a period of $h=1$, $k=1$ and $l=1$ and thus should have the same value at the above points. Therefore, the measured values of J_C, for which polarization corrections were made, should be proportional to B^2. Fig. 10 shows that this relation holds at least approximately. Data shown in Fig. 7 for which no anomaly was observed are also added in Fig. 10, though these measurements were not made at (h k±0.1 l). The small disagreements in Fig. 10 seem to be caused by experimental errors which seem to be about 10%, by errors in the background drawn to separate J_C from J_T, by errors in the structure factors of Hoshino *et al.*[5], and by the fact that B^2 at (h k±0.1 l) is slightly different from B at (*hkl*). The proportionality between J_C and B^2 of Hoshino *et al.*[5] shown in Fig. 10 proves that δ is nearly equal to zero in Eqs. 3.

§ 4. Conclusions and Discussions

Our fundamental assumptions for the theoretical treatments given in Sec. 2 were that the phase transition in TGS is of the order-disorder type and that the actual crystal is a statistical mixture of two basic structures. These assumptions led us to the following conclusions: the structure factor F of the actual crystal is given by $\langle F\rangle = A - iSB$ (Eq. 10), the intensity of the critical scattering is expressed by B^2 times a periodic function in reciprocal space (Eq. 19), and that periodic function should have an anomaly at the Curie point as suggested by Eq. 33. Experimental observations described in Sec. 3 agree with these theoretical predictions and prove that the ferroelectric phase transition in TGS is essentially of the order-disorder type.

δ is nearly equal to zero as suggested especially by the relation shown in Fg. 10. From this fact we can decide how much each atom is displaced during a reversal of polarity, referring to the atomic coordinates determined by Hoshino *et al.*[5] For instance, the sulfur atoms do not shift appreciably when the nitrogens of Glycine I (see Fig. 1) move by 0.99 Å along the *b*-axis. Since the sulfur atoms do not move, one can say that the various atoms displace within a framework of sulfur atoms. Existence of such a framework could be a condition for easy domain wall motion, i.e., a condition that a crystal is not simply pyroelectric but also ferroelectric.

Fig. 9 shows that the intensity of critical scattering at (0 8±0.1 0) drops rather abruptly just above the Curie point. This feature appears to be quite different from the ferromagnetic case[2], and to be suggestive of the difference between the interaction forces of ferromagnetic dipoles and those of ferroelectric dipoles. More detailed studies, however, seem to be necessary for definite conclusions.

The curves shown in Fig. 9 are different from Curve 1 of Fig. 3. This fact proves that putting Δ_s $(s\neq 0)$ equal to zero is not a good approximation. This follows, of course, from the Onsager[22], Kirkwood[23], and Fröhlich theories[19]. The approximate theory in which Δ_s $(s\neq 0)$ is put equal to zero is called the Bragg-Williams approximation in the alloy case, the Weiss theory for ferromagnetism, and an internal field theory or a local field theory for ferroelectrics. An internal or local field theory is however, sometimes discussed in connection with the Lorentz-Debye molecular field. The authors used " Bragg-Williams approximation " instead of a " local field theory " in the preceding sections, in order to make it clear that they have no intention to correlate this approximation with the electrostatic molecular field. The electrostatic interaction could make some contribution to the occurrence of ferroelectricity as has been discussed by Pirenne[25] and Devonshire[16]. Probably one can gain more insight into this problem by generalizing Fröhlich's theory[19] to anisotropic dielectrics.

It is interesting to observe that the spontaneous polarization is related to the Bragg reflections by Eqs. 8 and 11, while the dielectric constant is related to the critical scattering at the lattice points of reciprocal space as seen in Eq. 33. These facts imply that studies of weight distribution of critical scattering in reciprocal space can give more detailed information on transition mechanism than the usual dielectric studies. Quantitative information on the anisotropy and nature of the interaction between ferroelectric dipoles are expected to be obtained by evaluation of pair correlation functions, with the help of statistical mechanics. Measurements of diffracted X-rays have to be carried out in wider temperature range than in the present studies for reliable estimation of pair correlation function.

The theory presented in this paper can be applied also to $NaNO_2$. X-ray studies of the phase transition in $NaNO_2$ have been carried out by one of the present authors (I.S.).[27]

Acknowledgements

The authors wish to express their thanks to Professors R. Pepinsky and Y. Okaya for their encouragement during the course of this study. A part of this work was carried out at Brookhaven National Laboratory, Upton, New York, under the auspices of the U.S. Atomic Energy Commission. The authors are much indebted to Dr. B. C. Frazer for his many helpful discussions and his suggestion of the plot in Fig. 6. They are grateful also to Drs. G. J. Dienes and S. Hoshino for their criticism.

X-Ray Studies of the Ferroelectric Phase Transition in $NaNo_2$

By Iwao SHIBUYA

The Institute for Solid State Physics, University of Tokyo, Tokyo

(Received October 8, 1960)

Studies of the temperature dependence of Bragg reflections and critical scatterings of X-rays have been carried out for the ferroelectric $NaNO_2$ in a manner analogous to those made by Shibuya and Mitsui for $(glycine)_3 \cdot H_2SO_4$. Experimental observations agree with theoretical predictions which are based on an assumption that the phase transition in $NaNO_2$ is of the order-disorder type. A long-range order parameter and the spontaneous polarization are estimated as functions of temperature by using the temperature variation of Bragg reflections. The observed intensity of the critical scattering drops rather abruptly just above the Curie point in a manner similar to the case of $(glycine)_3 \cdot H_2SO_4$.

§ 1. Introduction

Studies of the temperature dependence of Bragg reflections and critical scatterings of X-rays have been carried out recently by Shibuya and Mitsui[1] for $(glycine)_3H_2SO_4$, TGS, both theoretically and experimentally. The present work on $NaNO_2$ is an extension of their work. As will be described in Sec. 2, the mechanism of the ferroelectric phase transition in $NaNO_2$ seems to have a strong resemblance to that in TGS; therefore, the theory which has been developed for TGS is expected to be applicable also to $NaNO_2$. A brief summary of theoretical assumptions and conclusions will be presented in Sec. 3; experimental results and discussions will be given in Sec. 4.

§ 2. Properties of $NaNO_2$

In 1943, Strijk and MacGillavry[2] found a phase transition in $NaNO_2$ at about 158°C by piezoelectric as well as X-ray studies. The crystal belongs to a pyroelectric class at room temperature[3], while centers of symmetry appear above the transition point[2]. In 1958, Sawada *et al.*[4] found that the pyroelectric phase was also ferroelectric along the *b* axis. (The crystallographic *a*, *b*, and *c* axes adopted by Strijk and MacGillavry[2] will be used throughout the present paper).

Structure analyses have been carried out by several workers for the high[2),5),6] and room-temperature phases[3),7),8),9]. The unit cell has two molecular units, both above and below the Curie point. The space group is *Im2m* at room temperature, and above the Curie point, the crystal gains a mirror plane perpendicular to the *b* axis, centers of symmetry are therefore obtained as in the case of TGS, and the space group becomes *Immm*. Strijk and MacGillavry proposed two models[2] to explain the appearance of mirror symmetry; one is an disordered structure due to large oscillational motions of atoms and the other is a positionally disordered structure. Later, they found that their X-ray data could be explained by the two models almost equally well[5]. The following physical properties of $NaNO_2$, however, suggest that the transition mechanism of this crystal is quite similar to those of TGS and KH_2PO_4, (KDP). The Curie-Weiss constant of $NaNO_2$ is 5000°K[4] compared

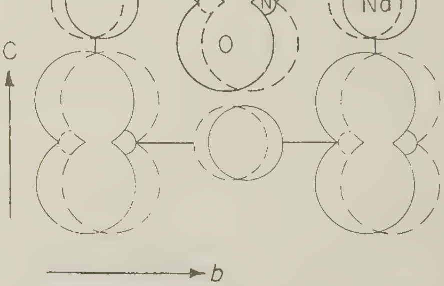

Fig. 1. The unit cell of $NaNO_2$. Atoms depicted by thin lines lie on the $x=0$ plane, and these by thick lines are at $x=1/2$. The solid lines correspond to the positive polarity and the dashed lines to negative polarity, respectively.

to 3280 of TGS[10] and 3260 of KDP[11]; the transition entropy of $NaNO_2$ is 0.7 cal./mol. deg.[4] compared to 0.48 of TGS[10] and 0.47[11] or 0.72[12] of KDP; therefore, the transition in $NaNO_2$ seems to be of the order-disorder type as in the cases of TGS and KDP. (For a detailed discussion, see reference 13).

Fig. 1 shows the unit cell of $NaNO_2$ proposed for the disordered structure by Strijk and MacGillavry[2].

§ 3. Theoretical Assumptions and Conclusions

It is assumed that the Na^+ and NO_2^- ions have two equilibrium positions as shown in Fig. 1. The positions depicted by solid lines will be called a positive position and those by dashed lines a negative position. It will be assumed that at sufficiently low temperature all atoms are in the positive positions in a domain of positive polarity; the corresponding assumption can be made for the case of negative polarity. The probability of finding an atom in the positive position is assumed to be equal to that in the negative position above the Curie point.

This is essentially the same model as is used for TGS, and the conclusions expected from this model are as follows. (See Sec. 2 of reference 1 for the exact definition of quantities and derivation of theoretical conclusions).

If the origin of the unit cell is put at a position where a center of symmetry exists above the Curie point, the structure factor of the unit cell in which all atoms are in the positive positions is given by $A+iB$ and that of the unit cell in which all atoms are in negative positions by $A-iB$. So that the structure factor F of the actual crystal is given, in terms of a long-range order parameter S, by

$$F=A+iSB ,$$

or

$$|F|^2=A^2+S^2B^2 . \qquad (1)$$

The relation holds both above and below the transition temperature.

Another conclusion we can derive from our assumptions (See Sec. 2 D of reference 1.) is that the critical scattering of X-rays should exhibit an anomaly at the Curie point as the dielectric constant does. It can be expected that in $NaNO_2$ the anomaly of critical scattering is observable since the peak height of the dielectric constant of $NaNO_2$ is about 1000, and is comparable to that of about 3000 of TGS.

§ 4. Experimental Results and Discussions

In the case of TGS, we evaluated S as a function of temperature by measuring the spontaneous polarization, and examined the validity of Eq. 1. This procedure can not be used for $NaNO_2$ since the coercive field increases rather rapidly with decreasing temperature. However, it seems certain that S is quite close to unity at room temperature as suggested by the excellent results of the neutron structure analysis of Kay and Frazer[9]; therefore, it is possible to put $F^2=A^2+B^2$ at room temperature according to Eq. 1. By Eq. 1, $F^2=A^2$ above the Curie point where $S=0$. To examine this conclusion, intensities of several Bragg reflections were measured at room temperature and at about 200°C using the usual multiple-film method with CuKα radiation. The crystals used for this experiment were grown from aqueous solution. The intensities were estimated visually by comparison with a standard scale and were corrected for the usual Lorentz and polarization factors. Due to the small liner absorption coefficient and the small radii of the cylindrical specimens (about 0.1 *mm*), no absorption correction was made. Some reflections with strong intensities, *e.g.* (020) and (101), were affected by extinction, and they were corrected for the secondary extinction using the usual formula

$$F_{\text{obs}}^{\text{corrected}}=F_{\text{obs}}\exp(gF_{\text{cal}}^2\,\text{LPF}) ,$$

(All symbols have usual meanings.), with $g=1.32\times10^{-4}$. The results are shown in Table I in comparison with the values of A_c, B_c, and F_c calculated on the basis of Carpenter's results[7]. The values of F_c are those given in Carpenter's paper[7]; A_c and B_c were calculated with his F_c and α_c for the new origin of the unit cell. As has been mentioned in Sec. 3, A and B in Eq. 1 had to be calculated putting the origin of the unit cell at the point where a center of symmetry appears above the Curie point. Carpenter put the origin referring to the position of oxygen atoms[7]. If we use his origin and our unit cell vectors*,

---

* Carpenter's b and c axes must be exchanged to adjust to the notation of the present paper.

Table I.

h	k	l	Room temperature				200°C
			A_c	B_c	$\|F_c\|$	$\|F_0\|$	$\|F_0\|$

* Corrections for secondary extinction effect were made for these reflections.

center of symmetry exists at (00.0470) at 200°C according to Strijk and MacGillavry[2]. Therefore, the values of A and B shown in Table I were calculated by putting the origin at the above point. In Table I, A_c, B_c, and F_c are expressed in the electron unit and the scale factors for F_0 were so determined that the following relations hold; $\sum|F_c|=\sum|F_0|$ for the room temperature structure, and $\sum|A_c|=\sum|F_0|$ for the high temperature structure. Table I proves that the relation $|F|^2=A^2$ holds for the high temperature phase at least approximately. The small discrepancy seems to be due partly to the temperature dependence of A. In the Table, one can also see that the large temperature variations of (130) and (150) are explained by their large B values.

Further investigations on the temperature dependence of Bragg reflections were made with another film method. The intensities of the (130), (150), and (200) reflections were recorded at several temperatures on a single film. As seen in Table I, the (130) and (150) reflections have large B values while (200) has zero B value due to the symmetry of the crystal. The obtained photograph again proved the prediction of Eq. 1; drastic intensity changes were observed in the vicinity of the Curie point for (130) and (150), but practically no change for (200).

In order to estimate the long-range order parameter and the temperature dependence of the spontaneous polarization, more accurate measurements of the (130) and (200) reflections were made with a General Electric X-ray unit, XRD-IV. CuKα radiation was used with the help of a nickel filter and a pulse-height discriminator put in the electronic circuit. The applied voltage was 45 KV and the current 15 mA, and a slit wide enough to get proper integrated intensities was used. The crystal was shaped into a small cylinder and rotated around the c axis. A care was taken to eliminate errors in intensity measurements due to the temperature variations of the cell dimensions. Azimuthal and longitudinal angles of the crystal settings were readjusted at each temperature by making the intensity of Bragg reflections maximum. The results obtained are shown in Fig. 2; they prove that the intensity of (130) decreases sharply below the Curie point, while that of (200) is not affected by the phase transition and decreases only slightly and linearly with increasing temperature.

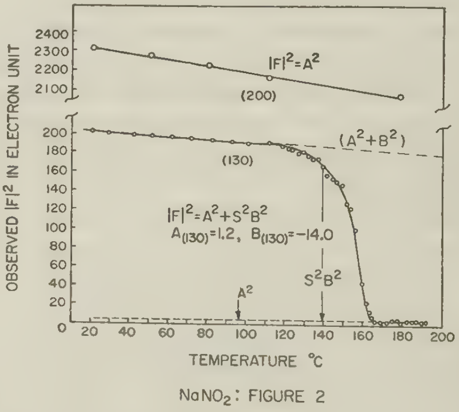

Fig. 2. The temperature dependences of $|F|^2$ of (200) and (130) reflections.

Equation 1 tells us that the long-range order parameter S can be estimated as a function of temperature if the temperature dependence of A and B are known. The $|F_0|^2$ *vs* temperature curve of (130) has a finite tangent at room temperature; this situation could be attributed either to the change of S or changes in A and B; however, an almost strictly linear change of $|F|^2$ from room temperature to about 100°C seems to suggest that the main part of the change is caused by temperature variations of A and B, since S usually has some curvature as a function of temperature when it changes. Therefore, it was assumed that the linear part of the $|F|^2$ *vs* temperature curve and its extrapolation to higher temperature give a temperature dependence of A^2+B^2. $|F|^2$ of (130) is almost constant above 170°C, and it was also assumed that the $|F|^2$*vs* temperature curve in this temperature region and its extrapolation to lower temperature give the temperature dependence of A^2. The extrapolated curves are shown by dashed lines in Fig. 2. The temperature dependence of $|F|^2$ of (200) in Fig. 2 suggests that the above assumptions are not unreasonable. Fig. 3 shows values of S calculated using Eq. 1 and the above assumptions. The transition in $NaNO_2$ is most likely to be of first order[4]; for a first order transition, by its definition, S should change discontinuously as demonstrated by a dashed curve in Fig. 3. (Note that this dashed curve has no quantitative significance.) The discrepancy seems to be attributed to the facts that the measured integrated intensity contained some contributions from the critical scattering as in the case of TGS[1], and also that the temperature was not quite uniform within the crystal during each measurement. The spontaneous polarization P_s is proportional to S as shown by Eq. 8 of reference 1; a scale for P_s is given on the right-hand side of the vertical axis in Fig. 3. This scale was determined using the value of P_s reported by Sawada *et al*[4] (6.4μC/cm² at 143°C). According to Fig. 3, P_s is about 7μC/cm² at room temperature and is consistent with the value obtained by a pyroelectric measurement reported by Nomura[14].

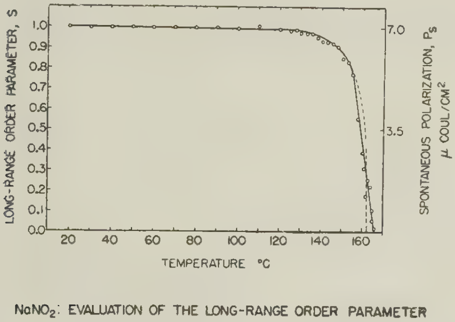

Fig. 3. The long-range order parameter S as a function of temperature (left-hand side of the vertical axis), and the temperature dependence of the spontaneous polarization P_s (right-hand side).

Measurements of the diffuse background were made at $(1-0.02|^{3}+0.05|0)$ and $(1+0.02|3-0.05|0)$ in the same manner as in the case of TGS. Fig. 4 shows the averaged intensities of these two sets of observations.

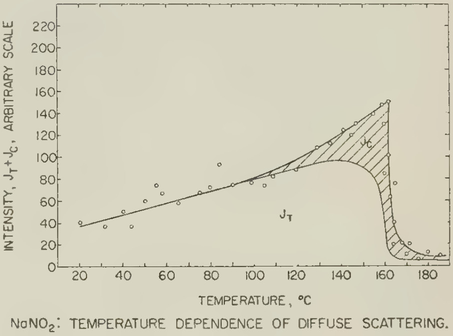

Fig. 4. Temperature dependence of the diffuse background. See the text for the separation of J_C and J_T.

As discussed in Sec. 3, an anomaly was observed at the Curie point. The measured background is a superposition of the critical scattering J_C, the thermal diffuse scattering J_T, incoherent scattering due to the Compton effect, and natural counts of the countertube. To separate J_C from the total diffuse background, the following assumptions were made. (1) The incoherent and natural background is negligible compared to J_C+J_T; the assumption seems reasonable, since the total intensity becomes very weak above the Curie point. (2) The critical scattering J_C is negligible between the room temperature and 100°C. This is consistent with the assumption made in the treatment of Bragg reflections that $S=1$ in the above mentioned temperature range. (3) The expression of J_T, $J_T=|F|^2\sigma$, assumed for TGS (Eq. 34 of reference 1) can be rewritten as

$$J_T=|F|^2(aT+b) .$$

Here $|F|^2$ is given by Eq. 1 and is assumed to depend on the temperature only through S which is shown in Fig. 3. (In other words, for the calculation, the effect of the temperature dependence of A and B were included in $(aT+b)$ and the values of A and B given in Table 1 were put in Eq. 1.) T stands for the temperature, a and b are constants. The values of a and b were estimated by using the curve between 20°C and 100°C, where the backgrounds are equal to J_T according to the assumptions (1) and (2). The separation of J_C and J_T on these assumptions is illustrated in Fig. 4, and thus the separated J_C is shown in Fig. 5 as a function of temperature. These measurements of J_C are only preliminary ones; however, Figs. 4 and 5 show at least that the critical scattering is observable for $NaNO_2$, and it seems also worthwhile to note that J_C dropped abruptly just above the Curie point in Fig. 5 in a manner quite analogous to that of TGS.

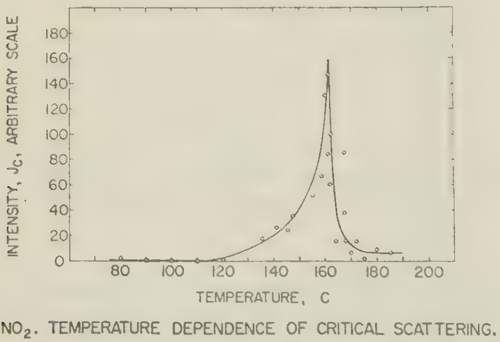

Fig. 5. The critical scattering at (1±0.02|3±0.05|0) as a function of temperature.

In conclusion, it may be stated that the experimental observations agree with the theoretical predictions based on the assumption that the phase transition in $NaNO_2$ is of the order-disorder type. In the case of TGS, it could be said that during a polarization reversal, various atoms displace within a framework of sulfur atoms[1], however, as seen in Fig. 1, there is no such framework in $NaNO_2$, This could be a reason why the coercive field of $NaNO_2$ increases rapidly with decreasing temperature; this feature is quite different from that of TGS.

Fortunately, the structure of $NaNO_2$ is quite simple and there seems to be a good hope of understanding its transition mechanism better than any other ferroelectrics with the order-disorder type phase transition. More detailed studies on the critical scattering is being planned. Estimations of the pair correlation function will be reported in a later paper.

Acknowledgments

A part of the present study was carried out in the Crystal Research Laboratory, Department of Physics, The Pennsylvania State University. The author wishes to thank Professor R. Pepinsky for his generous helps throughout the course of this study. He is particularly indebted to Professor T. Mitsui for his continued guidance in many valuable suggestions and for calling his attention to this problem. He also wishes to express his gratitude to Professor Y. Okaya for his critical reading of the manuscript.

P_s Function in Electron Diffraction*

By Yoshiro Kainuma
College of General Education, Nagoya University, Nagoya
and William N. Lipscomb**
School of Chemistry, Institute of Technology, University of Minnesota, Minneapolis, Minn.

(Received October 31, 1960)

The property of P_s function in electron diffraction was studied on the basis of the dynamical theory of diffraction. It was proved that P_s function in electron diffraction has the property similar to the P_s function in X-ray diffraction, as expected from pseudo-kinematical theory, i.e. kinematical theory using the complex atomic scattering factor.

§1. Introduction

The aim of the present article is to derive the properties of P_s function in electron diffraction on the firm basis of the dynamical theory of diffraction.

Friedel's law fails to hold in X-ray diffraction by a crystal if the wavelength of the incident X-rays lies in the short wavelength side of the absorption edge of heavy atoms contained in the crystal. Since several years ago many authors applied the failure of the law to the determination of the absolute configuration of atoms in optically active substances. The most direct use of the anomalous dispersion in structure analysis was given by the method of P_s function[1]. The P_s function is a function defined by the substitution of $\sin(2\pi \boldsymbol{h}\cdot\boldsymbol{r})$ for $\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{r})$ in the ordinary Patterson function. The P_s function gives an antisymmetric configuration of light atoms around heavy atoms. A few years before we tried to study the properties of P_s functions in electron diffraction. In the initial stage of the study it seemed to be promising. The phase shift of the electron wave scattered by heavy atoms was predicted and the complex atomic scattering factor electrons was introduced by Glauber and Schomaker[2] and calculated by Hoerni and Ibers[3]. The phase shift of the scattered electron wave is not an anomalous effect, but occurs generally in the scattering of the wave with any wavelength***. In the application of P_s function in electron diffraction there is no trouble such as selection of an X-ray tube with the target which gives characteristic X-rays with an adequate wavelength. However, we encountered unexpected difficulty that several authors[4,5,6] cast their doubts about the applicabilities of the kinematical theory of diffraction using the complex atomic scattering factors—Hoerni's pseudo-kinematical theory[7]—to crystals. According to them such a theory can be applied only to the diffraction of electrons by gas molecules. Thus only if we construct P_s function using the intensities of reflection calculated on the basis of the dynamical theory of diffraction, the properties of P_s function in electron diffraction can be elucidated.

However, there was another difficulty. According to Miyake, Kohra and Uyeda[8] Friedel's law in electron diffraction fails to hold when the simultaneous reflections by two or more net planes occur in non-centrosymmetric crystals. They had to calculate numerically the solution of the reduced fundamental equations of the dynamical theory taking only three waves into account. At that time there was no well-known method to treat the reflected intensities in many-wave problems in the dynamical theory of electron diffraction.

---

* The main part of this article was read by one of the authors in the seminar on theoretical problems in X-ray and electron diffraction by crystals held at Institute of Solid State Physics, Tokyo University on September 7 to 9, 1959.

** Now at Department of Chemistry, Harvard University, Cambridge, Mass.

*** The phase shift of the scattered electron waves comes from the multiple elastic scattering within a heavy atom. It should be noted that the true counterpart of the anomalous scattering of X-ray in electrons is not the multiple elastic scattering, but the elastic scattering accompanying the virtual transition of electronic state. See (2) of §4 of the present article.

Because the use of P_s function is a positive application of the failure of Friedel's law, we had to face the problem how to obtain the solution of the many-wave problem not numerically, but in an explicit analytical form.

Recently Fujimoto[5] and Niehrs[8] developed Niehrs and Wagner's theory[9] and formulated the dynamical theory by the use of scattering matrix and gave a general method to treat the many-wave problems. At the same time, Fujiwara[10] extended the Artmann's calculation[11] of the wave field within the crystal in the first order Born approximation to higher orders of approximation and derived the results of Cowley-Moodie's formulation[12] of the dynamical theory. The results of the Fujimoto's and Fujiwara's theories are proved to be essentially the same as each other.

These developements of the dynamical theory have enabled us to study the properties of P_s functions of electron diffraction on a firm basis.

§ 2. The Results of Fujimoto's Theory

For the convenience, we refer to the results of Fujimoto's theory. He assumes a thin single crystal, of which surfaces are prependicular to its c-axis. He gave the intensity of reflection, $\boldsymbol{h}=(hko)$, in the power series of the product of thickness of the crystal D and the wavelength of electrons λ as follows:

$$I(\boldsymbol{h})=I_2(\boldsymbol{h})+I_3(\boldsymbol{h})+I_4(\boldsymbol{h})+\cdots\ , \tag{1}$$

where

$$I_2(\boldsymbol{h})=\left(\frac{\lambda D}{4\pi}\right)^2\cdot|v_h|^2\ , \tag{2}$$

$$I_3(\boldsymbol{h})=\left(\frac{\lambda D}{4\pi}\right)^3\cdot\frac{i}{2}\left[v_{-h}\sum_g\sum{}' v_g v_{h-g}-v_h\sum_g\sum{}' v_{-g}v_{g-h}\right]\ , \tag{3}$$

$$\begin{aligned}I_4(\boldsymbol{h})=\left(\frac{\lambda D}{4\pi}\right)^4\cdot\frac{2}{4\,!}\Big[&3\,\Big|\sum_g\sum{}'\,v_g v_{h-g}\Big|^2-4\,|v_h|^2\cdot\mathrm{Re}(v_h{}^2)-8\,|v_h|^2\sum_g\sum{}'\,|v_g|^2\\&-4\,\mathrm{Re}\Big(v_{-h}\sum_g\sum{}'\underset{\neq}{}\sum_l\sum{}' v_g v_{l-g}v_{h-l}\Big)-4\mathrm{Re}\Big(v_{-h}\sum_g\sum{}' p_g v_g v_{h-g}\Big)\Big]\ .\end{aligned} \tag{4}$$

$\boldsymbol{g}=0$ and $\boldsymbol{g}=\boldsymbol{h}$ are excluded from the summation $\sum\limits_g\sum{}'$ in (3) and (4). v_h denotes the Fourier coefficient of the Fourier series:

$$-\frac{8\pi^2 me}{h^2}\cdot V(\boldsymbol{r})=\sum\sum_h\sum v_h\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{r})\ , \tag{5}$$

where $V(\boldsymbol{r})$ is the electric potential within the crystal. The parameter p_g in the right hand side of (4) has a value depending upon the direction and wavelength of the incident electrons and defined as follows:

$$p_h\equiv p_{(hko)}=-\{(h-\xi)\boldsymbol{a}^*+(k-\eta)\boldsymbol{b}^*\}^2 \tag{6}$$

where $\xi\boldsymbol{a}^*+\eta\boldsymbol{b}^*$ is the component of the wave vector (with the magnitude $1/\lambda$) of the incident electrons parallel to the surface of the crystal.

Fujimoto pointed out that the possibility of the failure of Friedel's law appears first in the term $I_3(\boldsymbol{h})$ of the series (1). We have $I_3(\boldsymbol{h})\neq I_3(-\boldsymbol{h})$ for non-centrosymmetric crystals, while we have always $I_2(\boldsymbol{h})=I_2(-\boldsymbol{h})$ for any kind of crystals.

Integrated intensity of the reflection $\boldsymbol{h}$ can be writtern as

$$J(\boldsymbol{h})=J_2(\boldsymbol{h})+J_3(\boldsymbol{h})+J_4(\boldsymbol{h})+\cdots\ . \tag{9}$$

corresponding to (1). Since there are included no parameters p_h's in the expression of $I_2(\boldsymbol{h})$ and $I_3(\boldsymbol{h})$, we can put

$$J_2(\boldsymbol{h})/I_2(\boldsymbol{h})=J_3(\boldsymbol{h})/I_3(\boldsymbol{h})=K\ , \tag{10}$$

where K is a constant.

§ 3. P_s Function in Electron Diffraction

P_s function in two dimensions can be written as follows:

$$P_s(\boldsymbol{r})=\sum_{h}\sum J(\boldsymbol{h})\sin 2\pi\boldsymbol{h}\cdot\boldsymbol{r} \tag{11}$$

Corresponding to the power series of $J(\boldsymbol{h})$ given in (9), P_s can be expanded as follows:

$$P_s(\boldsymbol{r})=P_{s2}(\boldsymbol{r})+P_{s3}(\boldsymbol{r})+P_{s4}(\boldsymbol{r})+\cdots . \tag{12}$$

From (7) we have always

$$P_{s2}(\boldsymbol{r})=0 . \tag{13}$$

For the calculation of P_{s3} it is convenient to write $I_3(\boldsymbol{h})$ as

$$I_3(\boldsymbol{h})=\left(\frac{\lambda D}{4\pi}\right)\cdot\frac{i}{2}\Big[v_{-h}\sum_{g}\sum v_g v_{h-g}-v_h\sum_{g}\sum v_{-h}v_{g-h}\Big] , \tag{14}$$

where the summation $\sum_{g}\sum$ is over all of g's including $g=o, h$, because we have

$$\left.\begin{aligned} v_{-h}\sum_{g}\sum v_g v_{h-g}&=v_{-h}\sum_{g}\sum{}' v_g v_{h-g}+2v_o\,|\,v_h\,|^2 ,\\ v_h\sum_{g}\sum v_{-g}v_{g-h}&=v_h\sum_{g}\sum{}' v_{-g}v_{g-h}+2v_o\,|\,v_h\,|^2 . \end{aligned}\right\} \tag{15}$$

It is to be noted that even if we use any value of v_o in (15) which is different from v_o defined in (5), we have still (14). In the following it is convenient to select the value of v_o which makes the values of the function

$$U(\boldsymbol{r})=\sum_{h}\sum v_h\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{r}) \tag{16}$$

vanish at the place far from the projected areas of atoms.

From (16) we have

$$U^2(\boldsymbol{r})=\sum_{h}\sum\Big(\sum_{g}\sum v_g v_{h-g}\Big)\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{r}) \tag{17}$$

The convolution integral of U and U^2 is given by

$$\begin{aligned}\iint_{S_a} U(\boldsymbol{r})\cdot U^2(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}&=S_a\cdot\sum_{h}\sum v_{-h}\cdot\Big(\sum_{g}\sum v_g v_{h-g}\Big)\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{u})\\ &=S_a\cdot\sum_{h}\sum v_h\cdot\Big(\sum_{g}\sum v_{-g}v_{g-h}\Big)\exp(-2\pi i\boldsymbol{h}\cdot\boldsymbol{u})\end{aligned} \tag{18}$$

where S_a is the area of the parallelogram with the sides of the unit cell, a_1 and a_2. Similarly the convolution integral of U^2 and U is given by

$$\begin{aligned}\iint_{S_a} U^2(\boldsymbol{r})\cdot U(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}&=S_a\cdot\sum_{h}\sum v_h\Big(\sum_{g}\sum v_{-g}v_{g-h}\Big)\cdot\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{u})\\ &=S_a\cdot\sum_{h}\sum v_{-h}\Big(\sum_{g}\sum v_g v_{h-g}\Big)\exp(-2\pi i\boldsymbol{h}\cdot\boldsymbol{u})\end{aligned} \tag{19}$$

By the use of (14), (18) and (19) we have

$$\begin{aligned}P_{s3}(\boldsymbol{u})&=\frac{K}{2i}\Big\{\sum_{h}\sum I_3(\boldsymbol{h})\exp(2\pi i\boldsymbol{h}\cdot\boldsymbol{u})-\sum_{h}\sum I_3(\boldsymbol{h})\exp(-2\pi i\boldsymbol{h}\cdot\boldsymbol{u})\Big\}\\ &=K\cdot\left(\frac{\lambda D}{4\pi}\right)^3\cdot\frac{1}{2S_a}\left\{\iint_{S_a} U(\boldsymbol{r})\cdot U^2(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}-\iint_{S_a} U^2(\boldsymbol{r})\cdot U(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}\right\}\end{aligned} \tag{20}$$

If we have a unit cell containing heavy atoms and light atoms, the heavy atoms will appear more emphasized than the light atoms in the function $U^2(\boldsymbol{r})$. Thus the convolution integral

$\iint_{S_a} U(\boldsymbol{r})\cdot U^2(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}$ shows peaks with the positions and weights given in Table I by the help of the same reasoning as given about the weights of the ordinary Patterson peaks[14]. In Table I, w_i^H denotes the weight of the peak of he $U(\boldsymbol{r})$ at the ith heavy atom in the unit cell H_i, i.e. $w_i^H=\iint_{S_a} U_i^H(\boldsymbol{r})d\boldsymbol{r}$, where $U_i^H(\boldsymbol{r})$ is the contribution of the ith heavy atom to the function $U(\boldsymbol{r})$ and the integral is over S_a. $(w^2)_i^H$ denotes the weight of the peak of the function $U^2(\boldsymbol{r})$ at H_i. w_k^L denotes the weight of the function $U(\boldsymbol{r})$ at the kth light atom in the unit cell L_k*. Similarly the convolution integral $\iint_{S_a} U^2(\boldsymbol{r})\cdot U(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}$ shows the peaks given in Table II.

Table I.

Positions	Weights
$\overrightarrow{H_i\ H_j}$	$w_i^H\cdot(w^2)_j^H$
$\overrightarrow{H_j\ H_i}$	$w_j^H\cdot(w^2)_i^H$
$\overrightarrow{L_k\ H_j}$	$w_k^L\cdot(w^2)_j^H$

Table II.

Positions	Weights
$\overrightarrow{H_i\ H_j}$	$(w^2)_i^H\cdot w_j^H$
$\overrightarrow{H_j\ H_i}$	$(w^2)_j^H\cdot w_i^H$
$\overrightarrow{H_j\ L_k}$	$(w^2)_j^H\cdot w_k^L$

Table III.

Positions	Weights
$\overrightarrow{L_k\ H_j}$	$+w_k^L\cdot(w^2)^H$
$\overrightarrow{H_j\ L_k}$	$-w_k^L\cdot(w^2)^H$

Let us assume that there is only one species of heavy atoms in the unit cell. Then, in the difference of the convolution integrals

$$\left\{\iint_{S_a} U(\boldsymbol{r})\cdot U^2(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}-\iint_{S_a} U^2(\boldsymbol{r})\cdot U(\boldsymbol{r}+\boldsymbol{u})d\boldsymbol{r}\right\}$$

the heavy-heavy peaks are cancelled by each other and we have the positive and negative light-heavy peaks given in Table III.

From Table III and (20), it is seen that the function $P_{s3}(\boldsymbol{r})$ gives the relative position of the light atoms to the heavy atoms. Thus the function $P_{s3}(\boldsymbol{r})$ has essentially the same property as P_s function in X-ray diffraction.

Moreover, under the following conditions we have

$$P_s^4(\boldsymbol{r})=0\ . \tag{21}$$

If the incident electrons form a convergent beam with a symmetric distribution of intensity around the normal of the crystal surface, we may aproximate the incident beam by a number of plane waves propagating in various directions. Then we can prove that

$$J_4(\boldsymbol{h})=J_4(-\boldsymbol{h}) \tag{22}$$

by the use (4) and above mentioned symmetrical intensity distribution. Thus we have $P_{s4}(r)=0$.

The same holds also in the case in which the incident beam is a plane wave propagating in a definite direction and the crystal is warped slightly and the average direction of the surface normals is parallel to direction of the incident beam.

Thus we have in these cases

$$P_s(\boldsymbol{r})=P_{s3}(\boldsymbol{r})+P_{s5}(r)+\cdots \tag{23}$$

and we can expect that P_s function has essentially the same property as P_s function in X-ray diffraction if the crystal is thin.

§ 4. Discussions

(1) *Pseudo-kinematical theory and dynamical theory.*

Miyake[4] concluded that the intensity of reflection in the limit $\lambda D\to 0$ does not tend to the pseudo-kinematical theory but to the kinematical theory on the basis of the dynamical theories of Fujimoto and Fujiwara. In the present article we pointed out that P_s function in electron diffraction shows essentially the same property as expected from the pseudo-kinematical theory on the same basis as used by Miyake.

According to Miyake the application of the complex atom scattering amplitude to thin crystal may give nothing but a misleading

---

[*] It should be noted that the value of $U(r)$ is made equal to zero at the places far from the projected areas of atoms by a choice of the adequate value of v_0.

conclusion. However, our present result shows that the use of such a complex atomic scattering factor affords the right clues to the structure of non-centrosymmetric crystals. In our view, Miyake pointed out the negative side of the pseudo-kinematical theory, and we pointed out the opposite positive side of the same theory.

In our view it can be expected that the pseudo-kinematical theory may give a good approximation in the thinnest crystal with a thickness of a unit cell. Our expectation was proved recently by Kainuma and Yoshioka[14], and Hayashi[15].

It should be noted that we tried to find an application of the dynamical theory of Fujimoto and Fujiwara in the initial stage of structure determination and Miyake gave a firm theoretical basis for attaining to higher accuracy in structure determination using the same theory.

(2) *Scattering of electrons accompanying virtual transitions.*

In the present artical we have derived the property of P_s function in electron diffraction by thin crystals taking into account only the existence of many weak reflected-waves on the basis of the dynamical theory of electron diffraction. The result of the calculation in thin crystals has been found essentially the same as expected from the kinematical theory of diffraction using the complex atomic scattering factor due to the multiple elastic scattering within an atom.

However, it should be noted that the true counterpart of the anomalous scattering of X-rays in electrons is not the elastic multiple scattering, but the elastic scattering accompanying the virtual transition of electronic states of the atom, because the anomalous scattering of X-rays accompanies the virtual electronic transitions also.

When atoms compose a crystal, the elastic scattering accompanying the virtual transitions of the electronic states of the crystal and the phonon states of the lattice vibrations can occur. The dynamical theory of diffraction taking into account these virtual transitions have been studied by Yoshioka[16] and Yoshioka and Kainuma[17]. It seems very desirable to study the property of P_s functions taking into account not only the effect of many weak waves but also these virtual transitions. However, it is left still unstudied yet.

(3) *Overlapping of the projections of atoms.*

In § 3 we assumed that the heavy atoms will appear more emphasized than the light atoms in the function $U^2(\boldsymbol{r})$. This assumption was used as the basis of the derivation the property of P_s function.

If the projections of atoms in a unit cell overlap each other, the above assumption cannot be appropriate, because the overlapping light atoms may appear emphasized as well as the heavy atoms in the function $U^2(r)$. Then there will appear the additional positive and negative peaks at the positions from the overlapping light atoms to light atoms and from light atoms to the overlapping light atoms in the two-dimensional P_s function. Thus the overlapping of the projections of atoms will make the two-dimensional P_s function very complicated and diminish the practical merit of the P_s function.

It should be noted that these additional peaks in the P_s function in not expected from the pseudo-kinematical theory. In (1) of this section it was mentioned that in thin crystals pseudo-kinematical theory and dynamical theory of many waves gives essentially the same intensities of reflections. However, the overlapping of the atoms on the projection parallel to the incident beam deteoriates the equivalence of the pseudo-kinematical theory to the dynamical theory even in the thinnest crystal with one molecular thickness. This will be proved also in the forthcoming articles by Kainuma and Yoshioka[14] and Hayashi[15]

(4) *Practical applications of P_s function in electron diffraction.*

We will find several difficulties in the practical use of P_s function in electron diffraction.

The extremely accurate measurement of the reflected intensities is required as it was required for the application of P_s function in X-ray diffraction, because P_s function is estimated from the difference of the reflected intensities, $J(\boldsymbol{h})-J(-\boldsymbol{h})$, as shown in (11)*.

---

* The application of P_s function in electron diffraction will be found only in the analysis of the crystal containing many light atoms for each heavy atom. Cowley[21] concluded that the failure of Friedel's law can be observed in the transmission photograph only by using the specimen of such a crystal. He could not observe the failure of Friedel's law in the transmission through the crystal of basic lead carbonate.

In the present article we have treated P_s function in a two-dimensional projection and the crystal has been assumed to be thin. In many crystals the lattice constant c_0 of the unit is larger than a_0 and b_0, if the crystal has a remarkable crystal habit and it is thin in the direction of c-axis. Then we will have many overlapping peaks in the projection parallel to c-axis.

There is a reason to believe that the property of P_s function does not change essentially even if the crystal is not a thin parallel-sided plate but a small polyhedron. The reason may be found in the implication of Kato's extension[19] of Bethe's dynamical theory[20] to polyhedral crystals. Broadly speaking, the finite areas of the facets of the small crystal cause the diffraction of waves through the apertures with the same shapes and areas as the facets of the crystal. Thus the integrated intensity of reflections by the small crystal connot be very different from that by the thin parallel-sided plate of the same crystal. Although there is still no investigation on the extention of the dynamical theory of many waves to the small polyhedral crystal, the above reasoning will not be far from truth. Thus the property of P_s function will be independent of the external shape of the crystal if the averaged thickness of thin crystal in the direction parallel to the incident beam is the same.

Thus the practical application of P_s function in electron diffraction will be found by the help of the accurate measurement of the reflected intensities by the small polyhedral crystal.

Finally, the authors wish to express their sincere thanks to Professor Ryozi Uyeda for his encouragement during the study.

Our thanks are expressed also to Drs. F. Fujimoto and K. Fujiwara for letting us read their manuscripts of their articles before the publications. The present study was supported partly by the Grant-in-aid for Fundamental Scientific Research from the ministry of education, Japan. The travel grant of Fulbright Commission given to Y. K. and the reasearch fund of the National Science Foundation given to W. N. L. enabled the present study also.

Electron Distribution in Cu_2O Crystal

By Tadasu SUZUKI

Institute of Physics, College of General Education, University of Tokyo. Meguro-ku, Komaba, Tokyo

(Received November 5, 1960)

The atomic scattering factor and the electron distribution were studied by X-ray diffractometry in order to know the electronic state of oxygen in crystalline Cu_2O. The intensity measurements were performed within an experimental error of about 1 to 3%. The atomic scattering factor of oxygen was determined referring to the scattering factor of copper, and was compared with theoretical values of O^{2-}, O and O^{2+}. The observed value corresponds best to the scattering factor of O^{2-}. However, a small deviation from the ideally ionic O^{2-} state, for example the state of $O^{1.85-}$, is possible, which may be expected from the positive hole model for Cu_2O crystal. The electron distribution in some special planes of the unit cell of the crystal was determined by three dimensional Fourier synthesis. The electron distributions were found to be almost spherical around each atom except the overlapping of the electron cloud in the region between neighbouring Cu and O atoms.

§1. Introduction

The previous x-ray study of the binding properties of Cu_2O and Ag_2O crystals by the present author[1] has shown that the root-mean-square amplitude of the thermal lattice vibration is 0.26A for Cu_2O and is 0.40A for Ag_2O, the mean lattice strain is 0.15% for Cu_2O and is 1.4% for Ag_2O, and the thermal expansion coefficient of the lattice is $1.9\times10^{-6}/C°$ for Cu_2O. These results suggest that the binding force between the metallic atom and the oxygen atom is much weaker in Ag_2O than in Cu_2O, a result which can not be expected from the purely ionic model for both crystals. Especially, the thermal expansion coefficient of Cu_2O deviates remarkably from Megaw's empirical rule[2] for purely ionic crystals. Furthermore, the nearest Cu-O distance in Cu_2O, 1.85A, is too short to be expected from the ionic radii of O^{2-} and Cu^+, which are known to be 1.36A and 0.96A, respectively.[3]

The purpose of the present work is to study the electron distribution in Cu_2O by x-ray diffractometry in order to know the bonding type of the crystal.

§2. Experimental Conditions

The powder samples used for the intensity measurement were the same as those used in the previous work. The particle size was about one micron as determined microscopically. The purity of the samples was determined to be 98.9% by chemical analysis, and no trace of impurity could be observed in the diffraction patterns. It was shown in the previous work that the lattice constant of the crystal is 4.268±0.001A.

Measurements were performed with a Norelco diffractometer. The x-ray source was a copper target tube operated at 35 kV and 15mA. The scattered intensities were measured by a proportional counter with a nickel filter of 0.013 mm in thickness.

In order to monitor the intensity variation of the incident x-ray beam, an aluminum foil was set up at the another window of the same target tube and the (200) reflection from the foil was observed by a Geiger counter.

§3. Measurements

(1) *Preliminary, Survey*

Preliminarily, integrated intensities were measured on chart with a planimeter. The measurements were repeated twelve times by remounting the samples in each case. The standard deviation of the observed intensities from the mean value of the total measurements was about 2% for the strong reflections and about 9% for the weak ones. It was concluded from this survey that both samples and experimental conditions are satisfactory for precise intensity measurement.

The stepwise- and the continuous-counting methods were compared by measuring the integrated intensities of the two weak reflections, (110) and (331). The fixed count was taken as 10,000 counts and the intensity was measured by scanning stepwise over the diffraction profile with the finest step of 1/100 degree. The continuous counting was performed with the slowest scanning speed, 1/8 degree per minute. The intensities of (110) and (331) obtained by the two methods agree well, as shown in Table I. Therefore, the continuous counting method was adopted for the main measurements in order to survey many specimens.

Table I. A comparison between the fixed counting and the continuous counting. The integrated intensities in counts of (110) and (331) are tabulated.

hkl	fixed counting	continuous counting
(110)	1.657×10^5 counts	1.648×10^5 counts
(331)	1.979×10^5 counts	1.965×10^5 counts

The apparent density of manually packed powder samples, used in the preliminary measurements, was about 2.0 gr/cm³, while the density of the solid Cu_2O is 6.2 gr/cm³. Measurements were performed on specimens having different apparent densities, 3.0~3.4 gr/cm³, which were packed by a hand press machine into a cylindrical specimen holder. The mean value of the observed intensities of these specimens is tabulated in the last column of Table II. No large difference was found among the samples having different densities so far as the relative intensities are concerned.

The effect of extinction was examined by the procedure suggested by Vand.[4] The ratio of the observed intensity, I_0, to the calculated one, I_c, was plotted against the square of the calculated crystal structure factor F_c^2 corrected for the effect of thermal lattice vibration. The structure factor F_c was obtained from the same relation described in § 6 of the previous work. The attenuating factor due to thermal lattice vibration can be expressed by the Debye temperature factor

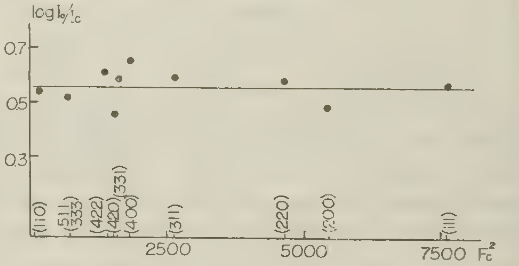

Fig. 1. The logarithmic plot of the ratio I_0 to I_c against to F_c^2. The plots are on a nearly constant line and show that the extinction effects are negligible.

Table II. The main observed intensity with the probable error for the measurements of six times. The third column, *j*, indicates the multiplicity of the reflection by the powder specimen. In the last column, the observed intensity of the pressed specimen is tabulated. The observed intensities were normalized each other to its total sum of all the observed reflections.

hkl	structure factor	*j*	observed intensity (main meas.)	probable error	observed intensity (pressed sample)
110	$2f_0$	12	290	2.3%	287
111	$4f_{Cu}$	8	4820	0.9	4824
200	$4f_{Cu}-2f_0$	6	1664	1.8	1650
211	$2f_0$	24	70	3.0	70
220	$4f_{Cu}+2f_0$	12	1383	1.1	1385
311	$4f_{Cu}$	24	1060	1.1	1066
222	$4f_{Cu}-2f_0$	8	236	3.3	236
400	$4f_{Cu}+2f_0$	6	125	1.1	128

M, as $\exp(-2M)$, where M is equal to $B\cdot\sin^2\theta/\lambda^2$, and θ and λ are the Bragg angle and the wave length of the radiation, respectively. B relates to the mean-square amplitude of thermal vibration, $\overline{u^2}$, as $B=8\pi^2\overline{u^2}/3$. An approximate value for B, 1.75A^2, was used, which had been determined in the previous work as an avaraged quantity for copper and oxygen atoms. As is shown in Fig. 1, $\log(I_0/I_c)$ against $F_c{}^2$ is nearly constant within the standard deviation of about 9%, and the extinction effect can be neglected in the present samples.

(2) *Main procedure*

The samples were manually packed into a cylindrical sample holder, which was 20 mm in diameter and 1.5 mm in depth. The sample holder was rotated around its axis one revolution per second in order to avoid the effect of preferred orientation and of surface roughness. The integrated intensity was obtained by subtracting the background counts from the total counts. The half breadths were 0.18 degree for the (110) reflection and 0.5 degree for (333). The background intensity was determined by counting at both tails distant enough from the maximum of the peak, for example 1.5 degrees for (110) and 2.0 degrees for (333). The observed intensities were corrected by monitoring when the variation in intensity of the x-ray out-put exceeded about 1.5% from its mean value. The measurements were repeated six times on remounted samples for each reflection. The standard deviation of the observed values from the mean value was 0.9% for the stronger reflections and about 3% for the weak ones. The obtained integrated intensities were tabulated in Table II with their standard deviations.

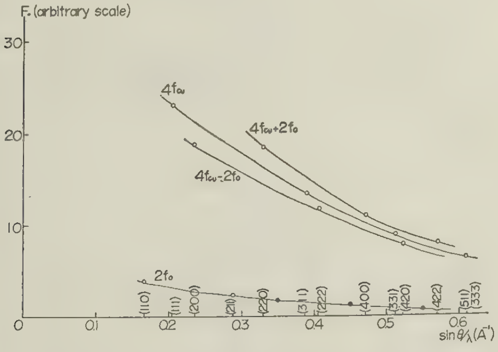

Fig. 2. The crystal structure amplitude F_0 in arbitrary scale, determined from the observed intensity I_0. The open circles are obtained directly from I_0, and the solid circles are deduced from F_0 of the type of $4f_{Cu}\pm2f_0$.

§ 4. Computation Based Upon the Observed Data

(1) *Scattering factors*

The observed structure factor F_0 was determined from I_0 and is shown in Fig. 2. The atomic positions of copper and oxygen in Cu_2O are as follows:

copper: (0, 0, 0,) (0, 1/2, 1/2,) (1/2, 1/2, 0,)
(1/2, 0, 1/2,)
oxygen: (1/4, 1/4, 1/4,) (3/4, 3/4, 3/4,)

and the crystal has cubic symmetry. Therefore, the structure factor for the present crystal consists of the following four combinations of the atomic scattering factors of copper and oxygen: $4f(\text{Cu})$, $2f(\text{O})$ and $4f(\text{Cu})\pm2f(\text{O})$, as is tabulated in the second column of Table II.

The measurements were obtained on a relative scale, and the atomic scattering factor, f, determined from the observed F_0-values must be normalized to the absolute scale. Here, the theoretical value of the atomic scattering factor of oxygen can not be assumed as a standard, since the electron configuration of oxygen atoms in Cu_2O is the present interest and is considered to be quite different according to the models, for example O^{2-} and O^{2+} for the ionic- and the covalent model, respectively. The atomic scattering factor of copper, on the other hand, would be affected not so seriously by its valence electron except in the region of $\sin\theta/\lambda$ smaller than 0.1A^{-1}, because the total electron number of the copper atom is far larger than that of the oxygen atom. The $f_{\text{ob}}(\text{Cu}^+)$ was compared with the theoretical value of the scattering factor $f_{\text{cal}}(\text{Cu}^+)$. The $f_{\text{ob}}(\text{Cu}^+)$ was obtained from F_0-values of (111), (311) and (333)+(511) reflections which were reflected by the atomic plane consisting of copper atoms only.

If the electron distributions around each atom deviate seriously from spherical symmetry, the reflected intensities of (333) and (511) may be different to some extent. The integrated intensities of (333) and (511) were observed to be equal within the experimental error by measurements on single crystals, as will be described in the Appendix. Therefore, the f-values of (333) and (511) were assumed to be equal in the following analysis.

The $f_{\mathrm{cal}}(\mathrm{Cu}^+)$ was taken from the computations of Berghuis et al,[5] and the dispersion effect was corrected by the values of Dauben and Templeton.[6]

The values of $f_{\mathrm{ob}}(\mathrm{Cu}^+)$ and $f_{\mathrm{cal}}(\mathrm{Cu}^+)$ are in the relation

$$f_{\mathrm{ob}}(\mathrm{Cu}^+)=kf_{\mathrm{cal}}(\mathrm{Cu}^+)e^{-M} ,$$

where k is a constant relating to the experimental condition and M is the Debye temperature factor as in §4 (1). Plotting the logarithmic ratio of f_{ob} of f_{cal} against $\sin^2\theta/\lambda^2$ as is shown in Fig. 3, B and k can be determined independently. The scaling constant k was 3.53 and B was 1.40A². The rms amplitude $\sqrt{\overline{u^2}}$ of copper was determined from the value of B to be 0.23 A by the relation described in the last section.

The observed relative f-value of oxygen could now be reduced to the absolute value using the above constant k. The $f_{\mathrm{ob}}(\mathrm{O})$ can be obtained directly from the (110) and (211) reflections and indirectly from structure factors of the type, $4f(\mathrm{Cu})\pm 2f(\mathrm{O})$. The $f_{\mathrm{ob}}(\mathrm{O})$-values are shown in Fig. 4 in absolute scale with the theoretical f-values of O, O^{2-} and O^{2+} computed by Freeman[7] and by the present author.[8] The f-values of the above three electronic states of oxygen differ from one another in the region of $\sin\theta/\lambda$ smaller than about 0.25A⁻¹, since outer electrons contribute mainly to the scattering factor at lower angles. The $f_{\mathrm{ob}}(\mathrm{O})$-value corresponds best to the $f_{\mathrm{cal}}(\mathrm{O}^{2-})$ curve with the appropriate temperature factor for a rms amplitude of 0.29A for oxygen atoms. The $f_{\mathrm{ob}}(\mathrm{O})$ can not be adjusted to the f_{cal}-values of O and O^{2+}, because the normalized f_{ob} is larger than the f_{cal} of O and O^{2+} as seen in Fig. (4).

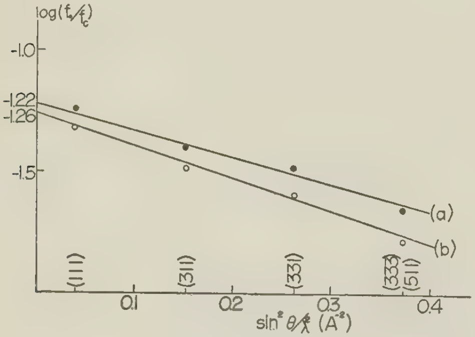

Fig. 3. The plot of $\log(f_0/f_c)$ against to $\sin^2\theta/\lambda^2$. The scaling constant k can be obtained from the section of the $\sin^2\theta/\lambda^2=0$. From the slop of the line, $\overline{u^2}$ can be determined. (a) and (b) refer to the theoretical and experimental f_{Cu}, respectively.

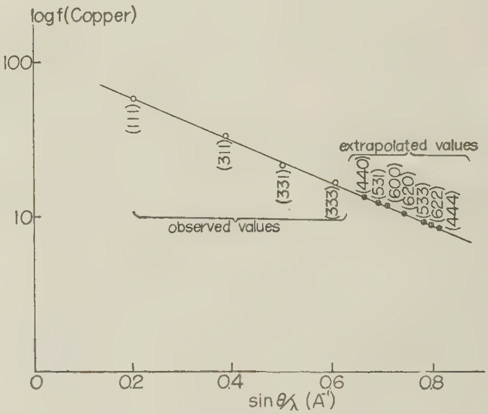

Fig. 5 (a).

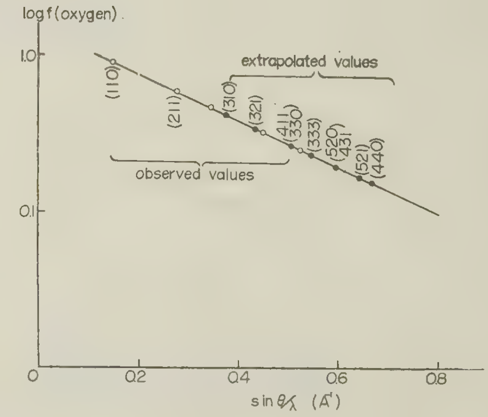

Fig. 5 (b).

Fig. 5. The extrapolation with the exponential approximation of the observed scattering factor to the higher order spectra. (a) for f_{Cu} and (b) for f_{O}.

(2) *Electron distributions*

The electron distributions for the special planes of $(xy0)$, $(xy\frac{1}{4})$ and (xyy) were determined by three dimensional Fourier syntheses. The three dimensional difference Fourier synthesis for the (xyy) plane was also calculated. In order to exclude the termination effect in the synthesis caused by terminating the f_{ob}-values of higher order reflections due to the wave length of the employed radiation, f_{ob}-value was extrapolated after Hartree,[9] to the higher region of $\sin\theta/\lambda$ by an exponential approximation. The logarithmic plot of $f_{\mathrm{ob}}(\mathrm{Cu})$ against $\sin\theta/\lambda$ lies fairly well on a straight line, as shown in Fig. 5(a). The line was extrapolated to about $\sin\theta/\lambda=0.8$, and the f-value of copper was obtained for the reflections from (440) to (444). The f-value of oxygen was also extrapolated by the same method, as is shown in Fig. 5(b). Table III shows the structure factor F_0 of Cu_2O, determined by the observed intensities and the

above extrapolations. The values were normalized to the absolute value by comparing the total sum ΣF_{ob} with ΣF_{cal}. The electron distributions obtained are shown in Fig. 6. The calculation was done by the PC–1 computor of the University of Tokyo.

§ 5. Discussion and Conclusion

(1) *The ambiguity of the scattering factor of copper*

The $f_{\mathrm{cal}}(\mathrm{Cu}^+)$ of Berghuis et al, which was taken as a standard for the absolute scale, is based upon the wave function computed with the self-consistent method including the exchange interaction of electrons[10], and is considered to be quite reliable. However, the estimation of the dispersion correction is, in general, not so reliable.

Brindley[11] and Rusterholz[12] determined the absolute $f(\mathrm{Cu}^+)$ experimentally with Cu $K\alpha$ radiation comparing it with the atomic scattering factor of aluminium. The consequence of taking the above experimental $f(\mathrm{Cu}^+)$, instead of the theoretical $f(\mathrm{Cu}^+)$, as an absolute standard must, therefore, be examined. Both $f(\mathrm{Cu}^+)$-values are shown in Fig. 7. The experimental $f(\mathrm{Cu}^+)$-values of Brindley and Rusterholz are smaller than the theoretical value about 1.5 over the whole observed range. However, the scaling constant, k, referred to the different f-values varies not so much, as is shown in Table IV and Fig. 3,

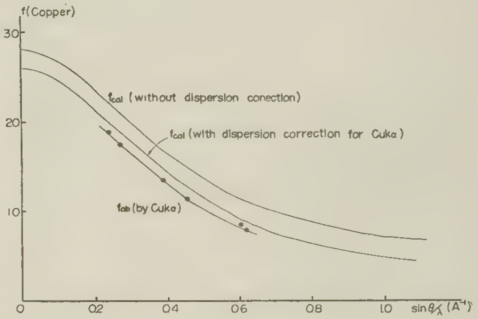

Fig. 7. The scattering factor of copper in absolute scale: without and with the dispersion correction, and the experimental value of Brindley and Rusterholz.

Table IV. (a) The variation of k and $\sqrt{\overline{u^2}}$, and (b) f_{ob}-values for oxygen according to the referred f-value of copper.

	Referred to	
	theoretical vulue	experimental value
k	3.53	3.39
$\sqrt{\overline{u^2}}$	0.23 A	0.21 A

sin θ/λ	hkl	Absolute f_{ob} (0) referred to	
		theoretical value of $f(\mathrm{Cu}^+)$	experimental value of $f(\mathrm{Cu})$
0.16 (A^{-1})	(110)	6.56	6.40
0.28	(211)	4.23	4.07
0.35	interpolated	2.82	2.71
0.45	interpolated	1.59	1.53
0.55	interpolated	1.06	1.02

since there are two adjustable constants k and $\overline{u^2}$. Both the two f_{bo} (oxygen)-values in absolute scale, referred to the different f(Cu), are tabulated in Table IV (b). The difference is appreciable only in the region of smaller $\sin\theta/\lambda$, and is within the experimental error.

(2) *Consideration of the different symmetry for the electron distribution of oxygen*

The f-value of O^{2-}, O and O^{2+}, shown in Fig. 4, were computed with a spherical model for the electron distribution. The electron configuration of O^{2-} is considered to be a neon-like closed shell, and the electron distribution can be safely assumed to be spherically symmetric. However, the electron configuration of O^{2+}, assumed in the co-valent model of Cu_2O, is similar to that of carbon atom in diamond, and the effect of non-sphericity of the electron distribution must be taken into account. McWeeny[13] has computed the scattering factor of a carbon atom in diamond for some particular directions referring to the bonding direction. As can be seen in Fig. 4, the difference between the f-values of the different electron configurations can be recognized only at the (110) reflection in the present case. The scattering direction of the (110) reflection in Cu_2O corresponds to $\hat{S}_3$ of McWeeny's notation. McWeeny's result showed that the f-value of carbon atom in valence- and free-state differs only a little.[*] The difference between the models of spherical and non-spherical electron distribution for O^{2+} may also be assumed to contribute negligibly to the scattering factor. The pure O^{2+} model is, therefore, not adequate for the present case, independently of the difference in symmetry of the electron distribution.

(3) *Electron distribution*

The electron distributions around the copper and oxygen atoms are almost spherically symmetric, as can be seen in the electron density maps of the $(xy0)$ and $(xy\frac{1}{4})$ planes shown in Fig. 6. In the regions between the nearest neighbouring atoms, however, the electron distributions are not zero, but are about 0.5 electrons/A^3, suggesting that the overlapping of the electron distributions of different atoms exists there to some extent.

(4) *Possibility of the deviation from the purely ionic model*

As is discussed in § 5 (2), § 6 (1) and (2), the *purely* co-valent model for the electron configuration of the oxygen atom in Cu_2O is not adequate. Moreover, any model which gives a smaller f-value than f_{ob}(O), can not be adopted. The f_{ob}(O)-value of the (110) reflection lies at about the midpoint between the theoretical f-value of O and O^{2-}. If the electronic state of oxygen atom deviates a little from the purely ionic model, the scattering factor of such an electron configuration might be a little smaller than the f-value of the O^{2-} model and yet larger than f_{ob}(O).

Considering the (100) reflection, the theoretical f(O) value can be brought to fit to the f_{ob}(O)-value with an adequate $\overline{u^2}$. The mean-square amplitude of the thermal lattice vibration of the oxygen atoms was not smaller than that of the copper atoms in the present case, as is described in § 4 (1). So the *possible minimum* f_{cal}(110)-value can be assumed to be 6.65, if the rms amplitude of oxygen atoms is *tentatively* taken as 0.23A, equal to that of copper atoms. The value of 6.65 for f_{cal}(110) corresponds to $O^{1\cdot 85-}$, which is interpolated from the theoretical values of O^{2-} and O.

(5) *Conclusion*

From the above considerations about the atomic scattering factor and the electron distribution, it can be concluded that the oxygen atom in Cu_2O is nearly ionic, but slight deviation from the purely ionic model can not be excluded. The state of $O^{1\cdot 85-}$ is of course an extreme case and the true electronic state of the oxygen atoms in Cu_2O would be between O^{2-} and $O^{1\cdot 85-}$ in its mean value.

The semiconductivity of Cu_2O was investigated by many workers. Dünwald and Wagner[14] studied the electronic conductivity of Cu_2O and concluded that the semiconductivity of Cu_2O should be ascribed to positive holes in the crystal due to excess oxygen atoms. Feldman[15] also supported this result. The comparatively large oxygen ion, however, could not enter interstitially into the crystal. Positive holes of Cu^+ might, therefore, be considered. As a result, one of the O^{2-} ions surrounding the positive hole should be O^{1-} in order to neutralize the electronic charge as a whole. The mean lattice strain of 0.15% in the present sample might be ascribed to the defects of Cu^+, and the possibility of the deviation of oxygen atom from the purely ionic state might correspond to the above consideration.

---

[*] cf. Fig. 4 of McWeeny's paper.[13]

§ 6. Appendix: Measurement on Single Crystals

Measurements on single crystals were performed in order to examine the extinction effect and to obtain the intensity of the (333) and (511) reflection separately, which have the same diffraction angle and can not be separated in the Debye diagram.

Natural single crystals of about 1 mm cube were cracked into small pieces of about 10 ~ 40 microns in diameter. Nearly spherical specimens having about 14, 24 and 48 microns in diameter were selected for the measurement. A small crystal was held by a thin collodion membrane sustained on a small nickel wire ring, and attached on the goniometer head of a Weissenberg camera. A suitable rotation axis, for example, [110] was selected for each specimen, and the sample was oscillated 3 to 4 degrees about the axis through a predetermined scattering angle. The scattered radiation was observed by a scintillation counter instead of photographic films. The collimator for the incident beam was 0.5 mm in diameter and 50 mm in length. The window of the counter was 5mm × 10mm. The counter can be rotated around the sample, having the center of rotation at the sample, so the counter could be always perpendicular to the reflected radiation. The monitoring method was the same as described in § 2 (b). The $K\alpha$ radiations of Mo, Cu, Fe, Co and Cr were used, each with a suitable filter.

An example of the observed integrated intensities was tabulated in Table V(a). Any values which were disturbed by the nickel wire ring were omitted. The variation of the values among the equivalent spectra seems to be due to the absorption effect, since the shape of the samples was not ideally spherical. The observed intensity of the single crystals for various radiations was

Table V (a). An example of the observed intensities of the equivalent reflections from a single crystal. The crystal size was 48 microns in diameter and the radiation of Cu $K\alpha$ was used.

333		60	18	84			

tabulated in Table V(b).

The intensity of (333) is about 5% smaller than that of (511), but the difference is within the range of experimental error, and the intensities of both spectra were assumed to be equal.

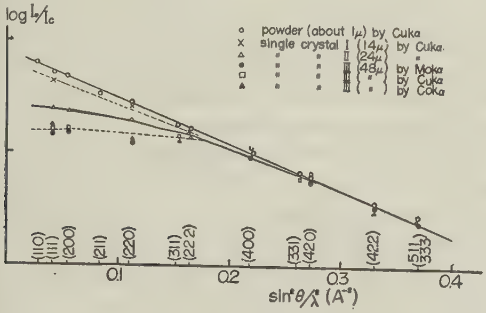

Fig. 8. The plot of log I_0/I_c against to $\sin^2\theta/\lambda^2$. The deviation from the straight line shows the extinction effect.

The logarithms of the ratio of the observed intensity I_0 to the theoretical value I_c were plotted against $\sin^2\theta/\lambda^2$, as shown in Fig. 8. The observed values were corrected with the absorption factor for a spherical crystal according to each μR tabulated in Table V(b). The temperature factor was not included in the theoretical value I_c. The deviation of the plot from a straight line, therefore, implies an extinction effect. It can be concluded that a size of about 15 microns in diameter is not small enough in order to avoid extinction.

Acknowledgement

This work was mainly performed in the Institute for Solid State Physics of the University of Tokyo. The author wishes to express his sincerely thanks to prof. S. Miyake for his kind permission to perform this work in his laboratory. Concerning the use of the PC–1 computor, the author thanks to prof. H. Takahashi, Dr. Marumo and Mr. M. Tokonami.

The author's thanks are due to Mr. T. Sakurai and Mr. S. Togawa for their kind help in the course of the experiment and to profs. S. Miyake, S. Hosoya, Dr. M. Kuriyama and Mr. T. Sakurai for helpful discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 3, MARCH, 1961

A Theory of Electron Impact on Some Polyatomic Molecules

By Tsutomu WATANABE*
Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan

(Received January 23, 1960)

A method by which we can get mass spectral pattern of a polyatomic molecule from the data of appearance potentials of various ions and those of optical measurement has been obtained. It is theoretically expected that the total molecular ionization cross section and relative yields of ions do not so much depend on the incident energy, except the low incident energy region, and that the total cross section does not always rise linearly with the increase of incident energy at a threshold.

Applications to CH_4 and CD_4 have been carried out and the results are in plausible agreement with mass-spectroscopic data. In the course of the application, we have taken two ionized states ($^2A_1$, $^2T_2$) into account and have assumed that the potential energy surfaces of ionized states are not so different from that of the ground state of the parent molecule with respect to almost all normal modes except one or two. It is also theoretically expected that we have a larger abundance of parent ion in the CD_4 case than in the CH_4 case by isotope effect. The experimental data shows the tendency predicted by the theory.

§ 1. Introduction

Recently, the experimental researches of electron impact on molecules have drawn much attention not only from the viewpoint of the mass-spectroscopic analysis, but from that of the study of irradiation effects on molecular compounds. It is difficult for us to know immediately the primary processes in which various ions and radicals are produced during irradiation with high energy radiations. It is, however, possible to investigate these processes by means of the electron impact data. These data offer information on what kinds of metastable products are formed under irradiation and how radiation-chemical processes occur. From these data we may gain various informations about, for example, the possibilities of charge transfer, excitation transfer, ion recombination and radical formation. Especially, the relation between appearance potentials of various ion fragments and their relative yields are important for the kinetics of unimolecular decomposition of parent ion into its daughters.

A few theoretical studies on the problem under consideration have been made. Stevenson[1] derived the ratios of H^+/H_2^+ and D^+/D_2^+ theoretically, neglecting the non-orthogonality between the wave functions of H_2 and H_2^+ and applying the Frank-Condon principle. Further, N_2 and CO_2 were treated in the work by Schaeffer[2] who calculated the ratios of N^+/N_2^+ and C^+/CO_2^+, and their isotope effects. In each of these papers, two mechanisms of bond-rupture were considered, that is, (1) the transition to a repulsive electronic level, for instance $^1\Sigma_g^+(H_2)\rightarrow{}^2\Sigma_u^+(H_2^+)$, (2) the transition to an attractive electronic level with nuclear vibrational energy higher than the dissociation energy, for instance $^1\Sigma_g^+(H_2)\rightarrow{}^2\Sigma_g^+(H_2^+)$. The transition probability of (1) was considered to be smaller than that of (2) because of the approximate similarity of the ground state wave function H_2^+ to one electron MO function of the ground state of H_2. The method of treatment adopted by Stevenson as well as by Schaeffer is not ambiguous in principle for the present problem, but unfortunately it is hardly applicable to the problems involving polyatomic molecules. The difficulties in the case of polyatomic molecules are from (1) the lack of sufficient information on their electronic levels as well as on their wave functions, (2) the occurrence of multi-fold integrals in the calculation of relative yields of various ions, and from (3) the ignorance of the potential energy surfaces in ionized states.

---

* Present address: Japan Atomic Energy Research Institute, Tōkai-Mura, Ibaraki, Japan.

However, there are other approaches to the polyatomic cases. Lennard-Jones and Hall[3] estimated the probability of ionization of each bond in *n*-octane by applying the equivalent orbital method. In a strict sence the assumption adopted in their calculation does not generally correspond to the probability of bond rupture by ionization. To obtain it, one must take into account the potential energy surface in ionized state. Rosenstock *et al*[4] studied the spectrum of various ions produced from C_3H_8. They assumed that an electron in each of the levels is ionized with equal probability and the excess electronic energy is imparted to the ion at the time of electron impact and converted into vibration energy through radiationless transitions. These vibrationally excited parent ions decompose adiabatically by competing and successive unimolecular processes. The statistical assumption is essential in the work by Rosenstock *et al*, and is useful for large molecules. There seems, however, to be an ambiguity in the choice of the parameters appearing in the treatment through the work. In almost all the previous works, it was assumed *a priori* that either only one electronic level needed to be taken into account, or, the cross sections of transition to various ionized electronic levels were equal to one another.

In this paper, firstly, the information on the electronic levels and on their wave functions of molecules is obtained by the equivalent orbital method. Secondly, the general formulation of the calculation for each ion abundance is deduced and the dependence of mass spectrum on incident energy is discussed. Finally, applications to CH_4 and CD_4 are carried out as examples.

The following assumptions and treatments have been made in the course of this work:-

(1) The ionization cross section of molecules is assumed to be expressible in terms of its atomic contributions.

(2) The ionization is always considered to occur vertically upward so as to satisfy the Franck-Condon principle.

(3) The various electronic levels of the parent ion are taken into account.

(4) The dissociation of the parent ion occurs along the path on the potential energy surface in the direction in which the entropy due to the motion of nuclear system increases most rapidly.

§ 2. Theoretical Formulation and General Properties of Molecular Ionization Cross Section

When a polyatomic molecule is impacted and is ionized by electron beams with a wave number k_0, the parent ion dissociates into several daughter ions or ion fragments by unimolecular reaction processes. The parent ion is produced in a considerably higher excited state of nuclear vibration by vertical transition. If electronic levels of the molecule under consideration are well separated, the amount of kinetic energy transferred to nuclear vibration is determined both by nuclear configuration of the ground state and by the potential energy surface of the ionized state. The parent ion will remain stable when the amount of the gained kinetic energy is smaller than the dissociation energy of molecular ion in this state. The ion fragment which appears next to the stable parent ion is produced in the case when ionization energy falls into the value between the appearance potential of this ion fragment and the next higher one, as well as in the case when ionization energy is over the next higher appearance potential and the parent ion decomposes into various ions by competing processes which occur in proportion to the change of internal degree of freedom multiplied by the symmetry number of the path of decomposition from the parent ion to its fragments. Other ion fragments are also produced by the same way. As mass spectra are measured about 10^{-5} sec after the time of electron impact, the nuclear motion with period $\sim 10^{-12}$ sec is well considered to be in a thermal equilibrium.

We assume that a cross section of an electron in a molecular orbital (MO) Q is expressed in terms of atomic cross section of rth atomic orbital (AO) Q_r as

$$Q = A \sum_r a_r^2 \cdot Q_r \tag{2.1}$$

where A is a proportional constant of molecular cross section to atomic one, and a_r is the coefficient of rth AO in MO under consideration[5]. The ionization cross section of an AO which has Z_r electrons with ionization potential E is expressed by Bethe[6] as

Table I[6]. Values of c_m for various electronic states.

Shell	$1s$	$2s$	$2p$	$3s$	$3p$	$3d$	$4s$	$4p$	$4d$
c_m	0.28	0.21	0.13	0.17	0.14	0.07	0.15	0.13	0.09

$$\left.\begin{aligned} Q&=\frac{2\pi me^4c_rZ_r}{\hbar^2k_0{}^2E}\log\left(\frac{2\hbar^2k_0{}^2}{\alpha mE}\right) \\ \text{and}\qquad & \\ c_r&=\frac{Z^2_{\text{eff}}}{n^2a_0{}^2}\iint\psi_r x\psi_\kappa d\tau d\kappa\ . \end{aligned}\right\} \qquad (2.1')$$

Here c_r is calculated by Bethe[6] as shown in Table I where α is a parameter of the order of unity, and meaning of the other quantities are as usual. In the incident energy region $E_0 \leq (\hbar^2/2m)k_0{}^2 \leq 200\,\text{eV}$ where E_0 is the appearance potential of the parent ion (*i.e.* between the value of incident energy corresponding to $Q_r=0$ and that neighbourhood of the maximum of Q_r), Q_r shows fairly good agreement with experiment with the choice of $\alpha=4$. Therefore we take 4 as the value of α.

Let us consider a molecule of which q_i is the ith normal coordinate of nuclear motion (an equilibrium point in the ground state is at the origin of every coordinate, *i.e.* at every $q_i=0$), q_{i0} is the coordinate of an equilibrium point in an ionized state, and λ_i is the force constant of nuclear vibration in the ionized state. The ionization potential of the molecule changes as a function of the nuclear configuration with the energy interval between the ground state and the potential surface of ionized state as

$$E=E_0+\sum_{i=1}^{n}(\lambda_i/2)(q_i-q_{i0})^2 \qquad (2.2)$$

where n is the number of degrees of internal freedom.

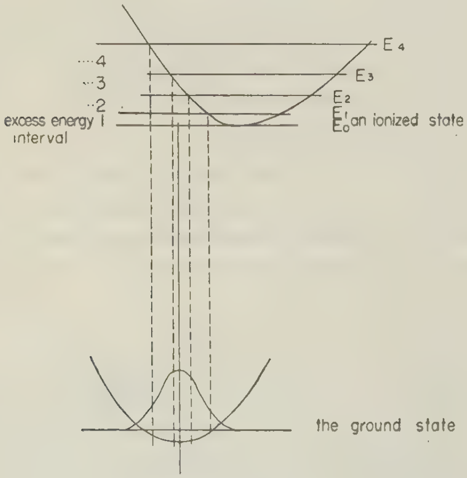

Fig. 1. Schematic figure of the Franck-Condon transion.

The cross sections for the ionizations into the parent ions which have excess energies between E_{l-1} and E_l are determined by the ionization cross section of the molecule not involving the effect of nuclear motion $Q(E)$ and by the ground state probability density $|\Psi_N(q_1, q_2, \cdots, q_{3N})|^2$ of nuclei at any configuration q_i or x_i, y_i, z_i which makes possible the transition into the energy interval $E_0+E_{l-1} \leq E \leq E_0+E_l$ by vertical transition where x_i, y_i, z_i are the Cartesian coordinates and N is the number of nuclei in the molecule. Thus the cross section for the parent ion with excess energy interval between E_{l+1} and E_l $P(E_l, E_{l-1})$ may be given in the form

$$\begin{aligned} P(E_l, E_{l-1})&=\int|\Psi_N|^2Q(E)\prod_{i=1}^{N}dx_idy_idz_i \\ P(E_l, E_{l-1})&=P(E_l, 0)-P(E_{l-1}, 0)\ . \end{aligned} \qquad (2.3)$$

The integration should be made over the whole region of x_i, y_i and z_i of which the nuclear configuration makes possible the transition into the energy interval $E_{l-1}+E_0 \leq E \leq E_l+E_0$, because an ionization energy is a function of x_i, y_i and z_i ($i=1, 2, \cdots, 3N$). We have also the cross section for the total ionization involving the effect of nuclear motion

$$P(\infty, 0)=\int|\Psi_N|^2Q(E)\prod_{i=1}^{N}dx_idy_idz_i \qquad (2.3')$$

where the integration should be made over the whole region of x_i, y_i and z_i. The parent ion with excess internal energy $E-E_0$ ($E_l \leq E-E_0 \leq E_{l+1}$) is considered to decompose into various sets of daughter ions and radical fragments so as to satisfy the condition of energy conservation through the decomposition process. The yield of each set of ion and radical fragments may be in proportion to the number of reaction coordinates along the paths of decomposition from the parent ion into its fragments. The number of reaction coordinates is assumed to be given by $\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l$ where n_ν is the degree of internal freedom of an ion fragment ν, n_μ is that of radical fragment μ, and σ_ν is the symmetry number of decomposition. Thus, the sets may be produced in porportion to the ratio of $\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l$ to its sum over all sets of ν for lth energy internal. Then the relative aboundance of various ion fragment F_ν's is expressed in the form

$$F_\nu=\sum_l \frac{\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l}{\sum_\nu \sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l}\,\frac{P(E_l, E_{l-1})}{P(\infty, 0)} \tag{2.4}$$

where the sum over the excess energy interval l should be taken for all the cases when the decomposition into the ion fragment ν is considered energetically possible[*].

To carry out the integration in (2.3) we introduce new coordinates, namely $X_i=x_i/(m_i)^{1/2}$, $Y_i=y_i/(m_i)^{1/2}$, $Z_i/=z_i/(m_i)^{1/2}$ where m_i is the mass of ith atom.

We can transform the above coordinates to the normal coordinates by a unitary transformation and can separate the coordinates of translation and rotation of the molecules as a whole from the remaining internal coordinates. The Jacobian of transformation X_i, Y_i, Z_i to q_i is 1 because of its unitarity. Then we have

$$P(E_l, 0)=\prod_{i=1}^{N} \sqrt{m_i}^3 \int\cdots\int |\psi_N(q_{n+1}, \cdots, q_{3N})|^2 \prod_{j=n+1}^{3N} dq_j$$
$$\times\int\cdots\int_{E=0}^{E=E_l} |\psi_N(q_1, q_2, \cdots, q_n)|^2 Q(E) \prod_{i=1}^{n} dq_i \tag{2.5}$$

where $n=3N-6$ for nonlinear molecules, and $n=3N-5$ for linear molecules. We see by (2.5) that the absolute $P(E_l, 0)$ can depend on the states of molecular translation and rotation and therefore on experimental conditions. However the ratio of $P(E_l, 0)/P(\infty, 0)$ does not depend on these conditions. At room temperature we may consider that all the vibrational modes are in the ground states, so that ψ_N is expressed as follows:

$$\psi_N(q_i)=\prod_{i=1}^{n}\frac{1}{N^2}\exp\left(-\sum\frac{\alpha_i}{2}q_i^2\right) \qquad \text{for} \quad 1\leq i\leq n$$
$$\alpha_i=\nu_i/h \qquad N=\sqrt{\frac{\alpha_i}{\sqrt{\pi}}} \tag{2.6}$$

and

$$\psi_N(q_j)=(\text{rotational wave function})\times(\text{translational wave function}) \qquad \text{for} \quad n+1\leq j\leq 3N$$

where ν_i is the frequency of each normal vibrations of nuclei which is obtained from the

---

[*] To illustrate the matter more clearly, we take the case of CH_4^+ as example. According to the experimental data we separate the excess energies into the following intervals $E_0=13.12$ eV, $E_1=1.27$ eV and $E_2=2.28$ eV for ${}^2T_2$ state, and $E_0=19.42$ eV, $E_1=0.68$ eV, $E_2=3.68$ eV and $E_3=7.38$ eV for ${}^2A_1$ state (see Fig. 5a and 5b). Consider the case when $l=2$ for ${}^2T_2$ state, *i.e.* when the parent ion gains its excess internal energy between 1.27 and 2.28 eV, and two ways of decomposition $CH_4 \rightarrow CH_3+H$ and $\rightarrow CH_2+H_2$ are considered to be energetically possible. In the former reaction $n=9$, $n_\nu=6$, $n_\mu=0$ and $\sigma_\nu={}_4C_1$ because σ_ν is the number of ways of choosing one H atom from CH_4^+. In the latter reaction $n_\nu=3$, $n_\mu=1$ and $\sigma_\nu={}_4C_2$,. *ie.* the number of ways of choosing two H atoms from CH_4^+. In this case $\sum_\nu \sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_2=42$ and $\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_2=12$ for $CH_3^+ + H$, and $=30$ for CH_2+H_2. In order to obtain the relative yield of CH_2^+ from CH_4^+ parent ion with every excess internal energy, one should take account of the two reactions of decomposition $CH_4^+ \rightarrow CH_2^+ + H_2$ and $CH_2^+ \rightarrow 2H^+$. In the former reaction $l=3$ for ${}^2T_2$ state and $l=1, 2, 3, 4$ for ${}^2A_1$ state should be taken into account (see Fig. 5b). For each energy interval between 1 and $l-1$ the quantity

$$\frac{\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l}{\sum_\nu \sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l}\,\frac{P(E_l, E_{l-1})}{P(\infty, 0)}$$

is estimated, one take the sum of it over l and then one can obtain the relative yield of CH_2^+ fragment.

data of Raman and infra-red spectra.

The information about potential surfaces of ionized states has not been obtained experimentally, in most cases, so we do not know the values of λ_i and q_{i0}. But it may properly be said that for the molecule of which the data of Raman and infra-red spectra are well explained by the calculation based on the valence force field picture, the vibrations of nuclei are mainly determined by the valence forces and are almost independent of the contributions of the repulsive interactions between cores which are not directly bonded by chemical valences with each other. The potential energy surface of an ionized state may be obtained by the same procedure as in the case of the ground state, and the change by ionization in the valence force between every couple of atoms is considered to resemble to the case of diatomic molecules.

In some diatomic molecules there are not so large change in the vibrational frequencies and in the internuclear distances by ionization of an electron in a nonbonding orbital, as illustrated in Table II[7]. We assume that the frequencies and the internuclear distances are approximately the same with those of the ground state for almost all the vibrational modes if measured data of vibrational frequencies can be well explained by the calculation based on the valence force field picture. We take the changes of vibrational frequencies and equilibrium points into account only of the modes which may be very different from those of the ground state from the viewpoint of the symmetry of total electronic wave function in the ionized state. The effect of these changes may be important in the case of a molecule in which the stable atomic configuration in the ionized state is quite different from that of the ground state (for example, NH_3 and H_2O).

Table II[7]. Vibration frequencies and internuclear distances of diatomic molecules and molecular ions.

Molecule	Distance (in Å)	Frequency (in cm⁻¹)	Ion	Distance (in Å)	Frequency (in cm⁻¹)

HBr	1.413	2649	HBr^+	1.459	
HCl^{35}	1.2764	2989.7	$(HCl^{35})^+$	1.3153	2675
DCl^{35}	1.2749	2090	$(DCl^{35})^+$	1.3153	1863

We now rewrite (2.5) with the aid of (2.6) as

$$P(E_i, 0)=B\int_{E-E_0}^{E-E_0+E_i} \exp\left(-\sum_{i=1}^{n} \alpha_i q_i^2\right) Q\left(E_0+\sum_{i=1}^{n} \frac{\lambda_i}{2} q_i^2\right) \prod_{i=1}^{n} dq_i$$

$$B=\left(\prod_{i=1}^{n} \sqrt{m_i^3}\right)\left(\prod_{i=1}^{N} \sqrt{\frac{\alpha_i}{\sqrt{\pi}}}\right)\int\cdots\int |\text{rot. wave function}|^2 \qquad (2.7)$$

$$\times\, |\text{trans. wave function}|^2 \times \prod_{j=n+1}^{3N} dq_i\,.$$

Here we have neglected the change in the equilibrium configuration by ionization, *i.e.* we have assumed $q_{i0}=0$ for all i. Let the variable ξ_i be taken in the place of q_i, namely

$$\xi_i=\left(\frac{\lambda_i}{2E_l}\right)q_i^2\,,\quad \beta_i=\beta_0-\frac{2E_l}{\lambda_i}\,,\quad \beta_0=\frac{1}{n}\left(\sum_{i=1}^{n}\frac{2E_l}{\lambda_i}\alpha_i\right),\quad \lambda_i=4\pi^2\nu_i^2\,. \tag{2.8}$$

The function $\exp(\sum_i \beta_i\xi_i)$ is expanded in power series ξ_i and the integration in (2.7) is to be carried out over any value of ξ_i under the condition of $\sum_{i=1}^{n}\beta_i\leq 1$.

The integration in (2.7) can be reduced to a single integral by means of the Dirichlet's integral[8]. In order to make the expression of the result of integration not depend on E_l, we may rewrite the result in terms of y instead of ξ where $y=\beta_0\xi$. Making use of $\sum_{i=1}^{n}\beta_i=0$, we have

$$P(E_l,0)=B\prod_{i=1}^{n}\left(\frac{E_l}{2\lambda_i}\right)^{1/2}\frac{\{\Gamma(\frac{1}{2})\}^n}{\Gamma(\frac{1}{2}n)}\int_0^{\beta_0}\exp(-y)Q\left(\frac{E_l y}{\beta_0}\right)F(y)y^{(n/2)-1}\,dy \tag{2.9}$$

and

$$F(y)=1+\frac{1}{n(n+1)}\sum_{i=1}^{n}\left(\frac{\beta_i}{\beta_0}\right)^2 y^2+\frac{4}{3n(n+2)(n+4)}\sum_{i=1}^{n}\left(\frac{\beta_i}{\beta_0}\right)^3 y^3$$
$$+\frac{1}{n(n+2)(n+4)(n+6)}\left[\frac{1}{2}\left\{\sum_{i=1}^{n}\left(\frac{\beta_i}{\beta_0}\right)^2\right\}^2+\frac{5}{2}\left\{\sum_{i=1}^{n}\left(\frac{\beta_i}{\beta_0}\right)^4\right\}\right]y^4+\cdots \tag{2.10}$$

One finds the integrand in (2.9) does not depend on E_l because y and the argument in Q do not include E_l, but that the integration depends on E_l through the upper limit of the integration β_0. Then, we can obtain any $P(E_l,0)$ from the same integrand $\exp(-y)Q(E_l y/\beta_0)\times F(y)y^{(n/2)-1}$ by taking $\beta_0=(2E_l/n)(\sum_{i=1}^{n}\alpha_i/\lambda_i)$ for the upper limit in integration over y. Thus we may obtain $P(E_l, E_{l-1})$ by taking $(2E_{l-1}/n)(\sum_{i=1}^{n}\alpha_i/\lambda_i)$ for the lower limit and $(2E_l/n)(\sum_{i=1}^{n}\alpha_i/\lambda_i)$ for the upper limit of the integration in (2.9). If $\sum_i(\beta_i/\beta_0)^2<1$ (in ordinary molecules $\langle(\beta_i/\beta_0)^2\rangle\sim 1/10$) the magnitude of higher power terms in (2.10) is negligible as compared with lower power term (see Appendix A).

Next we consider the case where the equilibrium points in normal coordinates change only in one mode or two. In the case of $q_{i0}\neq 0$ in (2.2), we transform variable q_i to ξ_i by the following relations:

$$\frac{\lambda_i}{2E_l}(q_i-q_{i0})^2=\xi$$

and

$$\exp(-\alpha_i q_i^2)=\exp\left(-\alpha_i\frac{2E_l}{\lambda_i}\xi_i\pm 2\alpha_i q_{i0}\frac{2E_l}{\lambda_i}\xi_i-\alpha_i q_{i0}^2\right) \tag{2.11}$$

in (2.7) where $\pm$ is taken as $q_i-q_{i0}\gtrless 0$. If $\alpha_i q_{i0}^2\ll 1$, $\exp(-2\alpha_i q_{i0}(2E_l\xi_i/\lambda_i)^{1/2})$ can be expanded in power series and treated by the same method as before. It is very complicated when $\alpha_i q_{i0}^2>1$ and is necessary to adopt another approximation. We can express the factor $\exp(-\alpha_i q_i^2)$ in terms of y by the method as shown in Appendix B. Thus we can transform $\exp(-\alpha_i q_i^2)$ into $\exp(-y)F(y)$, but in this case $F(y)$ is not always a slowly varying function of y.

As $Q(\xi)$ is a slowly varying function of ξ, for $\hbar^2k_0^2/2m>2E_0$, the dependence of $F_\nu\cdot P(\infty)$ of an ion fragment on k_0^2 are given by

$$E_\nu\cdot p(\infty,0)=\sum\frac{\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l}{\sum_\nu\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l}P(E_l,E_{l-1})$$
$$\propto Q(K_0^2)\propto A\cdot\log(CK_0^2)/K_0^2 \tag{2.12}$$

where $C=(\hbar^2/2mE)$. The relation between $P(\infty,0)$ or $F_\nu\cdot P(\infty,0)$ and incident energy is similar to that between the cross section of an atom and the incident energy. The general view of k_0^2 dependence of experimental $F_\nu \cdot P(\infty, 0)$ in the case of C_2H_2 is illustrated in Fig. 2[9], showing plausible agreement with tendency predicted by the theory.

The relative ratio of each ion fragment to the total ionization is expressed as

$$F_\nu = \sum_l \frac{\sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l \int_0^{\beta_0} e^{-y} F(y) y^{(n/2)-1} dy \left(1+\frac{\text{Const.}}{k_0^2-2mE_0/\hbar^2}\right)}{\sum_\nu \sigma_\nu(n-n_\nu-\sum_\mu n_\mu)_l \int_0^{\infty} e^{-y} F(y) y^{(n/2)-1} dy \left(1+\frac{\text{Const.}}{k_0^2-2mE_0/\hbar^2}\right)} \tag{2.13}$$

for high incident energy, namely F_ν is regarded as little dependent on the incident energy $\hbar^2k_0^2/2m$. In the case of CH_4 experimental data of relative abundances to the parent ion as functions of the incident energy are shown in Fig. 3[10] which give plausible agreement with theory.

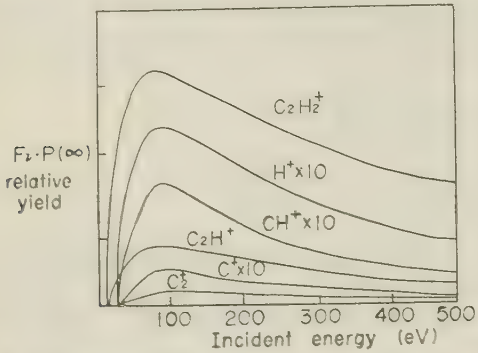

Fig. 2. Dependency of each ion fragment yield on incident energy[9].

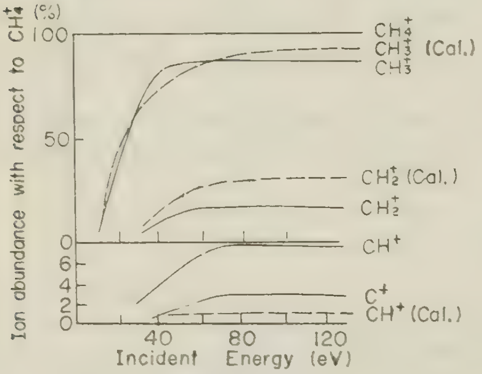

Fig. 3.[10] Energy dependency of each ion abundance with respect to CH_4^+.

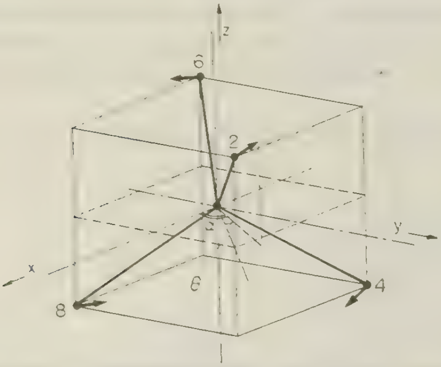

Fig. 4. ν_2 vibration mode and angle α and θ.

In the low incident energy region, the approximation for obtaining the cross section $Q(E, k_0^2)$ in (2.1′) can not be adoptable, and also its additivity of atomic components may not be valid. However, $Q(E, k_0^2)$ may well be given by Const.$\times(2m/\hbar^2k_0^2E)\log(\hbar^2k_0^2/2mE)$ because the general behaviour of the total ionization of molecules is shown experimentally to be resemble the cross section for ionization of atoms. When the incident energy $\hbar^2k_0^2/2m$ lies between E_0+E_{l-1} and E_0+E_l, the parent ion can gain its internal energies only below $\{(\hbar^2k_0^2/2m)-E_0\}$ according to energy conservation.

In the region of $E_0+E_{l-1}<\hbar^2k_0^2/2m<E_0+E_l$ one must take $\{(\hbar^2k_0^2/2m)-E_0\}(\sum_{i=1}^{\mu} \alpha_i/n\lambda_i)$ for the upper limit of integral of (2.9). Therefore, in the low energy region the dependencies of ion currents on incident energy near the threshold of appearance potential are obtained as

$$F_\nu = \frac{P(\gamma, \beta_0(l))}{P(\gamma, 0)} \tag{2.14}$$

where

$$P(\gamma, \beta_0(l)) = \int_{\beta_0(l-1)}^{\gamma} e^{-y} Q\left(\frac{E_l y}{\beta_0(l)}\right) F(y) y^{(n/2)-1} dy$$

$$\gamma = \frac{\Delta E}{n} \sum_{i=1}^{n} \left(\frac{\alpha_i}{\lambda_i}\right), \qquad \Delta E = \frac{\hbar^2k_0^2}{2m} - E_0 \,.$$

Considering that Q for ionization of molecules resembles that for ionization of atoms, $Q(E_l \cdot y/\beta_0(l))$ is given in the form Const. $\times(\log\gamma-\log y)$. When $(\hbar^2k_0^2/2m-E_0)$ is small, the total ion currents $\propto P(\gamma, 0) \propto \Delta E^{(n/2)+2}$, and when $\hbar^2k_0^2/2m$ is a little over E_l, $E_\nu(P(\gamma, \beta_0(l)) \propto (\Delta E-E_l)$ where the suffix ν in F_ν refers to the ion fragment which newly appears at E_l.

Wannier[11] has shown that the ionization yield (cross section) rises at the 1–1.27th power of the energy in excess of the threshold energy for atoms ($Q \propto \Delta E \sim \Delta E^{1.127}$). On the contrary, for molecules, it is expected that the ionization yields do not always rise linearly but can rise at higher power on account of the internal vibration of nucleus. Experimental data are expected to show a tendency that the total ionization rises at the higher power in the more complex molecules, but we have not yet confirmed that the experimental data have a tendency accounted for this effect.

§ 3. Application to CH_4 and CD_4

3.1. *Electronic States of CH_4*

The electronic levels of CH_4^+ have been found by Frost and Mcdowell[12] as shown in Fig. 5a and Table III. We ignore the ionization of electrons in the level of 1st orbital of C atom. $^2A_1$ is the electronic state where an electron in nondegenerate (except spin degeneracy) a_1 orbital is ionized. This state is totally symmetric with respect to all symmetry operations which belong to the point group T_d. $^2T_2$ is the state where an electron in triply degenerate t_2 orbital is ionized. This state has symmetry with respect to three planes of symmetry σ_d and is symmetric with respect to the two planes of symmetry σ_d and antisymmetric with respect to the other plane σ_d. We construct LCAOMO's for a_1 and t_2 from AO's, *i.e.*, the wave function of C2*s* orbital ψ_{2s}, those of C2*px*, C2*py*, C2*pz* orbitals ψ_{2px}, ψ_{2py}, ψ_{2pz}, and those of *i*th H1*s* orbital $\psi_{i(1s)}$ where the orientation *x*, *y*, *z* and the labelled number of H are shown in Fig. 4. The MO wave function of electron in each electronic level are expressed as in the following formula[13]

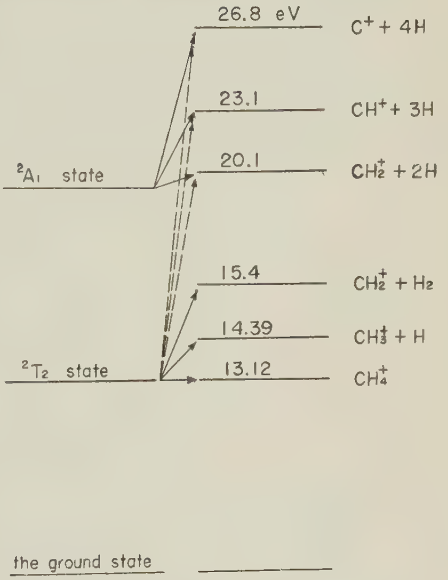

Fig. 5b. Energy diagram of CH_4 and of various ions from CH_4.

$$\left.\begin{aligned} \psi_s &= \frac{1}{\sqrt{N}}\left\{\lambda\psi_{2s} + \frac{1}{2}(\psi_{2(1s)} + \psi_{4(1s)} + \psi_{6(1s)} + \psi_{8(1s)})\right\} && \text{for } a_1 \text{ state} \\ \psi_x &= \frac{1}{\sqrt{N}}\left\{\lambda\psi_{2px} + \frac{1}{2}(\psi_{2(1s)} - \psi_{4(1s)} - \psi_{6(1s}+)\psi_{8(1s)})\right\} && \\ \psi_y &= \frac{1}{\sqrt{N}}\left\{\lambda\psi_{2py} + \frac{1}{2}(\psi_{2(1s)} - \psi_{4(1s)} + \psi_{6(1s)} - \psi_{8(1s)})\right\} && \text{for } t_2 \text{ state} \\ \psi_z &= \frac{1}{\sqrt{N}}\left\{\lambda\psi_{2pz} + \frac{1}{2}(\psi_{2(1s)} + \psi_{4(1s)} - \psi_{6(1s)} - \psi_{8(1s)})\right\} && \end{aligned}\right\} \qquad (3.1)$$

and λ is obtained from the dipole moment μ of C–H bond by the equation[14]

$$\mu = \frac{(\lambda^2 - 1)eR}{1 + \lambda^2 + 2\lambda S}$$

where R is internuclear distance, the value of λ is 1.15, $N=1+\lambda^2+2\lambda S$, and $S=\frac{1}{2}$. The appearance potentials of various ions from CH_4 are shown in Table IV[15]. A schematic diagram of energy states of ion is illustrated in Fig. 5b, and possible dissociation processes are indicated with arrows.

3.2. *Potential Energy Surfaces of Ionized States*

In $^2A_1$ state the symmetry property of the total wave function is the same with that of the neutral ground state (totally symmetric). Moreover, for the CH_4 molecule the vibration spectra of a CH_4 molecule are well explained by the valence force field picture and the contribution of H–H interaction to the potentical surface is considered to be small. Taking into account these features, one may properly consider that the potential energy curve only along the coordinate of ν_1 vibration mode changes by a transition from the ground state to $^2A_1$ state. Further we have assumed that the equilibrium point for $^2A_1$ state is the same with that for the neutral ground state, and also that the force constant for $^2A_1$ state $\lambda_1(^2A_1)$ becomes the value which is obtained by the force constant for the ground state λ_1(ground) multiplied by a ratio of the total binding energy for $^2A_1$ state $V_0(^2A_1)$ to that of the ground state V_0(ground), *i.e.* $\lambda_1(^2A_1)=\{V_0(^2A_1)/V_0(\text{ground})\}\times\lambda_1(\text{ground})$.

In $^2T_2$ state, however, the symmetry property of total wave function is not the same with that of the neutral ground state. One may expect that the atomic configuration in equilibrium is different from that of the ground state to some extent. Now let us consider the case when the electron in one of t_2 orbital that has a same symmetry of φ_{2pz} is ionized. It can easily be expected that the bond angles of H_2–C–H_8 and H_4–C–H_6 become larger (Fig. 4), and of all vibrations the ν_{2a} frequency is considered to render the most remarkable change. To estimate this increased value of the bond angles *i.e.* q_{i0} of the coordinate of ν_{2a} mode in (2.2), we calculate emprically the contribution of ionization of electron in t_2 orbital to the bond angle by the following procedure: (1) The binding energy and vibrational potentials along some normal coordinate of the ground state are expressed in terms of molecular integrals. (2) The binding energies in $^2A_1$ and $^2T_2$ state are also expressed in terms of molecular integrals. (3) The expressions for force constant and for the change of equilibrium point along ν_{2a} vibrational mode in $^2T_2$ are obtained in terms of the same molecular integrals. If V be the potential energy of molecular vibration, it may be expanded along a normal coordinate in a state near $q_i=0$ as

$$V=V_0+\lambda_i' q_i+\frac{\lambda_i}{2}q_i^2\ .$$

Through above procedure we obtain the expressions for V_0, λ_i', λ_i in terms of molecular integrals relating to some normal modes in each state.

To carry out above estimation, the wave functions φ_{2px}, φ_{2py}, φ_{2pz} are transformed by the vector model into their components of the bonds C–H_2, C–H_4, C–H_6 and C–H_8 *i.e.*, $\varphi_{1\sigma}$, $\varphi_{1\pi}$, $\varphi_{1\bar\pi}$: $\varphi_{3\sigma}$, $\varphi_{3\pi}$, $\varphi_{3\bar\pi}$: $\varphi_{5\sigma}$, $\varphi_{5\pi}$, $\varphi_{5\bar\pi}$ and $\varphi_{7\sigma}$, $\varphi_{7\pi}$, $\varphi_{7\bar\pi}$, respectively where we mean by $\varphi_{1\pi}$ one of π component of a C2p orbital with respect to C–H_2 bond and by $\varphi_{1\bar\pi}$ the other π component of a C2p orbital with respect to C–H_2 bond, and so on. Then we have

$$\varphi_{2px}=\frac{\cos\alpha}{\sqrt{1+\sin^2\alpha}}\varphi_{1\sigma}+\frac{2\sin\alpha}{\sqrt{1+\sin^2\alpha}}\varphi_{1\pi}$$

$$\varphi_{2py}=\frac{\sin\alpha}{\sqrt{1+\sin^2\alpha}}\varphi_{1\sigma}+\frac{1}{\sqrt{1+\sin^2\alpha}}\left(\frac{1}{\sqrt{2}}\cos\alpha\cdot\varphi_{1\pi}+\frac{1}{\sqrt{2}}\sqrt{1+\sin^2\alpha}\,\varphi_{1\bar\pi}\right)$$

$$\begin{aligned}
\psi_{2pz}&=\frac{\sin\alpha}{\sqrt{1+\sin^2\alpha}}\psi_{1\sigma}+\frac{1}{\sqrt{1+\sin^2\alpha}}\left(\frac{1}{\sqrt{2}}\cos\alpha\cdot\psi_{1\pi}-\frac{1}{\sqrt{2}}\sqrt{1+\sin^2\alpha}\,\psi_{1\bar{\pi}}\right)\\
\psi_{2px}&=-\frac{\cos\alpha}{\sqrt{1+\sin^2\alpha}}\psi_{3\sigma}-\frac{2\sin\alpha}{\sqrt{1+\sin^2\alpha}}\psi_{3\pi}\\
\psi_{2py}&=-\frac{\sin\alpha}{\sqrt{1+\sin^2\alpha}}\psi_{3\sigma}-\frac{1}{\sqrt{1+\sin^2\alpha}}\left(-\frac{1}{\sqrt{2}}\cos\alpha\cdot\psi_{3\pi}-\frac{1}{\sqrt{2}}\sqrt{1+\sin^2\alpha}\,\psi_{s\bar{\pi}}\right)\\
\psi_{2pz}&=\frac{\sin\alpha}{\sqrt{1+\sin^2\alpha}}\psi_{3\sigma}+\frac{1}{\sqrt{1+\sin^2\alpha}}\left(-\frac{1}{\sqrt{2}}\cos\alpha\cdot\psi_{3\pi}+\frac{1}{\sqrt{2}}\sqrt{1+\sin^2\alpha}\,\psi_{3\bar{\pi}}\right)
\end{aligned}\tag{3.2}$$

and similar expression for $\psi_{2p\text{'s}}$ in terms of $\psi_{5\sigma}$, $\psi_{5\pi}$, $\psi_{5\bar{\pi}}$ and $\psi_{7\sigma}$, $\psi_{7\pi}$, $\psi_{7\bar{\pi}}$ where α is the angle as shown in Fig. 4. The bond eigen-functions of C atom are

$$\begin{aligned}
\psi_{c1}&=\frac{1}{2}(\psi_{2s}+\psi_{2px}+\psi_{2py}+\psi_{2pz})\\
\psi_{c3}&=\frac{1}{2}(\psi_{2s}-\psi_{2px}-\psi_{2py}+\psi_{2pz})\\
\psi_{c5}&=\frac{1}{2}(\psi_{2s}-\psi_{2px}+\psi_{2py}-\psi_{2pz})\\
\psi_{c7}&=\frac{1}{2}(\psi_{2s}+\psi_{2px}-\psi_{2py}-\psi_{2pz})\ .
\end{aligned}\tag{3.3}$$

Then the Coulomb integral Q and the exchange integral J of bond eigen-function between C_1 and H_2 atomic orbitals are given by the following formula:

$$\begin{aligned}
Q(1,2)&=\frac{1}{4}\left[Q_{ss}+Q_{\sigma\sigma}+Q_{\pi\pi}+Q_{\bar{\pi}\bar{\pi}}+\frac{1}{\sqrt{1+\sin^2\alpha}}(2\cos\alpha+4\sin\alpha)Q_{s\sigma}\right]\\
J(1,2)&=\frac{1}{4}\left[J_{ss}+J_{\sigma\sigma}+J_{\pi\pi}+J_{\bar{\pi}\bar{\pi}}+\frac{1}{\sqrt{1+\sin^2\alpha}}(\cos\alpha+2\sin\alpha)(J_{s\sigma}+J_{\sigma s})\right]\ .
\end{aligned}\tag{3.4}$$

In the above expression each integral Q_{ss}, $Q_{\sigma\sigma}$, J_{ss} *etc.*, is defined as

$$\begin{aligned}
Q_{ss}&=\int\psi_s(1)\psi_h(2)\boldsymbol{H}\psi_s(1)\psi_h(2)d\tau_1d\tau_2\\
Q_{\sigma\sigma}&=\int\psi_\sigma(1)\psi_h(2)\boldsymbol{H}\psi_\sigma(1)\psi_h(2)d\tau_1d\tau_2\\
J_{ss}&=\int\psi_s(1)\psi_h(2)\boldsymbol{H}\psi_\sigma(1)\psi_h(2)d\tau_1d\tau_2\\
&\cdots\cdots\cdots\\
\boldsymbol{H}&=\boldsymbol{H}_{\text{total}}-\boldsymbol{H}_{\text{C}}-\sum_{i=1}^{4}\boldsymbol{H}_{\text{Hi}}
\end{aligned}$$

where $\boldsymbol{H}_{\text{total}}$ is the total Hamiltonian of molecule CH_4, $\boldsymbol{H}_{\text{C}}$ is the Hamiltonian of atom C, and $\boldsymbol{H}_{\text{Hi}}$ is that of ith H. The same treatment is carried out in calculating $Q(1,4)$, $Q(1,6)$, $Q(1,8)$, $Q(2,4)$, $\cdots$ and also $J(1,4)$, $\cdots$, that is, $Q(i,j)$ and $J(i,j)$ with all possible combination of i and j.

And we take summations of Q and J according to the following rule

$$V=\sum Q+\sum_a J-\frac{1}{2}\sum_g J+\sum V_{hh}\tag{3.5}$$

where the summation a is taken over the bonding orbitals only, and the summation b is taken over the non-bonding orbitals only. V_{hh} is the interaction potential of H–H, *i.e.*

$$V_{hh}=\frac{1}{4}D_0[\exp\{-2\beta(R-R_e)\}-2\exp\{-\beta(R-R_e)\}]+\frac{3}{4}A_0e^{-2R}R^{-4/3} \tag{3.6}$$

with $D_0=4.747\,\mathrm{eV}$, $\beta=2.0522\,\mathrm{a}_0^{-1}$, $R_e=1.4016\,\mathrm{a}_0$, $A_0=15.159\,\mathrm{eV}$ and $\alpha=0.357\,\mathrm{a}_0^{-1}$ which are derived from the spectroscopic data[7] and from Hirschfelder and Linnett's[16] calculation. We consider the variation for V with the normal coordinate along ν_{2a} vibration mode and put $\alpha=(\pi/4)+\theta$ in Fig. 4 where $\theta\ll 1$. V is expanded in power series of θ, and then one finds that the term of first power vanishes. From the zeroth power term, we obtain V_0, *i.e.* the total binding energy, and from the second power term we obtain also the potential curvature along the normal coordinate of vibration ν_{2a}, $V_{\theta 2}$. Then we have the potential curve along ν_{2a} vibrationed mode in the form

$$\left.\begin{aligned}
&V=V_0+\frac{1}{2}V_{\theta 2}\\
&V_0=\left(4Q_{ss}-\frac{1}{2}J_{ss}\right)+\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+2\left(4Q_{\pi\pi}-\frac{1}{2}J_{\pi\pi}\right)+\frac{3\sqrt{3}}{8}(J_{s\sigma}+J_{\sigma s})+6V_{hh}\\
&\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\text{for the ground state}\\
&\text{and along } \nu_1 \text{ vibrational mode we also have}\\
&V_{\theta 2}=16\pi^2\nu_2^2c^2m_{\mathrm{H}}R_0^2=-\frac{1}{2\sqrt{3}}(J_{s\sigma}+J_{\sigma s})-\frac{8\sqrt{2}}{3\sqrt{3}}\left(\frac{\partial V_{hh}}{\partial R}\right)R_0+\frac{16}{9}\left(\frac{1}{2}\,\frac{\partial^2 V_{hh}}{\partial R^2}\right)R_0^2\\
&\qquad\qquad(\nu_2\text{ is measured in cm}^{-1})\qquad\qquad\text{for the ground state}
\end{aligned}\right\} \tag{3.7}$$

where m_{H} is the mass of H atom and R_0 is the internuclear distance of C–H in equilibrium.

For ν_1 mode we can easily obtain the following formula by making use of the totally symmetric property, as

$$16\pi^2c^2\nu_1^2m_{\mathrm{H}}R_0^2=\left(\frac{1}{2}\,\frac{\partial^2 V}{\partial R^2}\right)_0R_0^2. \tag{3.8}$$

Since the normal coordinate along ν_3 and ν_4 modes depend both on the mass ratio of C to H, and on its geometrical scheme, each normal coordinate component of bond angle and C–H distance changes can not be obtained easily. However, assuming the valence force field picture, we can acquire relations between the force constants for ν_1, ν_2 and those for ν_3, ν_4, and find them to be in good agreement with the experimental data of Raman and infra-red spectra[17]. So we may expect that the values of molecular integrals which are obtained from the data of ν_1 and ν_2 will be nearly equal to those estimated from ν_3 and ν_4 according to a valence force field picture.

By the same procedure as described above, along ν_2 mode in $^2\mathrm{T}_2$ state is obtained as

$$\begin{aligned}
&V=V_0+V_{\theta 1}\cdot\theta+\frac{1}{2}V_{\theta 2}\theta^2\\
&V_0=\left(4\theta_{ss}-\frac{1}{2}J_{ss}\right)+\frac{5}{6}\left(4\theta_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+\frac{10}{6}\left(4\theta_{\pi\pi}-\frac{1}{2}J_{\pi\pi}\right)\\
&\qquad+\frac{\sqrt{3}}{2}\left(3-\sqrt{\frac{1}{2}}\right)(J_{s\sigma}+J_{\sigma s})+\frac{21}{4}V_{hh}\\
&V_{\theta 1}=\frac{4}{9}\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)-\frac{4}{9}\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+\sqrt{\frac{2}{3}}(J_{s\sigma}+J_{\sigma s})\\
&V_{\theta 2}=\frac{4}{27}\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+\frac{16}{27}\left(4Q_{\pi\pi}-\frac{1}{2}J_{\pi\pi}\right)-\frac{\sqrt{3}}{2}\left(\frac{1}{3}+\frac{1}{\sqrt{2}}\right)(J_{s\sigma}+J_{\sigma s})\\
&\qquad+\frac{7}{4}\sqrt{\frac{2}{3}}\left(\frac{\partial V_{hh}}{\partial R}\right)R_0+\frac{8}{3}\left(\frac{1}{2}\,\frac{\partial^2 V_{hh}}{\partial R^2}\right)R_0^2
\end{aligned} \tag{3.9}$$

In calculation for the above expression, we made an assumption that when an electron is ionized from a given orbital Q, J and V_{hh} become the value of $(N-1)/N$ times the initial values, where N is the total number of electrons in the orbital.

For ${}^2A_1$ state we can calculate V_0 by the same way into the form

$$V_0=\frac{1}{2}\left(4Q_{ss}-\frac{1}{2}J_{ss}\right)+\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+2\left(4Q_{\pi\pi}-\frac{1}{2}J_{\pi\pi}\right)+\frac{3}{2}\sqrt{\frac{3}{2}}(J_{s\sigma}+J_{\sigma s})+\frac{21}{4}V_{hh} \tag{3.10}$$

The experimental values of various V_0's are given by[18)]

$V_0=-15.50$ eV for the ground state

$V_0=-13.64$ eV for ${}^2T_2$ state

$V_0=-11.04$ eV for ${}^2A_1$ state

where we adopt 11.26 eV as the value of ionization potential of C$2p$ and 3.69 eV as the value of $2s$–$2p$ energy gap. From these values we obtain

$$\begin{aligned}&\sqrt{\frac{3}{2}}(J_{s\sigma}+J_{\sigma s})=-3.13\ \text{eV}\\&\left(4Q_{ss}-\frac{1}{2}J_{ss}\right)=-4.43\ \text{eV}\\&\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+2\left(4Q_{\pi\pi}-\frac{1}{2}J_{\pi\pi}\right)=-5.94\ \text{eV}\end{aligned} \tag{3.11}$$

Using the experimental data 4.096 eV for V_2 in (3.7) we obtain

$$-\frac{8}{3}\sqrt{\frac{2}{3}}\left(\frac{\partial V_{hh}}{\partial R}\right)R_0+\frac{16}{9}\left(\frac{1}{2}\frac{\partial^2 V_{hh}}{\partial R^2}\right)R_0^2=3.05\ \text{eV} \tag{3.12}$$

To value also obtained from the formula (3.6), being 16.31 eV. The values of the first and the second derivatives of H–H interaction potentials in CH_4 will be smaller than the values theoretically expected (~1/5). The result obtained in (3.12) may provide support for the good agreement by the explanation for vibration spectra in hydrocarbon molecules from the picture of valence force field.

We separate $(4Q_{\sigma\sigma}-(1/2)J_{\sigma\sigma})$ from $(4Q_{\pi\pi}-(1/2)J_{\pi\pi})$ in (3.11) by the method described in appendix C, and obtain $(4Q_{\sigma\sigma}-(1/2)J_{\sigma\sigma})=-8.05$ eV and $(4Q_{\pi\pi}-(1/2)J_{\pi\pi})=+1.05$ eV. Consequently we estimate $V_{\theta1}$ and $V_{\theta2}$ and obtain

$$V_{\theta1}=5.73\ \text{eV}\ ,\qquad V_{\theta2}=6.08\ \text{eV}\ . \tag{3.13}$$

From these results, we can see that the equilibrium point is changed to some extent in ${}^2T_2$ state from that in the neutral ground state, but that the frequency is not so changed from that of the neutral ground state. The equilibrium angle in ${}^2T_2$ state (*i.e.* θ for the minimum V in (3.9) is evaluated to be about 27° from the $V_{\theta1}$ in (3.13). However we can not conclusively determine the shape of nuclear configuration of ${}^2T_2$ state by the value of θ for the minimum V obtained above, because the expression (3.9) is only valid when θ is small, that is, when an ion in ${}^2T_2$ state is suffered small deformation from tetrahedral configuration along ν_2 mode. The result of (3.13) comes mainly from the following features. (1) For the ground state the frequency of ν_2 (1526 cm^{-1}) is smaller than that of ν_1 (2914 cm^{-1}), that is the curvature of potential energy surface along ν_2 vibration is smaller than that for C–H stretching. If the curveture along ν_2 vibrational mode in the ground state takes nearly the same value with that of ${}^2T_2$ state, the equilibrium point easily changes by a small amount of change for each valence force. It is the reason why $V_{\theta1}$ is not so small. (2) The H–H interaction is small and every ν_i is well explained by the valence force field picture in the ground state, and these pictures will be valid in the potential energy surface of $^2T_2$ state because of the smallness of the H–H interaction in ionized state of $^2T_2$ as in the ground state. (3) The little increase in frequency term $V_{\theta 2}$ for $^2T_2$ compared with that for the ground state is due to the effect of H–H interaction. In the above calculation, Q and J may vary to some extent with the adopted values of dissociation energies, but the situations of (1), (2) and (3) do not differ by a small variation of the dissociation energies in every case. As related later, the results of the integration of $P(\infty, 0)$, and of $F_\nu P(\infty, 0)$ are not influenced so much by the change of $V_{\theta 2}$, *i.e.* by the curveture change of surface, but influenced by that of V_1, *i.e.* by the change of internuclear distance in equilibrium.

3.3. *Results of Calculation*

To perform the integration (2.10) the parameters α_l, λ_l, λ_2, E_l, are obtained from experimental data as illustrated in Table V. In Table V we can see $\lambda_2' \neq 0$ for $^2T_2$ state, that is, $q_{20} = \lambda_2'/\lambda_2 \neq 0$ in (2.2), and we take

Table V. Adopted values of parameters α_l, λ_l, λ_2', E_l.

Parameter	Adopted value for the ground state	Adopted value for $^2A_1$ state	Adopted value for $^2T_2$ state
α_1	3.815 $a_0^{-2} m_H^{-1}$		
α_2, α_3	2.016 〃		
α_4, α_5, α_6	3.992 〃		
α_7, α_8, α_9	1.726 〃		
λ_1		0.8759 eV $a_0^{-2} m_H^{-1}$	0.6876 eV $a_0^{-2} m_H^{-1}$
λ_2		0.2401 〃	0.2945 〃
λ_2'			1.269 eV $a_0^{-1} m_H^{-1/2}$
λ_3		0.2401 eV $a_0^{-2} m_H^{-1}$	0.2401 eV $a_0^{-2} m_H^{-1}$
λ_4, λ_5, λ_6		0.9339 〃	0.9339 〃
λ_7, λ_8, λ_9		0.1758 〃	0.1758 〃
E_1		1.27 eV	0.68 eV
E_2		2.78 〃	3.58 〃
E_3			7.35 〃

m_H denotes the hydrogen mass, the symbols with suffix 1 relate to the normal coordinate for ν_1 vibration, those with suffix 2 relate to the normal coordinate for ν_2 vibration, λ_2' is the coefficient of the first power term of q_2 in $^2T_2$ state ($\lambda_2' = \lambda_2 q_{20}$ in (2.11)) and is calculated from V_1 in (3.13), the symbols with suffix 3 relate to the other normal coordinate for ν_2, vibration, those with suffix 4, 5 and 6 relate to the normal coordinates for ν_3 vibration, and those with suffix 7, 8 and 9 relate to the normal coordinate foa ν_4 vibration.

$$\xi_2 = \frac{\lambda_2'}{E} q_2$$

as a new variable in (2.8) because of $\lambda_2' q_2 \gg \lambda_2$ and we take also

$$\exp(-\alpha_2 q_2^2) = \exp(-\beta_2'(\xi_2 - \xi_{20})^2)$$

$$\beta_2' = \sqrt{\frac{E_l}{\lambda_2'}} \cdot \alpha_2, \quad \xi_{20} = \sqrt{\frac{2}{\beta_2}} \tag{3.14}$$

for ξ_2 normal coordinae part of the vibrational wave function of nuclei. Further, the function in (3.14) is calculated by the approximation method which shown in Appendix B.

When we put the relative aboundances of CH_4^+, CH_3^+, CH_2^+, CH^+ and C^+ with respect to the total ionization as F_1, F_2, F_3, F_4 and F_5, respectively, these ion abundances are obtained from Fig. 5 and Table IV according to (2.4) as

$$F_1 P(\infty, 0) = P_1(E_1, 0)$$

$$F_2 P(\infty, 0) = \frac{2}{7} P_1(\infty, 0) + \frac{5}{7} P_1(E_2, 0) - P_1(E_1, 0) + \frac{12}{119} P_2(\infty, 0)$$

$$+\frac{54}{6545}P_2(E_2,\,0)+\frac{96}{2145}P_2(E_1,\,0)$$

$$F_3P(\infty,\,0)=\frac{5}{7}P_1(\infty,\,0)-\frac{5}{7}P_1(E_2,\,0)+\frac{30}{119}P_2(\infty,\,0) \tag{3.15}$$

$$+\frac{27}{1309}P_2(E_2,\,0)+\frac{48}{4290}P_2(E_1,\,0)$$

$$F_4P(\infty,\,0)=\frac{36}{119}P_2(\infty,\,0)+\frac{162}{6545}P_2(E_2,\,0)+\frac{288}{2145}P_2(E_1,\,0)$$

$$F_5P(\infty,\,0)=\frac{9}{119}P_2(\infty,\,0)-\frac{9}{119}P_2(E_2,\,0)$$

where $P_1(E_l,\,0)$ means the symbol for ${}^2T_2$ state, and $P_2(E_l,\,0)$ means that for ${}^2A_1$ state.

The results of calculation are shown in Table VI and Fig. 2.

Table VI. Relative abundances to the parent ion.

Ion	Observed[19]	Calculated
CH_4^+	100	100
CH_3^+	86	93
CH_2^+	16	38
CH^+	8.1	0.6
C^+	2.8	0
CD_4^+	100	100
CD_3^+	83	64
CD_2^+	12.5	24
CD^+	7.23	0
C^+	2.19	0

3.4. *Isotope Effect*

We can find the value of β_0 for CD_4 in (2.8) is $\sqrt{2}$ times that for CH_4 and this increases of β_0 will cause a change of relative yield. We can expect that the parent ion becomes to have larger abundance than that for CH_4, because

$$F_1=\frac{\int_0^{\beta_0} e^{-y}F(y)Q\left(\frac{E_l y}{\beta_0}\right)y^{(n/2)-1}dy}{\int_0^{\beta_0} e^{-y}F(y)Q\left(\frac{E_l y}{\beta_0}\right)y^{(m/2)-1}dy} \tag{3.16}$$

and $Q(y/\beta_0)$ is such a slowly varying function of $(E_l y/\beta_0)$ that it can be regarded as nearly constant. The tendency obtained by the experiments in Table VI shows that the consideration is acceptable. It is considered to be equivalent in view of physical interpretation to the following meaning that the zero point energy of nuclear motion for CD_4 is lower than that for CH_4 and the wave function of nuclear motion concentrates nearer the equilibrium point for CD_4 than for CH_4.

Thus if the equilibrium point in the ionized state is not much different from that in the neutral ground stage, *i.e.* the parent ion can remain stable at considerable rate to the total ionization the nuclear system gains less kinetic energy with the Franck-Condon transition for CD_4 by the isotope effect and then the dissociation take place less easily.

The results of calculation are also shown in Table VI. They tell us that the tendency measured by the experiments from CH_4 to CD_4 is not so striking as is theoretically expected. The reason is not clear, but a part of the discrepancy comes from y depedency of the integrand in (2.14), and the integrand may be supposed to be more slowly varying function of y.

§ 4. **Discussion and Conclusion**

The similarity of the shape of the cross section-incident energy curve of molecules to that of atoms has been deduced in our case by our taking LCAO wave function for MO wave function. However, this similarity does not essentially depend on the structure of the wave function of an orbital to be ionized. Further, there is a possibility that the curve for molecules resembles those for composed atoms even when the additivity rule is not applicable.

The non-linearity behaviour of the curve of the relation between cross section and incident energy near a threshold is due to the effect of strong convergence of the integrand in (2.14) at the origin, that is, the probability of finding nuclei at the equilibrium configuration is rather small and is larger at a distance from it. The effect must appear in the cases of optical transition of an electron in molecules, of an electron capture by molecules or molecular ions, of all the electronic phenomena that are affected by the wave function of nuclear motion. It is, therefore, possible to consider that in optical transition of electronic excitation or ionization the maximum value of observed transition does not always correspond to that from the equilibrium point of nuclear motion in the ground state, even if the atomic configuration in equilibrium in an excited state is the same as that in the ground state. One must not apply the analogous consideration of diatomic molecules to that of polyatomic ones. The curve for the relation between the yield of product and the energy of the incident particle (electron, photon, *etc.*) has not always the maximum that corresponds to the vertical transition from the nuclear configuration of the maximum probability in the ground state (Fig. 6).

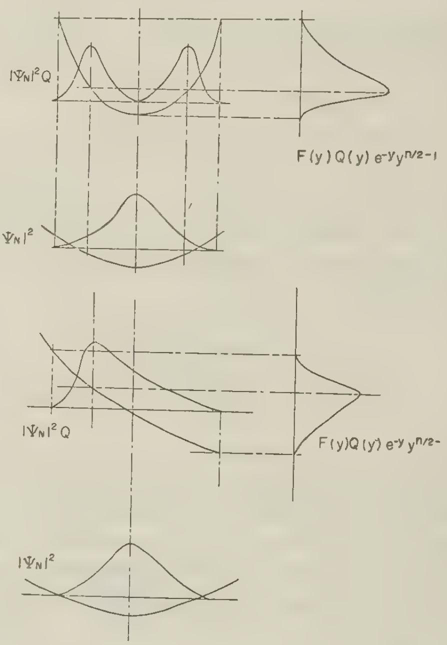

Fig. 6. Schematic figure of transition probabilities when $n>2$.

On account of several approximations adopted in the estimation of $V_{\theta 1}$ and $V_{\theta 2}$, each term of molecular integrals may not be so accurate that we can not discuss other properties of the molecule with these J and Q from the quantitative views. However, one may at least conclude the following remarks. (1) The relative abundance of each ion is much influenced by the change of equilibrium configuration, but not much by the change of force constant. (2) The value of parent ion abundance is considerably large when the equilibrium configuration of ionized state resembles that of the neutral ground state (more than 80% of the total ionization). (3) If the interaction between non-bonding two atoms is not small compared with the valence energy of bonding atoms (for example CCl_4), the feature may be different from that described above and one may consider that the abundance of parent ion is negligibly small in this case.

The poor agreement of the results of calculation with experiments for the abundances of CH^+ and C^+ is due to the assumption that the equilibrium configuration in the potential energy surface is the same with that of the ground state in $^2A_1$ state. We suppose that the integrand in (2.10) should be more slowly varing function and should not decay so rapidly with y in this case. It is also supposed that this correction may have good influence on the descrepancies of isotope effect. There is a possibility of the change of equilibrium configuration in $^2A_1$ state. The discrepancy seems to be due to the fact that the potential surface is not a true basin at the point where every $q_i=0$ in $^2A_1$ and the potential curve of the coordinate along the process such as

$$CH_4^+(^2A_1) \longrightarrow CH_3^+ + H$$

has not a minimum. The slope along these path may be considered to be large and the probability of ionization to $^2A_1$ state may extend over a wide range of the ionization potential E, that is, the integrand in (2.14) may be a more soothing function of y.

The absence of the appearance potential of new CH_3^+ at 19.42 eV, *i.e.* the energy level of $^2A_1$ state, seems to be attributable to the fact that CH_3^+ in the state refered to the surface of CH_4^+ in $^2A_1$ may be unstable, or to the fact that the surface in $^2A_1$ state may be combined with the surface in $^2T_2$ state. Otherwise the amount of this CH_3^+ ion may be too little to be detected by experiment. Generally speaking one must take every ion fragment for each electronic level into account.

In the above consideration, the production of negative ions H_2^-, H^-, *etc.* and positive ions H_2^+, H^+, have been ignored on account of small yields, especially, from the complexity of negative ion production processes. The small amounts of H_2^+ and H^+ ions may be due to the large negativities than those of CH_3^+, CH_2^+, CH^+ and C^+.

Acknowledgements

The author wishes to express his grateful thanks to Professor Ayao Amemiya for his helpful discussions and continuous encouragement for the present work. He is also grateful to Professor Ichirō Kanomata for his suggestions from experimental aspects and to Professor Masao Kotani and the members of his laboratory for their valuable discussions from the theoretical viewpoint. He further appreciates useful comments of Mr. Mitio Inokuti. A part of the calculation in the present work was carried out with the aid of the FACOM-128 Fuji automatic relay computer which is located in the Yurin Denki Seiki Co., and the writer is indebted to Mr. Sugayasu Hirano for use of the machine.

Appendix A

In (2.10) we obtain the formula

$$P(E_2,0)=B\prod_{i=1}^{n}\left(\frac{E_l}{2\lambda_i}\right)^{1/2}\frac{\{\Gamma(1/2)\}^n}{\Gamma\{(1/2)n\}}\left\{f_0+\frac{1}{n}\sum_i\beta_i f_1+\frac{1}{n(n+2)}\left[\sum_{i>j}\beta_i\beta_j+\frac{3}{2}\sum_i\beta_i^2\right]f_2\right.$$
$$\left.+\frac{1}{n(n+2)(n+4)}\left[\sum_{i>j>k}\beta_i\beta_j\beta_k+\frac{3}{2}\sum_{i\neq j}\beta_i^2\beta_j+\frac{5}{2}\sum_i\beta_i^3\right]f_3+\cdots\right. \qquad \text{(A1)}$$

where

$$f_i=\int_0^1\exp(-\beta_0\xi_i)Q(\xi)\xi^{(n/2)+i-1}d\xi$$
$$Q(\xi)=\sum_r\left\{\frac{2\pi Ame^4c_ra_r^2Z_r}{\hbar^2k_0^2E_l[(E_0/E_l)+\xi]}\right\}\log\left\{\frac{2\hbar^2k_0^2}{m\alpha_rE_l[(E_0/E_l)+\xi]}\right\} \qquad \text{(A2)}$$

and $\sum\limits_{i\neq j>k}$ means $\sum\limits_{\substack{i\neq j\\ i\neq k}}\sum\limits_{j>k}$.

Using the fact that $\sum\limits_i\beta_i=0$, (A1) becomes the following formula

$$P(E_l,0)=B\prod_{i=1}^{n}\left(\frac{E_l}{2\lambda_i}\right)^{1/2}\frac{\{\Gamma(1/2)\}^n}{\Gamma\{(1/2)n\}}\left\{f_0+\frac{\sum\beta_i^2}{n(n+2)}f_2+\frac{4\sum\beta_i^3}{3n(n+2)(n+4)}f_3\right.$$
$$+\frac{1}{n(n+2)(n+4)(n+6)}\left[\frac{1}{2}(\sum\beta_i^2)^2+\frac{5}{2}(\sum\beta_i^4)\right]f_4$$
$$+\frac{1}{n(n+2)(n+4)(n+6)(n+8)}\left[\frac{4}{3}(\sum\beta_i^2)(\sum\beta_j^3)+\frac{47}{10}(\sum\beta_i^5)\right]f_5$$
$$+\frac{1}{n(n+2)(n+4)(n+6)(n+8)(n+10)}\left[\frac{1}{6}(\sum\beta_i^2)^3+\frac{49}{8}(\sum\beta_i^2)(\sum\beta_j^4)\right.$$
$$\left.\left.+\frac{241}{72}(\sum\beta_i^6)\right]f_6+\cdots\right. . \qquad \text{(A3)}$$

Since $Q(\xi)$ is a decreasing function of ξ

$$f_i=\int_0^1 \exp(-\beta_0\xi)Q(\xi)\xi^{(n/2)+i-1}d\xi$$
$$\leq\frac{1}{\beta_0{}^{(n/2)+i}}\int_0^{\beta_0}\exp(-y)Q(y)\,y^{(n/2)+i-1}dy$$

where $\beta_0\xi=y$. As we have $f_i<\frac{\{(n/2)+i-1\}}{\beta_0}f_{i-1}$, then

$$f_i<\frac{(n/2)+i-1}{\beta_0{}^{(n/2)+i-1}}\int_0^{\beta_0}\exp(-y)Q(y)\,y^{(n/2)+i-2}dy\ .$$

Then we obtain

$$f_i<\frac{\{(n/2)+i-1\}\{(n/2)+i-2\}\cdots(n/2)}{\beta_0}f_0\ . \tag{A4}$$

We substitute (A4) into (A3), then we have

$$\frac{\sum\beta_i{}^2}{n(n+2)}f_2<\frac{1}{4}\sum\left(\frac{\beta_i}{\beta_0}\right)^2 f_0$$
$$\frac{4\sum\beta_i{}^3}{3n(n+2)(n+4)}f_3<\frac{1}{6}\sum\left(\frac{\beta_i}{\beta_0}\right)^3 f_0$$
$$\text{the term of } f_4<\left\{\frac{1}{32}\left(\sum\left(\frac{\beta_i}{\beta_0}\right)^2\right)^2+\frac{5}{32}\sum_i\left(\frac{\beta_i}{\beta_0}\right)^4\right\}f_0$$
$$\text{the term of } f_5<\left\{\frac{1}{24}\left(\sum\left(\frac{\beta_i}{\beta_0}\right)^2\right)\left(\sum\left(\frac{\beta_i}{\beta_0}\right)^3\right)+\frac{47}{320}\sum\left(\frac{\beta_i}{\beta_0}\right)^5\right\}f_0$$
$$\text{the term of } f_6<\left\{\frac{1}{384}\left(\sum\left(\frac{\beta_i}{\beta_0}\right)^2\right)^3+\frac{39}{512}\left(\sum\left(\frac{\beta_i}{\beta_0}\right)^2\right)\left(\sum\left(\frac{\beta_i}{\beta_0}\right)^4\right)+\frac{241}{4608}\sum\left(\frac{\beta_i}{\beta_0}\right)^6\right\}f_0\ . \tag{A5}$$

β_i/β_0 is the ratio of the difference of inverse frequency to the mean and is given in the form

$$\frac{\beta_i}{\beta_0}=\frac{(1/\nu_0)-(1/\nu_i)}{1/\nu_0}\qquad \frac{1}{\nu_0}=\frac{1}{n}\sum_{i=1}^{n}\frac{1}{\nu_i}\ . \tag{A6}$$

In practice the value of $\beta_i/\beta_0\leq 1/2$ and we may expect for most molecules the mean values of $\langle(\beta_i/\beta_0)^2\rangle\sim 1/10$. We shall consider molecules XY_4 and XY_3 as examples, *i.e.* $n=9$ and $n=6$ respectively. In those cases

$$\sum\left(\frac{\beta_i}{\beta_0}\right)^2\leq 1\ ,\qquad \sum\left(\frac{\beta_i}{\beta_0}\right)^3<1\ ,$$
$$\sum\left(\frac{\beta_i}{\beta_0}\right)^n\ll 1\qquad \text{for}\quad n\geq 4\ . \tag{A7}$$

Thus, we can conclude and that the equation (A3) converges when $n\leqq 9$.

Appendix B

If in (2.11) $q_2\lambda_2<\lambda_2'$ ($\lambda_2'=\lambda_2 q_{20}$), the potential (2.2) will be well expressed as

$$E=E_0+\sum_{i=1}^{n}{}'\frac{\lambda_i}{2}q_i{}^2+\lambda_2' q_2 \tag{B1}$$

where the primed $\sum$ means the summation over i except 2. Then the equation which corresponds to (2.7) becomes

$$P(E_{l1}D)=B\int_{E=E_0}^{E=E_l+E_0}\exp(-\beta_0\sum\xi_i)\exp(\sum_i{}'\beta_i\xi_i)Q(\sum_i\xi_i)\exp(-\beta_2'(\xi_2-\xi_{20})^2+\beta_2\xi_2)$$
$$\times\prod_i{}'\left(\sqrt{\frac{E_l}{2\lambda_i}}\frac{d\xi_i}{\sqrt{\xi_i}}\right)\left(\frac{E_l}{\lambda_2'}\right)d\xi_2 \tag{B2}$$

from the transformation of $\xi_2=(\lambda_2'/E_l)q_2$ and $\xi_i=(2\lambda_i/E_l)q_i^2$ for $i\neq 2$ and

$$\beta_i=\beta_0-\frac{2E_l}{\lambda_i}\alpha_i\,,\qquad \beta_0=\frac{1}{n-1}\Sigma'\left(\frac{2E_l}{\lambda_i}\right)\alpha_i\qquad \text{for}\quad i\neq 2$$

$$\beta_2'=\left(\frac{E_l}{\lambda_2'}\right)^2\qquad\qquad \xi_{20}=\sqrt{\frac{2}{\beta_2'}}\,.$$

The function $\exp(-\beta_2'(\xi_2-\xi_{20})^2+\beta_0\xi_2)$ is expanded in power series of $(\xi_2-\xi_{20})$ at $\xi_2=\xi_{20}$ in the form

$$\exp[-\beta_2'(\beta_2'-\xi_{20})^2+\beta_0\xi_2]=\left\{\sum_{n=0}^{\infty}\frac{(-)^n(\beta_2')^n(\xi_2-\xi_{20})^{2n}}{n!}\right\}\left\{\sum_{n=0}^{\infty}\frac{\beta_0{}^n(\xi_2-\xi_{20})^n}{n!}\right\}\exp(\beta_0\xi_{20})\tag{B3}$$

because the function of ξ_2 must have maximum at ξ_{20}. Then we can obtain $\exp(-\beta_2'(\xi_2-\xi_{20})^2+\beta_2\xi_2)$ in power series of ξ_2.

Appendix C

We consider a virtual vibration in the ground state as shown in Fig. 7 which resembles to ν_4 vibration of XY_4 in the case of $m_X \ll m_Y$. β, β' be the angles which are illustrated in Fig. 7, ψ_{2px}, ψ_{2py}, ψ_{2pz} are expressed in terms of $\psi_{1\sigma}$, $\psi_{1\pi}$, $\psi_{1\bar{\pi}}$, *etc.* by the same method in (3.2), that is

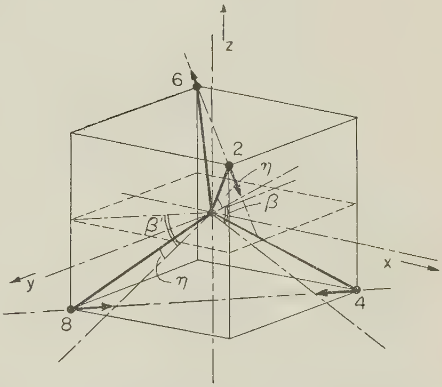

Fig. 7. Virtual vibration mode in Appendix C and angles β, β' and η.

$$\begin{aligned}\psi_{2px}&=-\frac{1}{\sqrt{2}}\cos\beta\psi_{1\sigma}+\sqrt{1-\frac{1}{2}\cos^2\beta}\left(-\frac{1}{\sqrt{2}}\cos\beta\psi_{1\pi}+\sqrt{1-\frac{1}{2}\cos^2\beta}\,\psi_{1\bar{\pi}}\right)\\ \psi_{2py}&=\frac{1}{\sqrt{2}}\cos\beta\psi_{1\sigma}+\sqrt{1-\frac{1}{2}\cos^2\beta}\left(-\frac{1}{\sqrt{2}}\cos\beta\psi_{1\pi}-\sqrt{1-\frac{1}{2}\cos^2\beta}\,\psi_{1\bar{\pi}}\right)\\ \psi_{2pz}&=\frac{1}{\sqrt{2}}\cos\beta\psi_{1\sigma}+\sqrt{1-\frac{1}{2}\cos^2\beta}\,\psi_{1\pi}\end{aligned}\tag{C1}$$

and similar expressions ψ_{2p}'s in terms of $\psi_{3\sigma}$, $\psi_{3\pi}$, $\psi_{3\bar{\pi}}$, $\psi_{5\sigma}$, $\psi_{5\pi}$, $\psi_{5\bar{\pi}}$ and $\psi_{7\sigma}$, $\psi_{7\pi}$, $\psi_{7\bar{\pi}}$.

By the similar procedure adopted in § 3 we make use of the relations

$$\begin{aligned}Q(R_2)+Q(R_4)+Q(R_6)+Q(R_8)&=4\left\{Q(R_0)+\frac{1}{2}\left(\frac{\partial^2 Q}{\partial R^2}\right)_{R=R_0}(\varDelta R)^2\right\}\\ Q(R_2)+J(R_4)+J(R_6)+J(R_8)&=4\left\{J(R_6)+\frac{1}{2}\left(\frac{\partial^2 Q}{\partial R^2}\right)_{R=R_0}(\varDelta R)^2\right\}\end{aligned}\tag{C2}$$

etc., where R_0 is C–H distance in equilibrium, $R_i=R_0+\varDelta R_i$ is C–H_i distance. When $(\varDelta R_i)^2=\eta^2R_0^2$ is taken as the change of C–H_i distance from equilibrium $(\beta=\tan^{-1}(\sqrt{1/2}+\eta))$, we obtain the formula $V=V_0+(1/2)V_{\eta 2}\cdot\eta^2$ where V_0 is the same with that in the case of ν_2 vibration and

$$\begin{aligned}V_{\eta 2}=&\frac{1}{2}\left(\frac{1}{2}\frac{\partial^2 V}{\partial R^2}\right)R_0^2-\frac{1}{4}\left(4Q_{\sigma\sigma}-\frac{1}{2}J_{\sigma\sigma}\right)+\left(4Q_{\pi\pi}-\frac{1}{2}J_{\sigma\sigma}\right)\Bigg|\\ &-\frac{3\sqrt{3}}{8}(J_{s\sigma}+I_{\sigma s})+\left(\frac{1}{2}\frac{\partial V_{hh}}{\partial R^2}\right)R_0^2\end{aligned}\tag{C3}$$

On the other hand, from the point of valence force field picture $V_{\eta 2}$ in (C3) is to be expressed in the form

$$V_{\eta 2}=\frac{1}{2}\left(\frac{1}{2}\,\frac{\partial^2 V}{\partial R^2}\right)R_0{}^2+V_{\theta 2}\ .$$

$$V_{\theta 2}=-\frac{1}{4}\left(4Q_{\sigma\sigma}-\frac{1}{2}\,J_{\sigma\sigma}\right)+\frac{1}{2}\left(4Q_{\pi\pi}-\frac{1}{2}\,J_{\pi\pi}\right)-\frac{3\sqrt{3}}{8}(J_{s\sigma}+J_{\sigma s})+\left(\frac{1}{2}\,\frac{\partial^2 V_{hh}}{\partial R^2}\right)R_0{}^2$$

Using the adjusted value by (3.12) for $\{(1/2)(\partial^2 V_{hh}/\partial R^2)\}R_0{}^2$ (0.187 times theoretical value). We obtain $(4Q_{\sigma\sigma}-(1/2)J_{\sigma\sigma})$ and the $(4Q_{\pi\pi}-(1/2)J_{\pi\pi})$ from (C7) and third equation of (3.11).

On the Additivity Rule in the Ionization Cross Section of Molecules

By Tsutomu WATANABE

Japan Atomic Energy Research Institute, Tokai-Mura,
Naka-Gun, Ibaraki-Ken, Japan

(Received April 15, 1960)

Validity of the additivity rule in the ionization cross section of molecules is investigated. So far as the present calculation is concerned, we have concluded that the rule is considered to be approximately valid within the allowance of 20% under the condition where electrons are impacted with incident energies more than 80 eV and the internuclear distance between every couple of atoms in a molecule is more than $2.5a_0$. If the internuclear distance is less than $2.5a_0$, one must take account of the diffraction effects due to the interference of waves scattered by the neighbour atoms. Numerical computation was carried out to the cases of C_nH_{2n+2} and C_nF_{2n+2}. The results for C_nH_{2n+2} were found in plausible agreement with mass spectroscopic data but those for C_nF_{2n+2} were found in small disagreement with data.

§ 1. Deduction

In an inelastic collision of an electron with a molecule, it has often been regarded that the inelastic cross section is given as the sum of the cross sections of atoms. This additivity rule is not necessarily self-evident from the theoretical viewpoint. In order to investigate the validity of the rule in the case of ionization by electron impact, we start with Schrödinger equation of many electron system with may centered field, namely

$$\left[-\frac{\hbar^2}{2m}\sum_{i=1}^{n}\nabla_i^2-E-\sum_{i,\alpha}V_\alpha(r_i)+\sum_{i>j}\frac{e^2}{r_{ij}}\right]\Phi=0 \tag{1.1}$$

where $V_\alpha(r_i)$ denotes the potential of α's core to the ith electron and m and $\hbar$ have their usual meanings. The total wave function Φ is assumed to be written in the form

$$\begin{aligned}\Phi=&F_0(\vec r_1)\Psi_0(\vec r_2,\vec r_3,\cdots,\vec r_n)\\&+\int F_\kappa(\vec r_1)\Psi_\kappa(\vec r_2,\vec r_3,\cdots,\vec r_n)\,d\kappa\\&+\sum_{i\neq1}\int G_\kappa^{i}(\vec r_i)\Psi_\kappa(\vec r_1,\vec r_2,\cdots,\vec r_{i-1},\vec r_{i+1},\cdots,\vec r_n)d\kappa\end{aligned} \tag{1.2}$$

where F_0 denotes the wave function in the field of a neutral molecule, F_κ the wave function of an inelastically scattered electron, G_κ^i that of an exchanged inelastically scattered one, Ψ_0 the total wave function of the neutral molecule, and Ψ_κ the product of the wave function of a molecular ion produced by ionization and that of an ejected electron. In the above description, the symbolic letters with suffix 1 relate to the incident electron, the letters with suffix i except 1 relate to an electron in the molecule, the suffix κ means the magnitude of momentum vector of the ejected electron, i in G_κ^i means the labeled number of which an electron is to be exchanged and scattered for the incident electron.

The wave function Ψ_0 may be written in the form of Slater's determinants which are constructed by one electron wave functions of molecular orbitals, and orthogonality relationship between every two molecular orbital wave functions of different kinds is assumed. When our wave function Ψ_0 in the form of Slater's determinants is expanded in terms of ψ_0 which is to be ionized in the form

$$\Psi_0=\sum_i(-1)^i\psi_0(\vec r_i)\Psi_0'(\vec r_2,\vec r_3,\cdots,\vec r_{i-1},\vec r_{i+1},\cdots,\vec r_n)\,, \tag{1.3}$$

the wave function Ψ_κ is assumed to be expressed by the wave function of the ejected electron ψ_κ and $\Psi_0'(\vec r_2,\vec r_3,\cdots,\vec r_{i-1},\vec r_{i+1},\cdots,\vec r_n)$ in the form

$$\Psi_\kappa=\sum_i(-1)^i\psi_\kappa(\vec r_i)\Psi_0'(\vec r_2,\vec r_3,\cdots,\vec r_{i-1},\vec r_{i+1},\cdots,\vec r_n)\,. \tag{1.4}$$

In short, the above description means that we neglect the change of Ψ_0' by ionization. We have adopted the analogical method of calculation to that for electronic collisions with atoms for use in the calculations of differential cross section for ionization of molecules[1], and then we have taken account of the influence of exchange effect of an incident electron for an electron in the molecule as well as the influence of distortion effect of an incident electron by a neutral molecular field on differential cross sections. Owing to the fact that the interaction potential between an incident electron and a molecule is not spherically symmetrical the calculation of a cross section for ionization needs proper approximation. Our incident electron may be scattered by the electron in the individual atomic orbitals in LCAOMO as independent scattering centers so that the amplitudes for scattering by the electron in the individual AO with proper allowance for phase difference may be determined by the same method as in elastic collision of electron with molecules.

The differential cross section for ionization of a molecule $I_\kappa(\theta,\varphi)$ in terms of the antisymmetrical scattered amplitude by an electron in rth AO $\phi_r^-(\theta,\varphi)$ is given by

$$I_\kappa(\theta,\varphi)=\frac{k_\kappa}{k_0}\left\{\sum_r a_r^2|\phi_r^-(\theta,\varphi)|^2+\sum_{r\neq r'} a_r a_{r'}|\phi_r^-(\theta,\varphi)\cdot\phi_{r'}^-(\theta,\varphi)|\exp\left(-i(\vec{k}_0-\vec{k}_\kappa)\vec{R}_{rr'}\right)\right\} \tag{1.5}$$

where $(k_\kappa/k_0)|\phi^-(\theta,\varphi)|^2$=differential cross section of an atom for ionization of rth AO, a_r is the coefficient of rth AO in LCAOMO, k_0, k_κ, and κ are the magnitudes of wave vectors of incident, scattered and ejected electrons respectively, θ and φ are the angles of scattering and of ejection with respect to the direction of the incident electron, and $R_{rr'}$ is the internuclear distance between r and r'th atom.

Usual experiments are carried out on molecules in the gas phase so that the orientation of molecule with respect to the direction of the incident electron should be considered at random, and one must average $I_\kappa(\theta,\varphi)$ over the molecular orientation, namely

$$\left.\begin{aligned}\frac{1}{4\pi}\int_\sigma I_\kappa(\theta,\varphi)\,d\sigma&=\frac{k_\kappa}{k_0}\left[\sum_r a_r^2|\phi_r^-|^2+\sum_{r\neq r'} a_r a_{r'}|\phi_r^-\cdot\phi_{r'}^-|\,\frac{\sin(K\cdot R_{rr'})}{K\cdot R_{rr'}}\right]\\ Q&=\frac{1}{4\pi}\int_0^{\kappa_{\max}}\int_\Omega\int_\omega\int_\sigma I_\kappa(\theta,\varphi)\,d\Omega\,d\omega\,d\kappa\,d\sigma\end{aligned}\right\} \tag{1.6}$$

where the integration is to be carried out over the solid angle $d\sigma$ of direction of molecule, over the solid angle $d\Omega$ of scattered electron, and over that of ejected electron $d\omega$.

Eqs. (1.5) or (1.6) shows that the total cross section can be expressible only in terms of atomic cross sections and the interactions between all possible couples of antisymmetrical scattered amplitudes caused by different AO's in the molecule which depend on $R_{rr'}$. If cross terms in (1.6) are regarded to be negligible compared with square terms, we can take the total ionization cross section as the sum of its atomic components. To verify this we consider the homonuclear diatomic case. $\phi_r^-(\theta,\varphi)$ does not depend on the coordinate of atom r and $|\phi_r^-\cdot\phi_{r'}^-|=|\phi_r^-|^2$ in the homonuclear case. Then we assume that the θ-, φ- and κ-dependences of each $|\phi_r^-|^2$ and also $|\phi_r^-\cdot\phi_{r'}|$ resemble to the differential cross section of hydrogen atom in its θ-, φ- and κ-dependences. Massey and Mohr[2] obtained analytically the θ-, φ- and κ-dependences of the cross section for hydrogen atom by means of Born's approximation and by taking the Coulomb function for the wave function of an ejected electron and plane wave for that of scattered one. The θ- and φ-dependences for hydrogen atom obtained through Born's approximation are found in plausible agreement with experimental data in the incident energy region above 80 eV[3]. According to the numerical results of θ- and φ-dependences which were obtained by Massey and Mohr[2], we take a following approximate formula for $\int|\phi_r^-|^2 d\omega$

$$\int|\phi_r^-|^2 d\omega=\frac{A}{K^2}\,\kappa\exp\left(-\sqrt{\frac{3\hbar^2}{2mE}}\cdot\kappa\right) \tag{1.7}$$

where A is a constant, K is the magnitude of the momentum change between incident and scattered electrons, i.e.

$$K^2=k_0^2+k^2-2k_0k\cos\theta\ .$$

By numerically integrating $|\phi_r^-|^2$ and

$$|\phi_r^-|^2\sin(K\cdot R_{rr'})/(K\cdot R_{rr'})$$

over K and κ with the aid of IBM–650 computor under the condition of momentum and energy conservation throughout the process of ionization, we have obtained the results as shown in Fig. 1. From this figure we can see that the validity of the additivity depends rather on the magnitude of internuclear distance $R_{rr'}$ than on the magnitude of wave vector of the incident wave k_0. It is found that in the range of the incident energy above 80 eV and in the range $R_{rr'}$ larger than $2.5a_0$ the total ionization cross section is expressible in terms of atomic components rather well within the allowance of 20%.

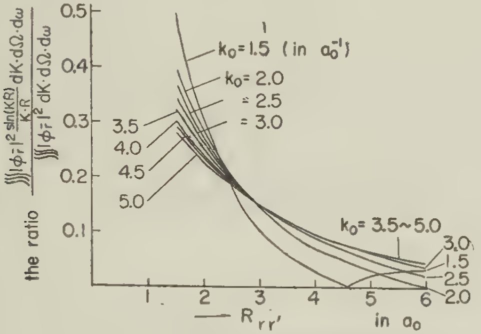

Fig. 1. The $R_{rr'}$ and k_0 dependences of the ratio of cross term to square terms

$$\iiint|\phi_r^-|^2\frac{\sin KR}{K\cdot R}d\kappa\, d\Omega\, d\omega\Big/\iiint|\phi_r^-|^2\, d\kappa\, d\Omega\, d\omega\,.$$

in the H–H case

§ 2. Applications to Hydro- and Fluorocarbons

According to the previous results, we compare the total ionization measurement of saturated hydro- and fluorocarbons with our calculations. Considering the results in Fig. 1 and adopting $2.916a_0$ and $2.083a_0$ as the internuclear distances of C–C and C–H bonds in hydrocarbons, and $2.953a_0$ and $2.499a_0$ as those of C–C and C–F bonds in fluorocarbons[4),5)], we may safely say that it is enough to take account of the cross terms between the nearest neighbour atoms in (1.6) and neglect those between the atoms which are more distant each other. From this we obtain the expression of the total ionization cross sections for hydro- and fluorocarbons in the form

$$\left.\begin{aligned} Q&=\sum_r a_r^2Q_r+\sum_{r\neq r'}a_ra_{r'}Q_{rr'}\\ Q_r&=\iiint|\phi_r^-|^2\, d\kappa\, d\Omega\, d\omega\\ Q_{rr'}&=\iiint|\phi_r^-\phi_{r'}^-|\,\frac{\sin(K\cdot R_{rr'})}{K\cdot R_{rr'}}\,d\kappa\, d\Omega\, d\omega \end{aligned}\right\} \tag{2.1}$$

where the sums $\sum_{r\neq r'}$ are taken only over the couples of nearest neighbour atoms. Assuming that the φ- and κ-dependencies of each ϕ_r^- are not different from each other, we have

$$Q_{rr'}=\int A_0\sqrt{I_r}\sqrt{I_{r'}}\,\frac{\sin(K\cdot R_{rr'})}{K\cdot R_{rr'}}\,d\Omega \tag{2.2}$$

where I_r is a differential cross section for ionization of an atom and A_0 is the ratio of the atomic component of a cross section of a molecule to the cross section of an atom. Each Q_r and I_r were expressed by Bethe in the forms

$$\left.\begin{aligned} Q_r&=A_0\frac{4\pi m^2e^4c_rZ_r}{\hbar^4k_0^2E}\log\left(\frac{2\hbar k_0^2}{mE}\right)\\ I_r&=\frac{4k_\kappa m^2e^4c_rZ_r}{\hbar^4k_0EK^2} \end{aligned}\right\} \tag{2.3}$$

where e is electronic charge, Z_r is the number of electron in an atomic orbital, E is the ionization energy of a molecular level under consideration, and

$$c_r=(Z_{\text{eff}}^2/n^2a_0^2)\int|(r|x|\kappa)|^2\, d\kappa$$

which was calculated and taburated in Bethe's paper[6)]. The expressions (2.3) were obtained by the method of Born's approximation as well as by the treatment in which the plane waves were adopted as the wave functions of scattered and ejected electrons, and only dipole matrix elements were taken into account under calculation. However, we may well take (2.3)'s for the proper calculation, because I_r is not so much different from the experimental data in the point of K dependency over the incident energy above 80 eV[3)].

We ignore the contribution from the ionization of $(1s)$ orbital electrons of C or F atom in the total cross sections for ionization. The bonding orbitals of C atoms are considered to be the tetrahedrally hybridized orbitals of $(2s)(2p)^3$ and the bonding orbitals of F atoms are considered to be $(2p\sigma)$ orbitals. We have the total cross section for ionization in the forms

$$\begin{aligned} Q_{\text{h.c.}}=n[&2a_{\text{H}}^2Q_{\text{H}}+2a_{\text{C}}^2Q_{\text{C}}+2a_{\text{C}}'^2Q_{\text{C}}\\ &+4a_{\text{C}}a_{\text{H}}Q_{\text{CH}}+2a_{\text{H}}^2Q_{\text{HH}}+2a_{\text{C}}^2Q_{\text{CC}}]\\ &-2a_{\text{C}}^2Q_{\text{CC}}+4a_{\text{C}}'a_{\text{H}}Q_{\text{CH}}+4a_{\text{H}}^2Q_{\text{HH}}\\ &+2a_{\text{H}}^2Q_{\text{H}}+2(a_{\text{C}}^2-a_{\text{C}}'^2)Q_{\text{C}} \end{aligned} \tag{2.4}$$

for saturated hydrocarbons

$$Q_{\text{f.c.}}=n[2a_F{}^2Q_F+2a_C{}^2Q_C+2a_C{}'^2Q_C+4a_Ca_FQ_{CF}+2a_F{}^2Q_F+2a_C{}^2Q_{CC}]$$
$$-2a_C{}^2Q_{CC}+4a_C{}'a_FQ_{CF}+4a_F{}^2Q_{FF}+2a_F{}^2Q_F+2(a_C{}^2-a_C{}'^2)Q_C$$

for saturated fluorocarbons, where n is the number of carbon atoms. Here

$$Q_C=\frac{1}{4}Q_{C2s}+\frac{3}{4}Q_{C2p}\ ,$$

$$Q_F=\left[\frac{2}{a_F{}^2}Q_{F2s}+\frac{4}{a_F{}^2}Q_{F2p}+Q_{F2p}\right],$$

$$Q_{CC}=\iiint A_0\left(\frac{1}{4}I_{C2p}+\frac{3}{4}I_{C2p}\right)\frac{\sin(K\cdot R_{CC})}{KR_{CC}}\,d\kappa\,d\Omega\,d\omega\ ,$$

$$Q_{CH}=\iiint A_0\left(\frac{1}{4}I_{C2s}+\frac{3}{4}I_{C2p}\right)^{1/2}I_H{}^{1/2}\frac{\sin(K\cdot R_{CH})}{K\cdot R_{CH}}\,d\kappa\,d\Omega\,d\omega\ ,$$

$$Q_{HH}=\iiint A_0I_H\frac{\sin(K\cdot R_{HH})}{K\cdot R_{HH}}\,d\kappa\,d\Omega\,d\omega\ ,$$

$$Q_{CF}=\iiint A_0\left(\frac{1}{4}I_{C2s}+\frac{3}{4}I_{C2p}\right)^{1/2}I_{F2p}{}^{1/2}\frac{\sin(K\cdot R_{CF})}{K\cdot R_{CF}}\,d\kappa\,d\Omega\,d\omega\ ,$$

and

$$Q_{FF}=\iiint A_0I_{F2p}\frac{\sin(K\cdot R_{FF})}{K\cdot R_{FF}}\,d\kappa\,d\Omega\,d\omega$$

where Q_F denotes the total cross section of F atom for ionization muliplied by A_0, Q_{F2s} that of F2s electron, I_{C2p} the differential cross section of C2p electron and so on. The atomic coefficients a_H, a_C, a_C', and a_F are calculated from the estimated dipole moments of C–H and C–F bonds[7] (a_C is the coefficient of C in C–C bond eigenfunction, a_C' is that in C–H or C–F bond eigenfunction). Here the electronic orbitals are constructed by the bond eigenfunctions of each C–C and C–H in the hydrocarbon case and by those of each C–C, C–F and the wave function of lone pair F2p electron in the fluorocarbon case.

Comparing the calculated values of C_4H_{10} and C_3F_8 with those obtained by experiment, we determine the values of A_0 for hydro- and fluorocarbons respectively. The both results of calculation are shown in Fig. 2 in plausible agreement with experiments[8]. Moreover, from the intercept and the slope of experimental curves (dotted lines), granting that $a_C{}^2=a_C{}'^2$ we can expect

$$\left.\begin{array}{l} -2a_C{}^2Q_{CC}+4a_C{}'a_HQ_{CH} \\ \qquad +4a_H{}^2Q_{HH}+a_H{}^2Q_H>0 \\ \text{for hydrocarbons and} \\ -2a_C{}^2Q_{CC}+4a_C{}'a_FQ_{CF} \\ \qquad +4a_F{}^2Q_{FF}+a_F{}^2Q_F\lesssim 0 \end{array}\right\}\quad(2.5)$$

for fluorocarbons.

The condition in (2.5) is acceptable for hydrocarbons but that for fluorocarbons does not seem to be acceptable. When we considered that Q_{CC}, Q_{CF}, or Q_{FF} are of the order less than one forth of Q_{F2p} or of Q_{F2s} from the condition in (2.5) for fluorocarbons, we may infer that the cross section of F atom is negative. Consequently, the validity of approximation (2.1) is questionable to the data for C_nF_{2n+2} in the strict sence.

The Optical Properties of Cadmium Telluride in the Far Infrared Region

By Akiyoshi MITSUISHI

Department of Applied Physics, Faculty of Engineering, Osaka University, Osaka, Japan

(Received November 9, 1960)

The reflection spectra of CdTe were measured in the spectral region from 20 μ up to about 400 μ at the two different temperatures, 90°K and 300°K. The Reststrahlen band was found at 65 μ with peak reflectivity of 92% at 90°K and 67 μ with the peak reflectivity of 77% at 300°K. The reflection spectra were analysed by Kramers-Kronig dispersion relation to obtain the optical constants n and k. Combining these values, the fundamental lattice dispersion frequencies of the bulk material were determined to be 140 cm^{-1} (71.2 μ) at 300°K and 144 cm^{-1} (69.5 μ) at 90°K. The damping constant was also obtained.

§ 1. Introduction

Cadmium Telluride is one of the $\mathrm{II_B}$–$\mathrm{VI_B}$ semiconductors, and it is also isoelectronic to InSb. The optical properties of this material have not been measured extensively[1]. Garlick *et al*[2] measured the refractive index in the near infrared region and suggested that the binding of the CdTe is almost homopolar, as the difference of the static and optical dielectric constant is small. The measurement of the Reststrahlen band is useful for the estimation of the polar character, and recently such measurements have been made for many diatomic semiconducting materials.

The fundamental lattice dispersion frequency of the powdered $\mathrm{II_B}$–$\mathrm{VI_B}$ compounds suspended in polyethylene have been reported in the recent note[3], but it was found that the value obtained with the powdered material was different from that of the bulk material. As a large crystal of CdTe, which is enough to make reflection measurement by the far infrared spectrometer, was obtained, the investigation was made in the spectral region from 20 μ up to about 400 μ at the two temperatures, 90°K and 300°K. The reflection spectra were analysed by Kramers-Kronig dispersion relation to obtain the optical constants n and k in the wavelength region around the reflection peak. Combining these values with Drude dispersion formula, the fundamental lattice dispersion frequency and the damping constant were obtained.

It is noted that the frequency of CdTe is smaller than that of InSb, but is larger than that of AgI which is also isoelectronic to CdTe.

In the meantime, Moss[4] reported that the effective charge e^*/e of CdTe was 0.83, when the Reststrahlen wavelength of 69 μ calculated from the compressibility data was used.

§ 2. Experimental

The far infrared vacuum grating spectrometer used in this investigation was already reported by Yoshinaga *et al*[5]. For the reflection measurement, the optical attachment shown in Fig. 1 is introduced in the optical path in front of the entrance slit. M_1 and M_3 are the plane mirrors and M_2 is a spherical mirror. These mirrors are mounted on a thick brass base-plate together with the positioning knock located at A to keep the cryostat in the correct position. The optical beam, which is focused on the entrance slit when this attachment is removed, is deflected by M_1 to form the image of source on the specimen mounted in the cryostat and the reflected beam from the specimen is focused on the entrance slit dy M_2 and M_3. The incident angle of the deam to the reflecting surface is 12°.

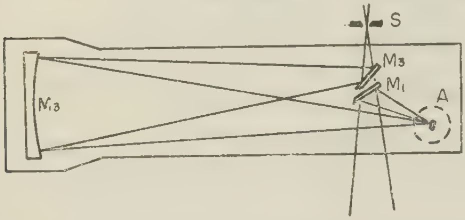

Fig. 1. The optical attachment for use in the reflection measurement at incident angle of 12°. M_1, M_3: plane mirror, M_2: spherical mirror, A: positioning knock, S: entrance slit.

The reference mirror and the sample to be measured were attached to the holder of the cryostat for reflection measurement. The cryostat is made of metal and it is so designed that either the reference mirror or the sample can be brought manually into the optical path by the rack and pinion mechanism without disturbing the vacuum of the spectrometer. The cryostat has the polyethylene window of 1 mm thick inclined to the optical axis of the spectrometer to avoid disturbance by reflection from the window surface and is evacuated separately from the vacuum tank of the spectrometer.

The sample used in this measurement is the zone refined polycrystalline crystal, the surface of which is ground and polished.

The reflectivity was measured by comparing the reflected intensity from the sample with that from the reference mirror. The final measurement was made by the point-by-point procedure to get the higher accuracy. The uncertainty in the percent reflectivity is ±1% in the spectral region shorter than 100 μ and about ±2% in the longer wavelength region.

§ 3. Experimental Result

Fig. 2 shows the reflection curve of CdTe at 300°K from 20 μ up to about 400 μ. General figure of the curve is similar to the other crystals of the zincblende structure and no side band was present. Impurity content of this specimen was not known. And, no free carrier effect was observed in this spectral region.

The change of the Reststrahlen band by lowering the temperature is shown in Fig. 3.

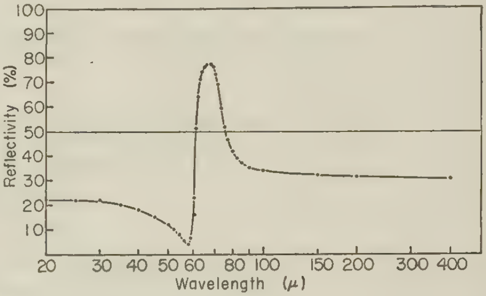

Fig. 2. The reflection spectrum of CdTe in the wavelength region from 20 μ to 400 μ at the temperature of 300°K.

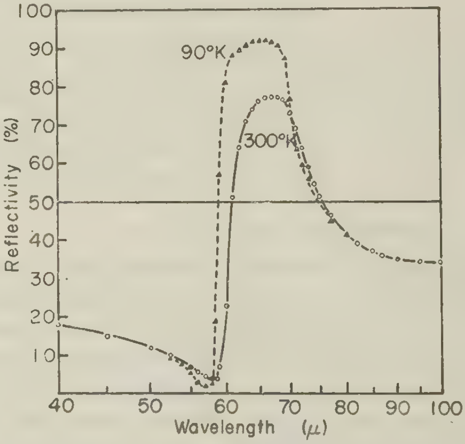

Fig. 3. The Reststrahlen reflection spectra of CdTe at the two temperature 90°K and 300°K

The band became steeper and shifted slightly to the shorter wavelength side with marked increase in the peak reflectivity. The peak reflectivity was 92% at 90°K compared with 77% at 300°K.

The minimum reflectivity was found at 57.5 μ at 90°K and 58.0 μ at 300°K. The Reststrahlen wavelength was 65 μ at 90°K and 67 μ at 300°K (The band center was assumed to correspond to this wavelength).

§ 4. Calculation of the Optical Constants

Kramers-Kronig relation was used to obtain the optical constants from the single reflection spectrum. This method of analysis has recently come into frequent use for various kinds of reflection spectra[6].

For the normal incident light the complex amplitude of reflection is given by

$$\rho=\frac{N-1}{N+1}=\frac{n-ik-1}{n-ik+1}=re^{i\theta}\,, \qquad (1)$$

where N is the complex refractive index and equal to $(n-ik)$, n is the real refractive index, k is the extinction coefficient, r is the square root of the reflectivity R, and θ is the phase shift upon reflection. The reflectivity R is given by

$$R=\left|\frac{N-1}{N+1}\right|^2=\frac{(n-1)^2+k^2}{(n+1)^2+k^2}\,. \qquad (2)$$

Kramers-Kronig dispersion relation interrelates $\ln r$ and θ. In the infrared region the reflectivity is easily measured and θ can be calculated from the following relation[6,7]

$$\theta(\lambda)=\frac{2\lambda}{\pi}\int_0^\infty\frac{\ln\sqrt{R_1}-\ln\sqrt{R}}{\lambda_1^2-\lambda^2}\,d\lambda_1\,. \qquad (3)$$

The integral covers the whole spectral region but, as the contribution from the wavelength remote from λ is small, it is enough if the detailed knowledge of the reflectivity in the spectral region around λ is learned.

With the calculated θ and the observed value of R, n and k can be calculated by the following relations derived from Eq. (1),

$$n=\frac{1-R}{1+R-2\sqrt{R}\cos\theta}\,, \qquad (4)$$

$$k=\frac{-2\sqrt{R}\sin\theta}{1+R-2\sqrt{R}\cos\theta}\,. \qquad (5)$$

The computation of θ was performed by the electronic computer. In this calculation the reflectivity was considered to be constant in the wavelength regions shorter than 20 μ and longer than 400 μ. The phase angle obtained is shown in Fig. 4.

The optical constants which were calculated from these phase angle were given in Fig. 5.

§ 5. Discussion of the Result

The properties of the Restsrahlen band are described by Drude dispersion formula

$$n^2-k^2=\varepsilon_\infty+\frac{(\varepsilon_0-\varepsilon_\infty)\left[1-\left(\frac{\omega}{\omega_0}\right)^2\right]}{\left[1+\left(\frac{\omega}{\omega_0}\right)^2\right]^2+\left(\frac{\omega}{\omega_0}\right)^2\left(\frac{\gamma}{\omega_0}\right)^2}\,, \qquad (6)$$

$$2nk=\frac{(\varepsilon_0-\varepsilon_\infty)\frac{\omega}{\omega_0}\frac{\gamma}{\omega_0}}{\left[1-\left(\frac{\omega}{\omega_0}\right)^2\right]^2+\left(\frac{\omega}{\omega_0}\right)^2\left(\frac{\gamma}{\omega_0}\right)^2}\,, \qquad (7)$$

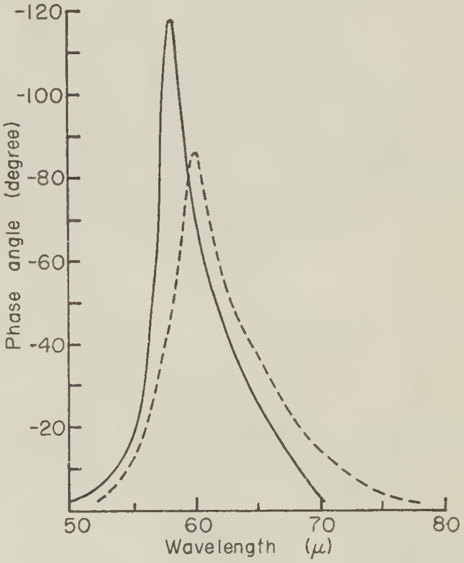

Fig. 4. The phase angle calculated by Eq. (3) for the Reststrahlen spectra of CdTe at 90°K and 300°K

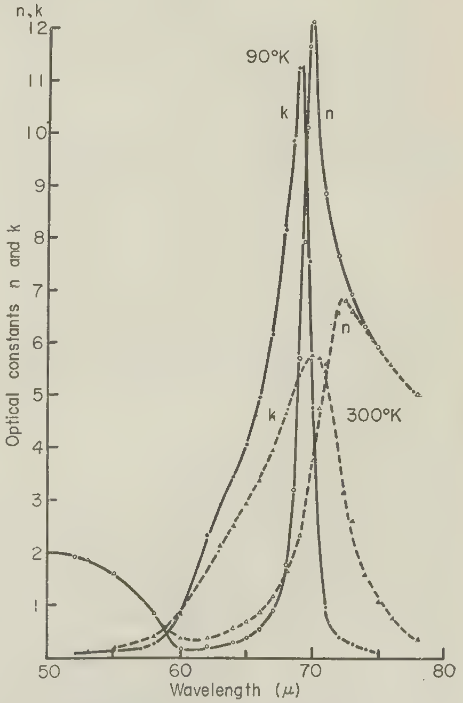

Fig. 5. Optical constant of CdTe around the Reststrahlen peak for the temperatures of 90°K and 300°K.

where ε_0 and ε_∞ are the static and optical dielectric constants, respectively, ω_0 is the fundamental lattice dispersion frequency, and γ is the damping constant. It is clear from Eq. (7) that $2nk\omega$ shows its maximum value at $\omega=\omega_0$. Thus the fundamental lattice dispersion frequency can be obtained from the plot of $nk\omega$ against frequency. Such a plot with wavelength is shown in Fig. 6 using n and k values given in Fig. 5. From the peak of these curve, ω_0 is determined to be 144 cm^{-1} (69.5 μ) at 90°K and 140 cm^{-1} (71.2 μ) at 300°K. From the compressibility data, Moss[4] calculated this wavelength to be 145 cm^{-1} (69 μ), which accords to the data mentioned above. In the previous note[3], the frequency of 150 cm^{-1} was reported as ω_0 with the powdered materials. It is observed for many other compounds[8] that the absorption maximum frequency obtained with the powder suspended in polyethylene is always larger than the infrared dispersion frequency of the bulk or evapolated materials.

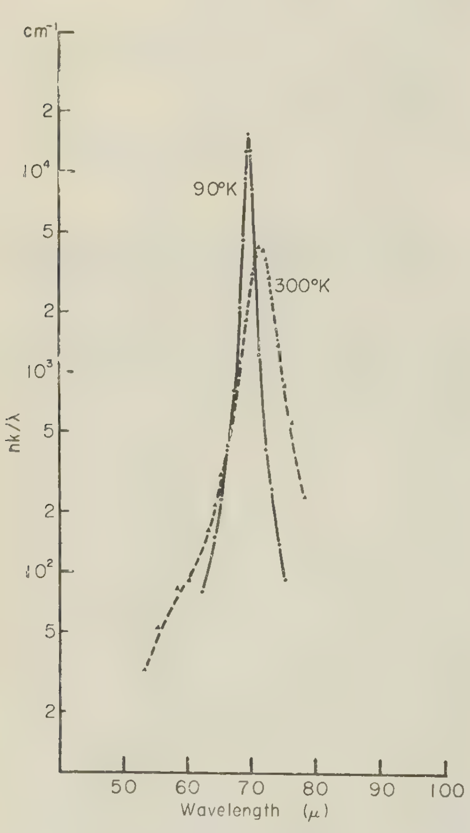

Fig. 6. The plot of $\frac{kn}{\lambda}$ against λ at the temperatures of 90°K and 300°K.

If the damping constant is neglected in Drude dispersion formula, perfect reflection is obtained in the frequency range from ω_0 to $\omega_l=\sqrt{\frac{\varepsilon_0}{\varepsilon_\infty}}\,\omega_0$. When γ increases from zero, the peak reflectivity decreases. Thus, the steep rise of the Reststrahlen band with the marked increase in the peak reflectivity at the low temperature may be understood by the interpretation that the damping constant becomes very small at the low temperature.

The damping constant is given by the following relation which can be derived from Eq. (7),

$$\frac{\gamma}{\omega_0}=\frac{(\varepsilon_0-\varepsilon_\infty)\omega_0}{2(nk\omega)_{\max}}\simeq\frac{\varepsilon_0-\varepsilon_\infty}{2(nk)_{\max}}\,. \tag{8}$$

The damping constant is also available from the following relation

$$\frac{\gamma}{\omega_0}=\left(1-\frac{\lambda_0}{\lambda_{1/2}}\right)\left(1+\frac{\lambda_{1/2}}{\lambda_0}\right), \tag{9}$$

where $\lambda_{1/2}$ is the wavelength by which $\frac{nk}{\lambda}$ becomes the half of its maximum value.

The value of ε_0 is reported to be 11[9]. The value of $\varepsilon_\infty(=n_\infty^2)$ is somewhat uncertain. Moss[4] obtained 2.68 for n_∞ by fitting the two measured values[2] of the refractive index to the simple dispersion formula. If the damping constant is neglected, rough estimate of n_∞ can be made by the relation

$$\frac{\lambda_0}{\lambda_{\min}}=\sqrt{\frac{\varepsilon_0-1}{n_\infty^2-1}}\,, \tag{10}$$

where $\lambda_{\min}$ is the wavelength of the minimum reflectivity. The values obtained are 2.7 for 90°K and 2.8 for 300°K. The reflectivity at 20 μ gives 2.7. Taking 2.68 for n_∞ in Eq. (8), the following values are obtained for $\frac{\gamma}{\omega_0}$.

	90°K	300°K
From Eq. (8)	0.02	0.06
From Eq. (9)	0.02	0.05

At the low temperature the damping constant decreases appreciably.

Recently Merten[10] has derived the following expression from the lattice dynamical theory for the transverse optical lattice frequency ν_t of the zincblende lattice,

$$\nu_t=\frac{1}{\pi}\sqrt{\frac{1}{M}\left(a\,c_{11}-1.30\,\frac{e^{*2}}{v_a}\right)}\,,$$

where M is the reduced mass, a is the lattice constant, c_{11} is the elastic constant, e^* is the effective charge and v_a is the volume of the unit cell. As c_{11} of CdTe, to the author's knowledge, is not known, it is not possible to compare the experimental value with this theory. It may be interesting to note that the fundamental lattice dispersion frequencies of InSb, CdTe, and AgI, which form the isoelectronic series, and the reduced masses and the lattice constants of them are almost the same, differ markedly. The Reststrahlen band of InSb was measured by Yoshinaga and Oetjen[11], and Spitzer and Fan[12]. The former give the Reststrahlen frequency of 183 cm^{-1} (54.6 μ). Analysing this Reststrahlen band, Moss *et al*[13] derived the fundamental lattice dispersion frequency of 177.6 cm^{-1}. The frequency of CdTe is 144 cm^{-1} (71.2 μ). The Reststrahlen band of AgI has not been measured. However, the absorption band at 110 cm^{-1} (91 μ) was observed with the powder suspended in polyethylene. As the higher value is usually obtained with the powdered material the frequency for the bulk material will be smaller than this value.

The effective charge e^*/e is calculated from the dielectric constant and the fundamental lattice dispersion frequency. For CdTe, Moss[4] obtained 0.83 with the wavelength of 69 μ. Present value of 71.2 μ does not change this value after all. The value for InSb is 0.36[12]. That for AgI is not known yet. Thus the lattice frequency increases as the ionicity decreases in this isoelectronic series. This property of the isoelectronic series was pointed out in the other isoelectronic compound[14].

Acknowledgement

The author wishes to express his cordial thanks to Prof. H. Yoshinaga for his valuable suggestion and encouragement throughout this work and is grateful to Dr. N. Munesue of the Electrical Communication Laboratory for providing CdTe crystal and Dr. S. Ibuki of the Mitsubishi Electric Co. for his interest in this work.

Interaction of Exciton with Electron Trapping Centers in Alkali Halide Crystals.

3. Exciton Induced Photoconductivity of U center*

By Masayasu UETA, Masamitsu HIRAI and Mikihiko IKEZAWA
Department of Physics, The Faculty of Science, Tohoku University, Sendai.

(Received November 10, 1960)

Photoconductivity of KCl and KBr crystals containing U centers has been investigated as a function of illuminating photon energy, in both the regions of U absorption and the fundamental absorption bands of host crystals. The maximum conductivity occurs where the fundamental absorption starts. The photoconductivity curve is similar to the spectral distribution of the quantum efficiency of U→F conversion as reported previously. The wavelength of light which enhances the maximum conductivity shifts to the longer wavelength side if the U center concentration is below 5×10^{16}/cc. This fact is in agreement with that of the quantum yield dependence on the concentration. The behaviour of Br-ion band in KCl crystal upon the photoconductivity was also investigated and it was concluded that localized excitons which may be considered to be produced by photons absorbed in Br band, have the same property as the free excitons in the host crystal so far as the effect on U centers is concerned.

§ 1. Introduction

It is believed that excitons are generated in alkali halide crystals when the crystals are irradiated with ultra violet light in the region of their fundamental absorption bands. On the problem of exciton effect upon F center, the investigations of photoelectric emission from the center has been performed by Apker and his co-workers[1]. They showed that excitons can ionize F centers.

Since a few years ago, we have been investgating the similar effect of ultra violet lighit on the color centers from the photochemical point of view and it was found that F, M, R and U centers can be easily destructed by the exciton[2,3]. A U center is considered to be an H^- ion subsititutionaly occupying the site of a halogen ion.

Recently we have reported on the measurements of the quantum efficiency of exciton-induced photochemical conversion of a U center to an F center[4]. It was shown that the ultra violet light absorbed in the host crystal can convert a U center with a quantum yield of nearly unity in both KCl and KBr crystals when the concentration of U center is larger than 1.0×10^{17}/cc, but the yield decreases when the concentration is below 5×10^{16}/cc. From this fact, the diffusion of an exciton has been proposed.

The present report deals with the photoconductivity measurements of U center in both spectral regions of U band and the fundamental absorption bands in KCl and KBr crystals. From the similar investigations in KCl crystals containing Br ion as an impurity, the nature of a localized exciton was discussed.

§ 2. Experimental Procedures

KCl and KBr crystals containing only U centers were prepared by the conventional method as described before. The concentrations were $4.0\times10^{16}\sim6.0\times10^{17}$/cc and $2.3\times10^{16}\sim3.1\times10^{18}$/cc in KCl and KBr crystals, respectively. Some of them were kept at room temperature for as long as five years after the preparation. The other crystals have various histories as tabulated in Table I.

Fig. 1 shows the crystal holder.* Crystals were held between two electrodes made of silver plated copper. One of them has holes of 1 mm in diameter which make light incident on the crystal. The other is the sensitive

---

* A preliminary note has been appeared in this journal vol. **15** (1960), 1356.

* This type of crystal holder was designed by Prof. H. Kanzaki. We are indebted to him for the construction.

electrode painted with varnish (Toshiba #36) to prevent the photoelectric emission from the electrode metal. The sensitive electrode was connected to a Cary model 31 vibrating reed electrometer through an input resistance of 10^{12} ohms. An electric field was applied on the crystal along the direction of illuminating light. Such a field direction is denoted here as "+direction". D. C. electric field of about 1000 volt/cm. was supplied with dry cells. Photocurrents were recorded with using a Yokokawa Type ER-22 electronic recorder of which time constant is three seconds. The noise current was 5×10^{-16} Amp. or less through all measurements.

A vacuum grating monochromator constructed in our laboratory was used in the spectral region between $\lambda\lambda$ 240 mμ and 170 mμ. Slit widths of the monochromator were set so that the band pass of each monochromatic light is less than 1 mμ. The intensity of light incident on the crystal was $\sim1\times10^{11}$ and 5×10^{11} photons per cm^2 per sec. in the regions of $\lambda\lambda$170 mμ–200 mμ and 200 mμ–240 mμ, respectively, as described previously.

Spectral distributions of photoconductivity of U center were measured as follows. In the case of KCl crystal, the polarization effect is very small if the intensity of monochromatic light is adjusted to produce the photocurrent of less than 10^{-13} Amp. Therefore, the saturation photocurrents are almost nearly the same but decrease a bit after repeated illuminations. However, it was confirmed that the polarization effect can be avoided by the illumination of the same light for the same period with applying an opposite electric field.

We have measured the saturation values of photocurrents with each monochromatic light. From the saturation values of these photocurrents, the photoconductivity curve of KCl crystal containing U center has been obtained with the correction of both absorption spectrum of the crystal and the relative spectral intensity distribution of illuminating light which was measured as described before³⁾. Corrections of the reflection loss of incident lights by the crystal surface were not made.

In KBr crystals, however, the photocurrents were much smaller, and moreover, the polarization effect was large, so, the measurement of the saturation value could not be carried out. Therefore, we have measured, at first, the response height on the recorder with a standard monochromatic light of λ 200 mμ for the period of three seconds' illumination. Next, the response with any light, for example, λ 205 mμ was measured for the same illumination period. After that, the measurement with the standard light of λ 200 mμ was made again. From these values, the relative photocurrent due to any monochromatic light was obtained with comparison to that of the standard light by the interpolation. The accuracy of measurements in KBr crystals is, therefore, a bit lower than that in KCl crystals.

All measurements in the present report have been done at room temperature, but the extension to the lower temperature has beening undertaken.

§ 3. Experimental Results and Discussions

3–1. *The spectral variation of the potoconductivity in KCl and KBr crystals containing U centers.*

Curve A in Fig. 2 shows an observed spectral variation of photocurrent in KCl crystal containing U center with a concentration of 5.9×10^{17}/cc. The crystal is #5 in Table I. The absorption curve of the crystal and the spectral intensity distribution of ultra violet light shown in curves B and C, respectively, were taken into consideration as corrections to obtain a real spectral variation of the photoconductivity. Curve D shows such a conductivity distribution obtained from curve A. The photocurrent is very small at the absorpsion peak of U band (λ 216 mμ), but it increases rapidly as the photon energy of illuminating light does, and reaches to the maximum value at the spectral region where the exciton absorption band starts.

B: Absorption curve of KCl+U crystal.

C: Spectral intensity distribution of illuminating light.

D: Spectral variation of photoconductivity obtained from curve A with corrections of curves B and C.

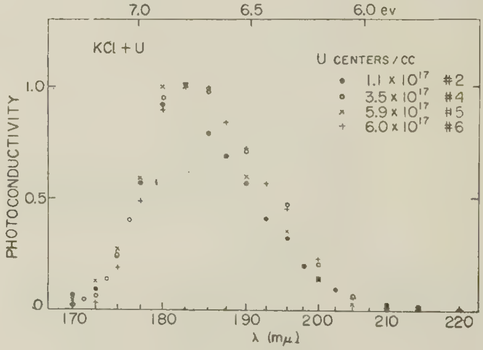

Fig. 3. Photoconductivity curves in KCl+U crystals of different histories.

Fig. 3 shows the similar photoconductivity curves in KCl crystals of different histories, where the maximum values are normalized to unity. The absolute values of photocurrent depend much on their history of preparation and heat treatment; however, all crystals have the maximum conductivity at λ 183 mμ.

On the other hand, U centers can be converted to F centers with ultra violet light. The spectral variation of the quantum yield of this conversion was investigated as reported previously[4)], and it was shown again in Fig. 4 for the comparison. The maximum yield occurs at λ 183 mμ too, and the correspondence between curves of the photoconductivity and quantum yield of U→F is clearly seen.

The similar relation between both curves was also obtained in KBr crystal as shown in Fig. 5. The maxima of the conductivity and the yield η occur at the same photon energy of λ 203 mμ. The photoconductivity curve has a shallow minimum at near the U-absorption peak and it increases toward the longer wavelength side. The shape of conductivity curve measured by Glaser[5)] is somewhat different from ours. He has observed a deep and a shallow minima at U-peak and at λ 210 mμ, respectively. The origin of such a defference is not clear. However, as seen from the Fig. 5 in his paper, U absorption band is much asymmetric and has a large absorption coefficient at the shorter wavelength side. This was considered, by Glaser, to be attributed to the overlapping of a broad band called X center. In our case, such a high concentration of X center was not detected and the U center has the symmetric bell shape.

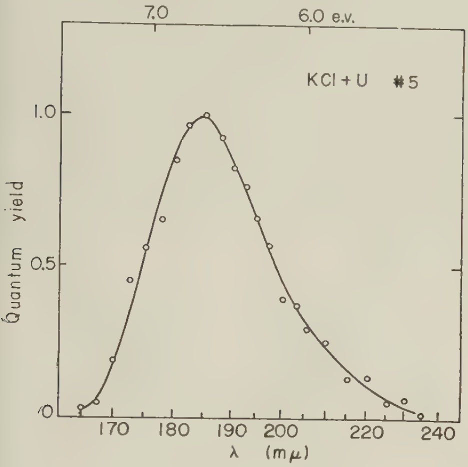

Fig. 4. Spectral variation of quantum yield of U→F in KCl crystal.

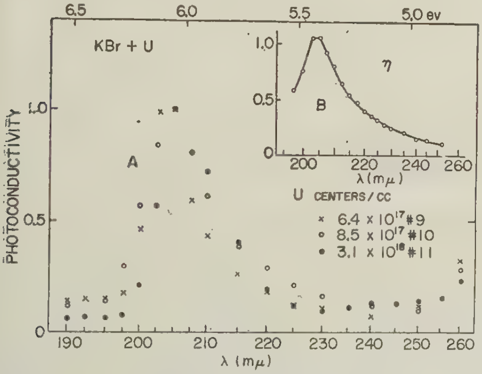

Fig. 5. The correspondence between curves of photoconductivity and quantum yield of U→F in KBr crystal.

A: Photoconductivity curve.

B: Spectral variation of quantum yield.

The OH band was not detected in KBr crystals but existed in KCl crystals. In Harshaw crystals the concentration was 8×10^{15}/cc, and 2×10^{15}/cc in other crystals. These concentrations are negligibly small compared to that of U center. However, it was confirmed that OH band does not show photoconduction.

All measurements of photocurrents were carried out with an electric field of "+direction". When the field was reversed, the photoconductivity curve in KCl was the same as that in "+direction" within an error of 20 per cent as shown in Fig. 6.

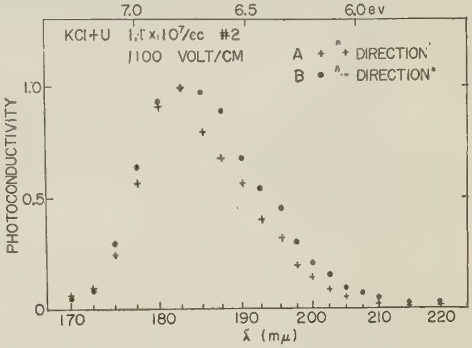

Fig. 6. Photoconductivity curve in KCl crystal with applying electric field of "+direction": curve A and "−direction": curve B.

From the detailed comparison between both curves of photoconductivity in Fig. 2 and quantum efficiency in Fig. 4, which were measured in KCl crystals #5 of the same history, it is seen that the relative value of photoconductivity in the region of U absorption band against the maximum value is very small compared to that in the case of quantum efficiency. For example, at λ 210 mμ, the photoconductivity is a few handredths of the maximum value at λ 183 mμ, but the quantum efficiency is about one fifth. This fact suggests us that the conversion of U→F occures with different mechanisms in both regions of U absorption band-peak and the shorter wavelength side.

The absorption band of U center in KCl crystal shows a shoulder in the shorter wavelength side. This is clearly seen in the absorption band of Fig. 7 measured at low temperatue. Therefore, it is probable to consider that U center has its higher excited or ionized states and absorption bands due to the transitions to these states are overlapping with each other. The similar results showing asymmetry of U band has been observed by Pohl[6] at room temperature.

We have tentatively concluded that in the region of U absorption peak, U center is excited with illumination of light and, in this excited state, the hydrogen atom diffuses to the interstitial position leaving an electron as suggested by Mott and Gurney[7], but in the region of the shorter wavelength side, an electron of U center is ionized directly or after obtaining a small activation energy. The hydrogen atom diffuses away leaving a negative ion vacancy. The ionized electron will come back to the vacancy forming an F center, because of the electrostatic attraction field.

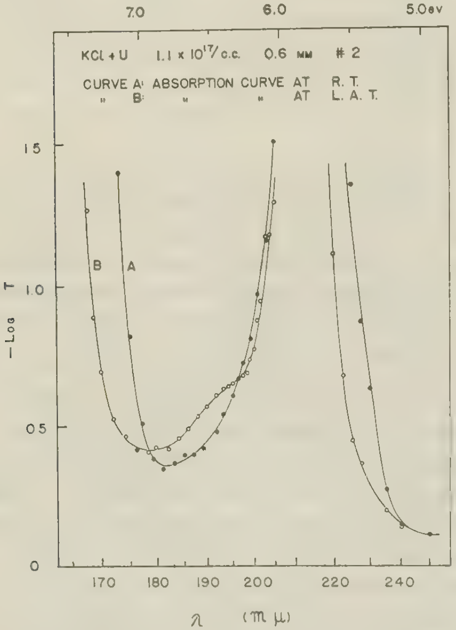

Fig. 7. Absorption curves of KCl+U crystal.
A: Measured at room temperature.
B: Measured at liquid air temperature.

When a crystal is irradiated with light in the tail of the characteristic absorption band, excitons are generated. The large photoconductivity in its absorption region indicates that excitons do ionize U centers. The sharp decrease of photoconductivity toward inside the exciton absorption band, will be attributed to the destruction of an exciton through its diffusion to the crystal surface or being trapped by imperfections probably existing more densely near the surface, because the penetration depth of light becomes small due to the high absorption coefficient.

3-2. *Dependence of Photoconductivity upon U center concentration.*

If the energy of excitons is transferred to U centers by the diffusion of excitons, it is expected that in crystals containing small concentration of U center, the photoconductivity in the exciton absorption band will decrease. As already shown in Fig. 5, in all crystals containing U centers more than 6.4×10^{17}/cc the maximum photoconductivity was observed to occur at λ203 mμ where the exciton absorption band starts. The maximum value was seven times larger than that at λ228 mμ corresponding to U-absorption peak. However in a crystal having a small concentration of 3.5×10^{16}/cc, the wavelength of light which enhance the maximum photoconductivity shifted to λ210 mμ as shown in Fig. 8, and the conductivity at λ203 mμ is only one half of that at λ228 mμ.

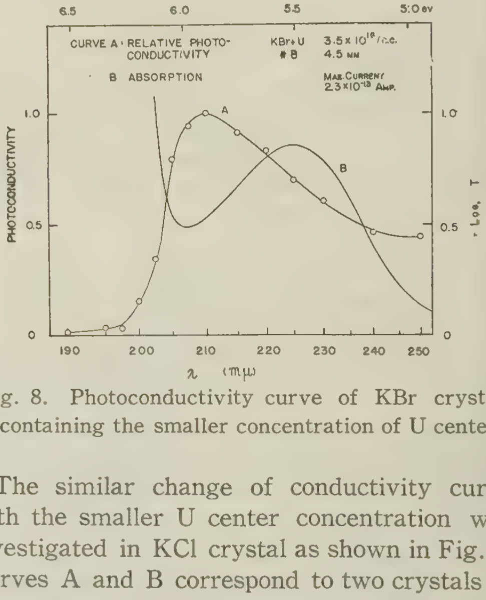

Fig. 8. Photoconductivity curve of KBr crystal containing the smaller concentration of U center.

The similar change of conductivity curve with the smaller U center concentration was investigated in KCl crystal as shown in Fig. 9. Curves A and B correspond to two crystals of #1 and 2, of which U center concentrations are 4.0×10^{16}/cc and 1.1×10^{17}/cc, respectively. The maximum point of conductivity shifted to λ185 mμ from λ183 mμ when the concentration is low, and especially the photoconductivity in the region of the fundamental absorption band decreases remarkably as in the case of KBr crystal. These facts showing the abrupt decrease in efficiency of the energy transfer from an exciton to U center, when the concentration is below 5×10^{16}/cc, will indicate the exciton diffusion through the crystal.

The same conclusion has been also deduced previously from the experiments carried out on the quantum efficiency of U→F conversion with varying the concentration. However, the present results of photoconductivity is more precise.

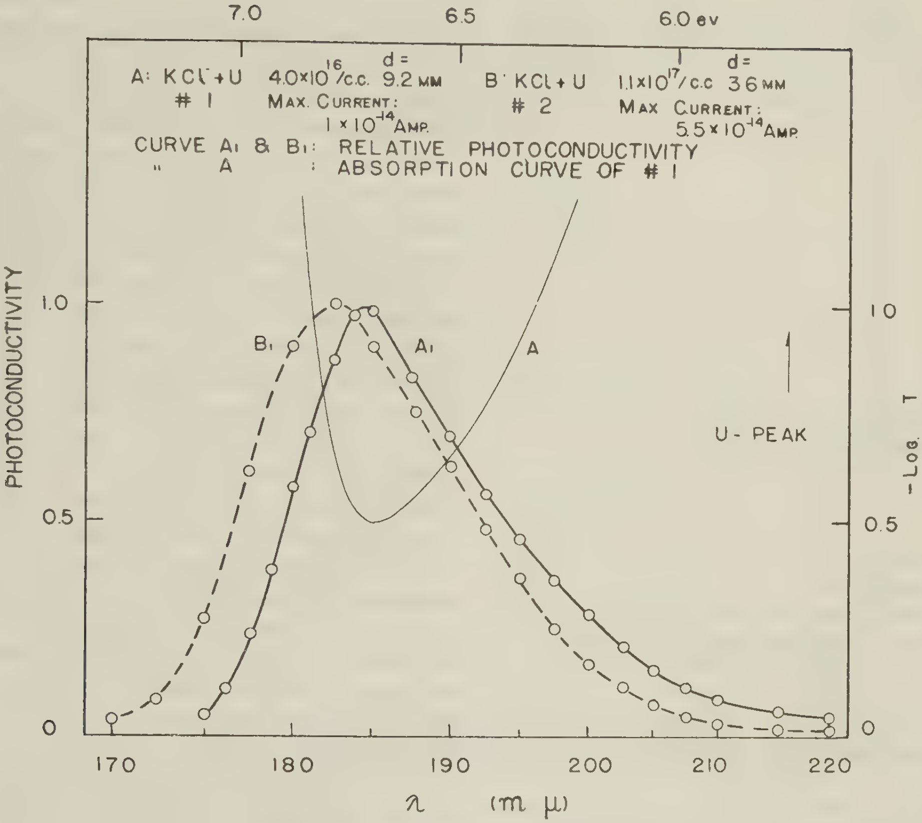

Fig. 9. Photoconductivity curves of KCl crystals containing different amount of U centers. U center concentrations are 4.0×10^{16}/cc, and 1.1×10^{17}/cc in A and B, respectively.

3–3. *Irradiation effect of ultra violet light upon the photocurrent.*

When a KCl crystal was irradiated by ultra violet light from a hydrogen discharge tube, F centers were created from U centers and the photocurrent decreases in the whole spectral region. Fig. 10 shows such an effect. Curve A shows the initial state of photoconductivity curve in a crystal of #6 before the irradiation. Curves B and C show photocurrents after 2 and 8 seconds' irradiation, respectively. The irradiation was performed at a distance of 5 cm in air through the fused quartz window of 2 mm thickness. After the 14 seconds' illumination, photocurrent drops to quite a small value as shown in curve D. At this stage, the concentration of F centers generated from U centers was only 1×10^{15}/cc. That is, inspite of that almost all U centers remain in the crystal, the decrease of photocurrent is quite large.

Next, with illuminating the crystal by white light, all F centers returned to U centers, but photocurrent recovered only a little as shown in curve E. However, it recovered gradually when the crystal was kept in dark at room temperature for 17 and 65 hours as indicated in curves F and G, respectively. Finally the initial height of photoconductivity was recovered after the crystal was annealed at 200°C for 30 hours.

From these results, it is considered that vacancies or imperfections were generated by ultra violet light and they acted as traps for electrons to make their Schubweg short. These traps seem to easily disappear by the annealing.

The similar decrease of photocurrents was observed if the crystals were heated at 520°C for 5 minutes and quenched rapidly to room temperature. Though the concentration of U center decreases to half of the initial value in this heating and quenching treatment, the photocurrent decreased to a very small value as in the case of irradiation of ultra violet light.

B and C: After 2 and 8 seconds' irradiations, respectively.

D: After 14 seconds' irradiation.

E: After white light illumination to bleach F center.

F and G: After keeping in dark at room temperature for 17 and 65 hours, respectively.

3-4. *The effect of Br ion impurity in KCl crystal.*

All KCl crystals investigated so far in the present work were confirmed to contain Br ion as an impurity of which concentration was given in Table I. The Br ion has its own absorption band and its peak locates at λ172 mμ. Due to this band the characteristic absorption tail of KCl crystal shifts to the longer wavelength side. Therefore, the question might exist that the observed phenomena in the region of exciton absorption band, will be attributed to Br ion, and not to the pure exciton in KCl crystal. Kobayashi and Tomiki[8] prepared the purer KCl crystals very carefully from $KHCO_3$ and HCl acid. The crystal is designated by #7. The Br ion concentration is as low as 9×10^{-6} mole fraction.

We have investigated the spectral variation of photoconductivity and efficiency of U→F conversion in the crystals of different amount of Br ion, in order to see the effect of Br absorption band.

Fig. 11 shows two extreme cases of the purest crystal #7 and that of high concentration of Br ion #3. Photoconductivity and absorption curves of crystals are shown by subscripts 1 and 2, respectively. Curves A and B indicate the purest and the other crystals, respectively.

As seen from the figure, the characteristic absorption tail shifts to the shorter wavelength side in the purest crystal and the maximum point of photoconductivity also shifts to λ180 mμ from λ185 mμ. On the other hand, in crystals obtained from Harshaw Chemical Co. in which the concentration of Br ion is 7×10^{-5} mole fraction, the fundamental absorption tail shifts to the longer wavelength side compared to the crystal of #7 and the maximum photoconductivity occurs at λ183 mμ.

The maximum quantum efficiency of U→F conversion occurs at the shorter wavelength side in the purer crystal as the Br ion concentration decreases as shown in Fig. 12 which was measured and will be reported in detail by Ishii. However, in every crystals, the maximum photoconductivity and quantum efficiency occur always near the edge of the host absorption band.

Even in the purest crystal of #7, absorption tail is somewhat modified by the Br ion, because it contains Br ion of 9×10^{-6} mole fraction. From the analysis of the band shape of Br ion, it was concluded that at λ175 mμ, 88 per cent of the total absorption coefficient of the crystal is due to the KCl and the remaining 12 per cent is due to Br ions[8], and at λ177 mμ, 50 per cent of absorption is due to the Br. At<λ173 mμ, almost all absorption is attributed to the pure KCl crystal. Therefore, from the photoconductivity and quantum yield measurements in Fig. 11 and 12, it is concluded that the observed phenomena in the region of absorption band of host crystal is attributed to the pure exciton in KCl crystal.

Inspite of the fact that in the crystal #3, as seen from the Fig. 11, all photon in the region of λλ182 mμ-177 mμ are absorbed in Br band and not in the host crystal, the photoconductivity and quantum yield of U→F have large values. This fact indicates that the photon energy absorbed in Br ion can be transferred to U center with high efficiency as that absorbed in the host crystal. This is very suggestive to the investigations of the nature of Br ion in KCl crystal. Photons absorbed in these ions may be considered to from the localized

excitons, but so far as the interaction with U center are concerned, there is no difference between these excitons and the free excitons.

Acknowledgements

We would like to thank Professor K. Kobayashi for the discussions on the fundamental absorption tail of KCl crystals containing Br ion as an impurity. One of the authors (M.U.) is indebted to Professor H. Pick for his kindness of discussing and showing the data of Pohl and Glaser. He also wishes to thank Professor Hilsch and Dr. Martienssen for the stimulating discussions. This work was supported by the Scientific Research Fund of the Ministry of Education.

Theoretical Prediction of the Pressure Distribution on a Non-lifting, Thin Symmetrical Aerofoil at Various Transonic Speeds

By Iwao HOSOKAWA

National Aeronautical Laboratory, Mitaka Shinkawa, Tokyo

(Received October 5, 1960)

Theoretical pressure distributions on a non-lifting, circular-arc aerofoil at various transonic speeds are obtained by application of a new method recently published by the author. The method consists essentially of a refinement of the linearized transonic flow theory in which the nonlinear characteristics of the fundamental equation are taken into account. The results reveal most of principal phenomena observed in experimental studies throughout the whole Mach number range.

§1. Introductory Remarks

Recently, a useful method of analysis on the transonic flows around a thin obstacle was proposed by the author.[1] Its basic idea consists in the correction of the linearized transonic flow theory[2],[3] in which the nonlinearity of the flow field is taken into account. In one of the previous papers,[1] the logical structure of the theory and the main features deduced from it are described together with two examples of calculation for the sonic flow case ($M_\infty=1$).

The other paper[4] treats the transonic flow past a wavy wall as a simple but interesting example of applications of the theory. The result for the lower critical flow is nearly in agreement with Kaplan's more exact one. Furthermore, it illustrates various flows including shock waves plausible for the higher free-stream Mach numbers.

However, there remains another family of the more important cases of the transonic flow, that is, the flow around an isolated aerofoil. In this paper, a symmetrical circular-arc aerofoil is dealt with as a typical example of such problems; first the behaviours of the sonic and shock points on the aerofoil in accordance with the change of the transonic similarity parameter are examined in detail, as a necessary process of the present method, and next, various velocity and pressure distributions on the aerofoil are obtained. Also the pressure drag is plotted against the transonic similarity parameter, and compared with data published by other authors. All the quantities are arranged in the reduced form consistent with the transonic similarity law for the sake of simplicity and convenience of utilization. In the next section, a summarized description of our method is given.

§2. Summary of the Method

The differential equation for the steady, two-dimensional transonic flow is as follows:

$$(1-M_\infty^2)\Phi_{xx}+\Phi_{yy}=(\gamma+1)M_\infty^2\Phi_x\Phi_{xx} \tag{2.1}$$

where $U_\infty\Phi$ is the perturbation velocity potential; γ is the ratio of specific heats; M_∞ and U_∞ are the Mach number and the velocity of the free stream respectively; and the x-axis is taken in the direction of the free stream.

In order to obtain the approximate solution, Oswatitsch[2] and Maeder[3] suggest to deal with the following equation (the linearized transonic flow theory);

$$(1-M_\infty^2)\varphi_{xx}+\varphi_{yy}=K\varphi_x \tag{2.2}$$

in which K is a constant having the meaning of the acceleration at a certain point of the flow field, as is known from comparison of (2.1) and (2.2).

Now it has been derived in the previous paper[1] that a more exact solution of (2.1) based upon reasonable assumptions could be obtained provided the solution of the linearized equation (2.2), $\varphi(x;\ K)$, were found. The procedure of refinement can be written as follows:

$$\Phi_x=(1-M_\infty^2)/[(\gamma+1)M_\infty^2]\pm\sqrt{Y(x)} \tag{2.3}$$

where

$$Y(x)=\left\{\frac{1-M_\infty^2}{(\gamma+1)M_\infty^2}\right\}^2+\varphi_x^2(c^*)-2\frac{1-M_\infty^2}{(\gamma+1)M_\infty^2}\varphi_x(x)+2\frac{K}{(\gamma+1)M_\infty^2}\{\varphi(x)-\varphi(c^*)\} \tag{2.4}$$

and the double sign corresponds to

$$\varphi_x\gtrless(1-M_\infty^2)/[(\gamma+1)M_\infty^2] \tag{2.5}$$

respectively. In the above equation, the unknown constants c^* and K should be determined according to the following prescriptions;

$$1-M_\infty^2=(\gamma+1)M_\infty^2\varphi_x(c^*;\ K) \tag{2.6}$$

$$K=(\gamma+1)M_\infty^2\varphi_{xx}(c^*;\ K) \tag{2.7}$$

The both constitute the simultaneous algebraic equations for c^* and K in case of usual transonic flow. The former represents that $x=c^*$ is the sonic point on the surface of the aerofoil. If (2.6) has more than one root for c^*, $x=c^*$ must be the sonic point in the accelerated region of the flow. The latter equation, on the other hand, serves in determining $K(>0)$ as equal to the acceleration of the flow at the sonic point on the aerofoil. In case of purely sub- or supersonic flow, (2.6) has no root; but also in this case c^* should take the fixed value of the (lower or upper) critical point in order to ensure the continuity of the solution from transonic to sub- or supersonic, and then K is determined by (2.7) for this value of c^*.

Finally, we shall now enumerate some characteristic features of our approach:[1]

1) The constant K is uniquely determined and there is no such ambiguity as is seen in the linearized transonic flow theory.

2) The occurrence of shock is predicted as the discontinuities in the pressure and velocity on the surface.*

3) The procedure of approximation is very simple, because it does not require any assumption or knowledge about the entire flow field and the whole shape of the sonic and shock lines; nevertheless the results obtained by the method are reliable, in so far as our estimation is valid on the order of magnitude of various quantities in the neighbourhood of the obstacle.

§ 3. The Linearized Transonic Flow

According to Maeder's theory, the formal solutions of (2.2) representing the linearized transonic flow past a thin, symmetrical aerofoil are written as follows:

$$\varphi(x,\ y)=-\frac{1}{2\pi}\int_0^1 F'(\xi)\frac{e^{\alpha(x-\xi)}}{\beta}K_0(\alpha\sqrt{(x-\xi)^2+\beta^2y^2})\xi p,\quad M_\infty\leqq1 \tag{3.1}$$

---

* Though it is not affirmed from the standpoint of the exact treatment of the problem (Lin and Rubinov[5]) that a normal shock wave stays on the curved surface, it may be admitted for an approximate treatment.

$$\varphi(x, y)=-\frac{1}{2}\int_0^{x-my} F'(\xi)\frac{e^{\alpha(x-\xi)}}{m} I_0(|\alpha|\sqrt{(x-\xi)^2-m^2y^2})d\xi\ , \quad M_\infty\geqq 1 \tag{3.2}$$

where α, β and m are related to each other as

$$\beta^2=1-M_\infty{}^2=-m^2\ , \quad \alpha=K/2\beta^2; \tag{3.3}$$

$F(x)$ is the cross-sectional area of the aerofoil, whose chord length can be assumed unity without loss of generality, the origin of the co-ordinate being at the leading edge; and K_0 and I_0 are the modified Bessel functions of the zeroth order.

1) *Subsonic case* ($M_\infty\leqq 1$)

On the aerofoil, we can have the limit:

$$\lim_{y\to 0}\varphi(x, y)=-\frac{1}{2\pi}\int_0^1 F'(\xi)\frac{e^{\alpha(x-\xi)}}{\beta}K_0(\alpha|x-\xi|)d\xi \tag{3.4}$$

since the integral is uniformly covergent when y tends to zero. Thus, its derivative is

$$\lim_{y\to 0}\varphi_x=\frac{1}{2\pi\beta}\int_0^1 F'(\xi)\frac{\partial}{\partial\xi}\{e^{\alpha(x-\xi)}K_0(\alpha|x-\xi|)\}d\xi \tag{3.5}$$

$$=\frac{1}{2\pi\beta}\left\{F'(\xi)\, e^{\alpha(x-\xi)}\, K_0(\alpha|x-\xi|)\Big|_{\xi=0}^{\xi=1}-\int_0^1 F''(\xi)e^{\alpha(x-\xi)}K_0(\alpha|x-\xi|)d\xi\right\}. \tag{3.6}$$

If $F(\xi)$ is expressed by a polynomial (which means a sharp-edged aerofoil), we can express $F''(\xi)$ with a power series:

$$F''(\xi)=\sum_{n=0} a_n\xi^n \tag{3.7}$$

and the integral in (3.6) can be reduced to the following forms:

$$J_n=\int\xi^n e^{\alpha(x-\xi)}K_0(\alpha|x-\xi|)d\xi\ , \quad n=0,\ 1,\cdots. \tag{3.8}$$

The integration can conveniently be carried out by taking account of Schläfli's integrals of Poisson's type for the modified Bessel functions[14] and their derivatives:

$$z^{-\nu}K_\nu(z)=z^{-\nu}K_{-\nu}(z)=\frac{\Gamma(1/2)}{2^\nu\Gamma(\nu+1/2)}\int_0^\infty e^{-zt}(t^2-1)^{\nu-1/2}dt \tag{3.9}$$

$$\frac{d}{dz}[z^{-\nu}K_{-\nu}(z)]=-\frac{\Gamma(1/2)}{2^\nu\Gamma(\nu+1/2)}\int_0^\infty te^{-zt}(t^2-1)^{\nu-1/2}dt\ . \tag{3.10}$$

First, we shall deal with J_0:

$$J_0=\int e^{\alpha(x-\xi)}K_0(\alpha|x-\xi|)\,d\xi=\int_0^\infty(t^2-1)^{-1/2}dt\int e^{\alpha(x-\xi)-\alpha|x-\xi|t}d\xi \tag{3.11}$$

$$=\int_0^\infty(t^2-1)^{-1/2}\frac{e^{\alpha(x-\xi)(1\mp t)}}{-\alpha(1\mp t)}dt$$

$$=-\frac{1}{\alpha}e^{\alpha(x-\xi)}\left\{-\int_0^\infty e^{-\alpha|x-\xi|t}(t^2-1)^{-3/2}\,dt\mp\int_0^\infty te^{-\alpha|x-\xi|t}(t^2-1)^{-3/2}dt\right\}$$

$$=-\frac{1}{\alpha}e^{\alpha(x-\xi)}\left\{\alpha|x-\xi|K_1(\alpha|x-\xi|)\mp\frac{d}{d(\alpha|x-\xi|)}\alpha|x-\xi|K_1(\alpha|x-\xi|)\right\} \tag{3.12}$$

in which the double sign corresponds to $x\gtrless\xi$, respectively. Thus we get

$$J_0=-e^{\alpha(x-\xi)}\{|x-\xi|K_1(\alpha|x-\xi|)+(x-\xi)K_0(\alpha|x-\xi|)\} \tag{3.13}$$

by use of the relation $d/dz(zK_1(z))=-zK_0(z)$. In a general case of J_n, a similar procedure leads to the result which includes the modified Bessel functions of the higher order with the aid of (3.9) and (3.10).

For a circular-arc aerofoil which is certainly the simplest case, we can obtain the following integrated expression of (3.1), taking account of $F(\xi)=4t(\xi-\xi^2)$ $(F''(\xi)=-8t)$ and (3.13);

$$\varphi_x=\frac{4t}{\pi\beta}\left[e^{\alpha(x-\xi)}\left\{\left(\frac{1}{2}-x\right)K_0(\alpha|x-\xi|)-|x-\xi|K_1(\alpha|x-\xi|)\right\}\right]_{\xi=0}^{\xi=1} \tag{3.14}$$

or

$$=\frac{4\pi}{\pi\beta}\left[e^{\alpha(x-1)}\left\{\left(\frac{1}{2}-x\right)K_0[\alpha(1-x)]-(1-x)K_1[\alpha(1-x)]\right\}\right.$$
$$\left.-e^{\alpha x}\left\{\left(\frac{1}{2}-x\right)K_0(\alpha x)-xK_1(\alpha x)\right\}\right]. \tag{3.15}$$

In the limit, $\alpha\to\infty$ and $\beta\to 0$ $(M_\infty=1-0)$, (3.15) becomes

$$\varphi_x=-\frac{2t}{\sqrt{\pi K}}(x^{-1/2}-4x^{1/2}) \tag{3.16}$$

as was already proved by another way in the previous work.[1)]

Differentiation of (3.15) gives

$$\varphi_{xx}=\frac{4t}{\pi\beta}\left[e^{\alpha(x-1)}\left\{\left(-\frac{1}{2}\alpha-1\right)K_0[\alpha(1-x)]-\frac{1}{2}\alpha K_1[\alpha(1-x)]\right.\right.$$
$$\left.\left.-e^{\alpha x}\left\{\left(\frac{1}{2}\alpha-1\right)K_0(\alpha x)-\frac{1}{2}\alpha K_1(\alpha x)\right\}\right]. \tag{3.17}$$

In Maeder's theory K should be determined as follows:

$$K=(\gamma+1)M_\infty^2\varphi_{xx}\left(x=\frac{1}{2};\ K\right). \tag{3.18}$$

After rearranging this equation, we get

$$\frac{\pi}{2}(-\xi_\infty)^{3/2}\left(\frac{\alpha}{2}\right)=\left(\sinh\frac{\alpha}{2}-\frac{\alpha}{2}\cosh\frac{\alpha}{2}\right)K_0\left(\frac{\alpha}{2}\right)+\frac{\alpha}{2}\sinh\frac{\alpha}{2}K_1\left(\frac{\alpha}{2}\right). \tag{3.19}$$

We know from this equation that $\alpha/2$ has a non-vanishing solution only when $(\pi/2)(-\xi_\infty)^{3/2}<1$, that is, $-(2/\pi)^{2/3}<\xi_\infty<0$. In addition to that, the equation has a trivial solution $\alpha=0$ for all negative values of ξ_∞. Thus the point $\xi_\infty=-(2/\pi)^{2/3}$ makes a branch point on the diagram of ξ_∞ versus α, or ξ_∞ versus c^*, as is seen in Fig. 1. Within the range between $-(2/\pi)^{2/3}<\xi_\infty<0$, we must of course adopt the finite solution since the significant characteristics of the transonic flow are given only by the non-vanishing solution of $\alpha/2$ or K; in the other range, however, the solution $\alpha=0$ is useful, which provides Prandtl-Glauert's approximation in itself. Maeder's theory is interesting in that it leads to an existence of a symmetric solution $(\alpha=0)$ which results in no pressure drag even at the supercritical state $(\xi_\infty>-(4/\pi)^{2/3}$, which is derived from (3.15)).

2) *Supersonic case* $(M_\infty\geqq 1)$

After the treatment similar to the previous case, we have

$$\lim_{y\to 0}\varphi(x,\ y)=-\frac{1}{2}\int_0^x F'(\xi)\frac{e^{\alpha(x-\xi)}}{m}I_0(|\alpha|(x-\xi)]d\xi \tag{3.20}$$

$$\lim_{y\to 0}\varphi_x=-\frac{1}{2m}F'(x)+\frac{1}{2m}\int_0^x F'(\xi)\frac{\partial}{\partial\xi}e^{-|\alpha|(x-\xi)}I_0[|\alpha|(x-\xi)]d\xi \tag{3.21}$$

$$=-\frac{1}{2m}\left\{F'(0)e^{-|\alpha|x}I_0(|\alpha|x)+\int_0^x F''(\xi)e^{-|\alpha|(x-\xi)}I_0[|\alpha|(x-\xi)]d\xi\right\}. \tag{3.22}$$

In this case I_0 appears in place of K_0 and we are now in a position to calculate

$$J_n' = \int \xi^n e^{-|\alpha|(x-\xi)} I_0[|\alpha|(x-\xi)]d\xi. \tag{3.23}$$

The integral expressions for the I-functions[14] are as follows:

$$z^{-m}I_m(z) = z^{-m}I_{-m}(z) = \frac{1}{2^m\Gamma(m+1/2)\Gamma(1/2)}\int_{-1}^{1} e^{-zt}(1-t^2)^{m-1/2}dt \tag{3.24}$$

$$\frac{d}{dz}[z^{-m}I_{-m}(z)] = -\frac{1}{2^m\Gamma(m+1/2)\Gamma(1/2)}\int_{-1}^{1} te^{-zt}(1-t^2)^{m-1/2}dt \tag{3.25}$$

where m is an integer. (This notation (m) is used only here, so that any confusion with the parameter m implying $\sqrt{M_\infty^2-1}$ does not occur.)

First,

$$J_0' = \int e^{-|\alpha|(x-\xi)} I_0[|\alpha|(x-\xi)]d\xi = \frac{1}{\pi}\int_{-1}^{1}(1-t^2)^{-1/2}dt \int e^{-|\alpha|(x-\xi)-|\alpha|(x-\xi)t}d\xi \tag{3.26}$$

$$= \frac{1}{\pi}\int_{-1}^{1}(1-t^2)^{-1/2}\frac{e^{-|\alpha|(x-\xi)(1+t)}}{|\alpha|(1+t)}dt$$

$$= \frac{1}{\pi|\alpha|}e^{-|\alpha|(x-\xi)}\left\{\int_{-1}^{1} e^{-|\alpha|(x-\xi)t}(1-t^2)^{-3/2}dt - \int_{-1}^{1} te^{-|\alpha|(x-\xi)t}(1-t^2)^{-3/2}dt\right\}$$

$$= -\frac{1}{|\alpha|}e^{-|\alpha|(x-\xi)}\left\{|\alpha|(x-\xi)I_1[|\alpha|(x-\xi)] + \frac{d}{d[|\alpha|(x-\xi)]}|\alpha|(x-\xi)I_1[|\alpha|(x-\xi)]\right\} \tag{3.27}$$

$$= -e^{-|\alpha|(x-\xi)}\{(x-\xi)I_1[|\alpha|(x-\xi)] + (x-\xi)I_0[|\alpha|(x-\xi)]\} \tag{3.28}$$

by use of the relation, $d/dz[zI_1(z)] = zI_0(z)$. Also integration of J_n's will be performed in a similar manner to the previous case.

For a circular-arc aerofoil we get from (3.22) and (3.28)

$$\varphi_x = \frac{4t}{m}e^{-|\alpha|x}\left\{\left(x-\frac{1}{2}\right)I_0(|\alpha|x) + xI_1(|\alpha|x)\right\}. \tag{3.29}$$

In the limit, $|\alpha| \to \infty$ and $m \to 0$ ($M_\infty = 1+0$), the above equation coincides with (3.16)

Differentiation of (3.29) gives

$$\varphi_{xx} = \frac{4t}{m}e^{-|\alpha|x}\left\{\left(\frac{|\alpha|}{2}+1\right)I_0(|\alpha|x) - \frac{|\alpha|}{2}I_1(|\alpha|x)\right\}. \tag{3.30}$$

The corresponding equation to (3.19) for the supersonic case in Maeder's theory is

$$\xi_\infty^{3/2}\frac{|\alpha|}{2} = e^{-|\alpha|/2}\left\{\left(\frac{|\alpha|}{2}+1\right)I_0\left(\frac{|\alpha|}{2}\right) - \frac{|\alpha|}{2}I_1\left(\frac{|\alpha|}{2}\right)\right\}. \tag{3.31}$$

From this we know that $|\alpha|/2$ has only a non-vanishing solution in this case.

§ 4. Sonic and Shock Points on the Aerofoil

The simultaneous equations (2.6) and (2.7) are rewritten in a much simplified form by introducing a new function,

$$f(x;\ \alpha) = \pm(\sqrt{|M_\infty^2-1|}/t)\varphi_x(x;\ K) \tag{4.1}$$

in which the double sign corresponds to $M_\infty \lessgtr 1$, as follows:

$$|\xi_\infty|^{3/2} = f(c^*;\ \alpha), \tag{4.2}$$

$$2\alpha|\xi_\infty|^{3/2}=f_x(c^*;\ \alpha)\ . \tag{4.3}$$

Here c^* and α are unknown, ξ_∞ being a parameter. In the present example, (3.15), (3.17), (3.29) and (3.30) give immediately $f(x;\ \alpha)$ and $f_x(x;\ \alpha)$.

On the other hand, the position of the shock wave on the aerofoil should be determined by the other root c^{**} of the same equation (4.2) for a definite α and ξ_∞, according to the prescription given in the previous work[1].

Actual calculation of the above equations, however, is not easy because they include transcendental functions. In our case of a circular-arc aerofoil, several steps of the successive calculation were necessary with the use of Newton's method.*

In solving (4.2) and (4.3) in the present case, it is useful to know beforehand by investigating analytically the asymptotic behaviours of the equations that for $\alpha=0$, $c^*=1/2$ and $\xi_\infty=-(4/\pi)^{2/3}$; for $\xi_\infty=0$, $\alpha=\pm\infty$ and $c^*=1/4$; and for $c^*=0$, $\alpha=-2$ and $\xi_\infty=2^{2/3}$. At the same time we have a knowledge by dealing with the equation of c^{**} that for $\alpha=0$ and $\xi_\infty=-(4/\pi)^{2/3}$, $c^{**}=1/2$; and for $\xi_\infty=0$ and $\alpha=\infty$, $c^{**}=1$. The calculated results are indicated in Table I as well as in Fig. 1.

In Fig. 1, the present result is compared with the theoretical ones by Maeder (linearized transonic flow theory) and by Spreiter (integral equation method)[6], and many experimental data.[7)-9)] The sonic and shock points appear at first both on the midchord of a circular-arc aerofoil at the critical speed of the free

* The author had recourse to an electric computer of relay type at Yulin Denki Seiki Co. Ltd..

stream, the former going ahead and the latter receding back monotonously with increasing Mach number. In this respect, Maeder's theory indicates a peculiar behaviour of the sonic point in the neighbourhood of the branch point, $\xi_\infty=-(2/\pi)^{2/3}$. The present result concerning the behaviour of the sonic point is in good accord with experiments throughout the whole transonic range of ξ_∞, though Spreiter's one is better for the smaller range of ξ_∞ near the critical speed. Furthermore the present method predicts the upper critical value of ξ_∞ very close to the exact one ($=1.74$, which can be found from the oblique-shock relation), whereas Spreiter's result by the local linearization method gives the value 2.08.[13]

Now with respect to the position of the shock wave on the aerofoil, it may be pointed out that the present theory predicts it much closer to the experimental data than Spreiter's although the experimental data show certain indefiniteness such that the shock wave changes its position considerably depending on the thickness ratio of the aerofoil and the Reynolds number of the flow*; the shock wave predicted

by Spreiter seem to recede too rapidly with increasing ξ_∞.

It is interesting to note that the nature of our curve which is nearly horizontal and flat at $x=0.5-0.75$ suggests unstableness of the position of the shock wave just after the lower critical value of ξ_∞ is surpassed. Namely if the main flow suffers non-uniformity expressed by ΔM_∞, the shock wave will be unstable and fluctuate from its original position by the amount

$$\Delta c^{**}=\frac{\partial c^{**}}{\partial \xi_\infty}\frac{2M_\infty^2+4}{3M_\infty\{(\gamma+1)M_\infty^2 t\}^{2/3}}\Delta M_\infty\,. \qquad (4.4)$$

The thinner the aerofoil is, the more unstable is the position for the same grade of the assumed non-uniformity of the free stream.

§ 5. Pressure and Velocity Distributions

By use of the reduced velocity $\bar{u}$ and $f(x, \alpha)$, (2.3), (2.4) and (2.5) are simplified, as follows:

$$\bar{u}=\frac{\{M_\infty^2(\gamma+1)\}^{1/3}}{t^{2/3}}\Phi_x \qquad (5.1)$$

$$=-\xi_\infty\pm\sqrt{\eta(x)} \qquad (5.2)$$

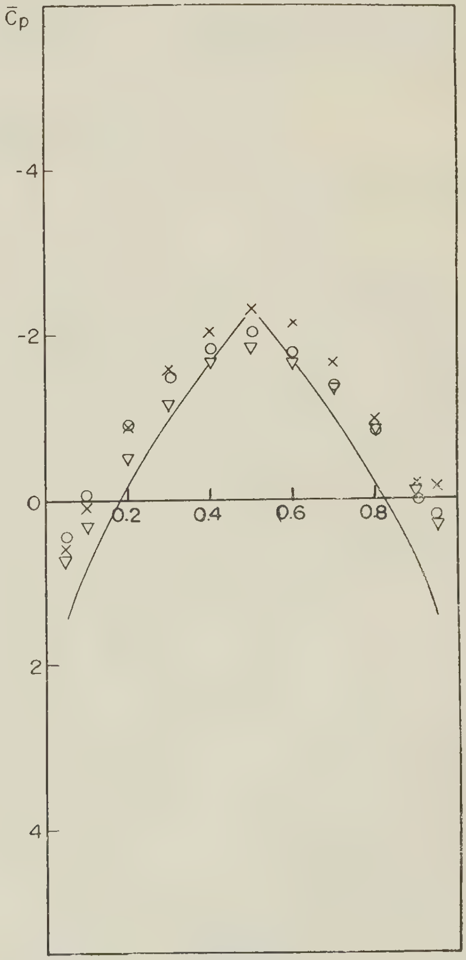

Fig. 5. Pressure distribution on a circular-arc aerofoil in the lower critical flow.
Theory —— Present ($\xi_\infty=-1.1745$)
Experiment, Michel et al[8)]
○ $M_\infty=0.770$, $t=0.12$ ($\xi_\infty=-1.3226$)
× $M_\infty=0.835$, $t=0.08$ ($\xi_\infty=-1.1567$)
▽ $M_\infty=0.870$, $t=0.06$ ($\xi_\infty=-1.0653$)

$$\eta(x)=\xi_\infty^2+(1/|\xi_\infty|)f^2(c^*;\ \alpha)-2\sqrt{|\xi_\infty|}\,f(x;\ \alpha)+4\alpha\sqrt{|\xi_\infty|}\int_{c^*}^{x}f(x;\ \alpha)dx \tag{5.3}$$

the double sign corresponding to

$$\left.\begin{array}{ll}\xi_\infty^2-\sqrt{|\xi_\infty|}\,f(x;\ \alpha)\leqq 0\,, & \text{for } M_\infty<1\\ \text{and} & \\ \xi_\infty^2-\sqrt{|\xi_\infty|}\,f(x;\ \alpha)\geqq 0\,, & \text{for } M_\infty>1\end{array}\right. \tag{5.4}$$

As α is uniquely related to ξ_∞, (5.2) is the expression consistent with the transonic similarity law.

By use of this expression, we obtain the two formulae for reduced physical quantities as follows;
for *pressure coefficient* C_p;

$$\bar{C}_p=\{M_\infty^2(\gamma+1)\}^{1/3}t^{-2/3}C_p=-2\bar{u} \tag{5.5}$$

$$=2\xi_\infty\mp2\sqrt{\eta(x;\xi_\infty)} \tag{5.6}$$

for *local Mach number* M;

$$\begin{aligned}\bar{u}+\xi_\infty&=\{(\gamma+1)tM_\infty^2\}^{-2/3}\{(\gamma+1)M_\infty^2\Phi_x-(1-M_\infty^2)\}\\&=(M^2-1)/\{(\gamma+1)tM_\infty^2\}^{-2/3}\cong2(M-1)/\{(\gamma+1)t\}^{-2/3}\end{aligned} \tag{5.7}$$

and we have only to remark that

$$\bar{u}+\xi_\infty \gtreqqless 0 \text{ corresponds to } M \gtreqqless 1\,. \tag{5.8}$$

The both results calculated for various values of ξ_∞ are shown in Figs. 2 and 3. The variations of them with ξ_∞ seem to be reasonable as a whole. In the sub- and supersonic extremities, they are in accord with the results obtained by the conventional linear theories. At the lower critical value of ξ_∞, the curve of the velocity distribution makes an angular shift at the sonic point and it is interesting to compare with the well-known critical state of the one-dimensional flow. For ξ_∞ above the lower critical value, a normal shock wave appears on the aerofoil, and arrives at the trailing edge at $\xi_\infty=0$.

Fig. 4 is presented for comparison with other theories.[11),12)] They are compared with Liepmann's experiment[10)] which was performed for a circular-arc aerofoil of $t=0.12$ in the supercritical flow of $M_\infty=0.895$ ($\xi_\infty\doteqdot-0.526$). First it is seen that Maeder's result[11)] is better in this régime of transonic flow (*cf.* Fig. 9), probably due to the viscous effect which destroys the formation of a shock wave near the aerofoil. Next, Spreiter's result[12)] overestimates the negative pressure on the aerofoil, particularly in the rear portion. This is in close relation to his prediction of rapid receding of the position of shock wave (described in the previous section). Thus, our prediction could be considered rather successful as a conclusion from the inviscid, nonlinear theory.

Figs. 5, 6 and 7 are provided in addition in order to compare our results with Michel's experiments (ONERA).[8)] They offer three typical examples of flows; that is, the lower critical, supercritical, and supersonic flows.

§ 6. Shock Wave at the Trailing Edge

We have learned that the normal shock arrives at the trailing edge when $\xi_\infty=0$. Then, what happens on the velocity discontinuity when ξ_∞ becomes positive? Certainly the velocity discontinuity will then lose the meaning of a normal shock and take the feature of an oblique shock, which we shall prove mathematically within the present theory as follows.

After the trailing edge, we should have

$$\varphi_x=\frac{1}{2m}\int_0^1F'(\xi)\frac{\partial}{\partial\xi}e^{-|\alpha|(x-\xi)}I_0[|\alpha|(x-\xi)]d\xi \tag{6.1}$$

$$= -\frac{1}{2m}\Big\{F'(0)e^{-|\alpha|x}I_0(|\alpha|x) - F'(1)e^{-|\alpha|(x-1)}I_0[|\alpha|(x-1)]$$

$$+ \int_0^1 F''(\xi)e^{-|\alpha|(x-\xi)}I_0[|\alpha|(x-\xi)]d\xi\Big\} \tag{6.2}$$

$$= \frac{2t}{m}\,[e^{-|\alpha|x}\{(2x-1)I_0(|\alpha|x)+2xI_1(|\alpha|x)\}$$

$$-e^{-|\alpha|(x-1)}\{(2x-1)I_0[|\alpha|(x-1)]+2(x-1)I_1[|\alpha|(x-1)]\}] \tag{6.3}$$

with the aid of (3.28). In the limit when x approaches the trailing edge upstream, this becomes

$$\varphi_x(1+0) = \frac{2t}{m}\,[e^{-|\alpha|}\{I_0(|\alpha|)+2I_1(|\alpha|)\}-1] < 0\ . \tag{6.4}$$

From (3.29), on the other hand, the limit when x approaches there downstream is obtained as

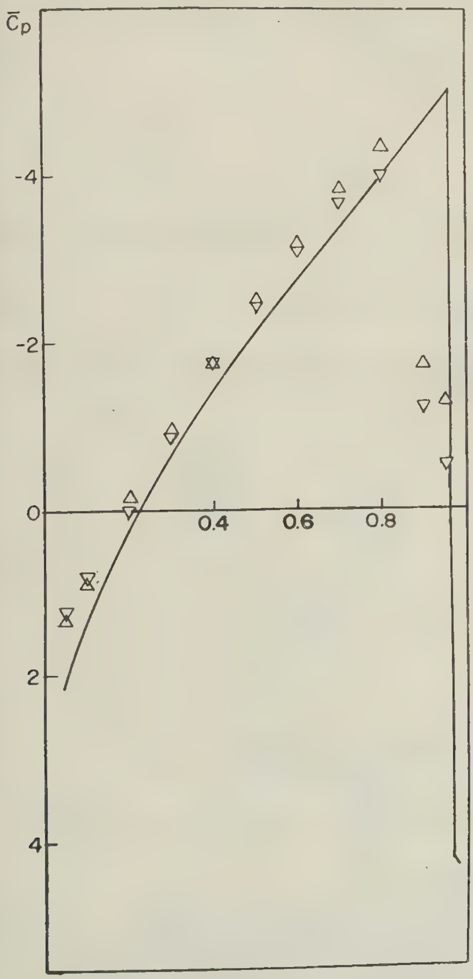

Fig. 6. Pressure distribution on a circular-arc aerofoil in the supercritical flow.
Theory ——— Present ($\xi_\infty=-0.2110$)
Experiment, Michel et al[8)]
△ $M_\infty=0.955,\ t=0.10\ (\xi_\infty=-0.2422)$
▽ $M_\infty=0.970,\ t=0.06\ (\xi_\infty=-0.2240)$

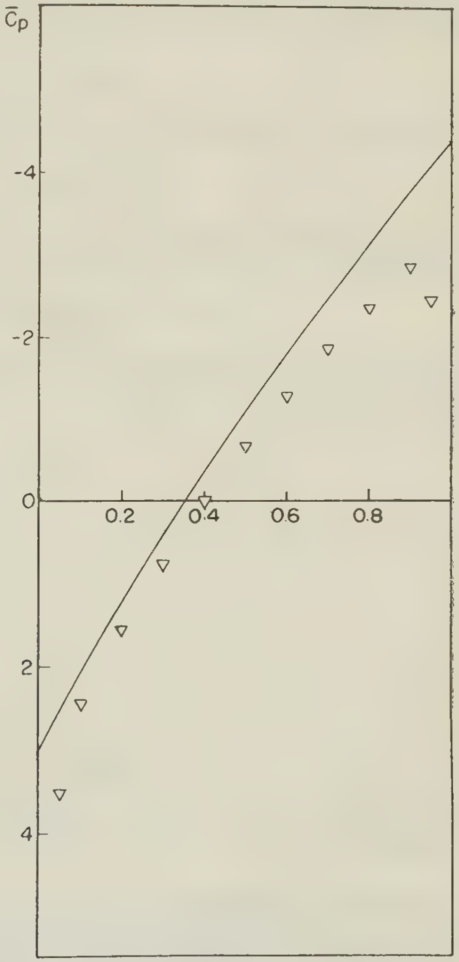

Fig. 7. Pressure distribution on a circular-arc aerofoil in the supersonic, but below upper critical flow.
Theory ——— Present ($\xi_\infty=0.8226$)
Experiment, Michel et al[8)]
▽ $M_\infty=1.125,\ t=0.06\ (\xi_\infty=0.8264)$

$$\varphi_x(1-0)=\frac{2t}{m}\,[e^{-|\alpha|}\{I_0(|\alpha|)+2I_1(|\alpha|)\}>0\,. \tag{6.5}$$

Now from (6.4) and (6.5), the following relation can be derived;

$$Y(1-0)\geqq Y(1+0) \tag{6.6}$$

(Here it is noted that the last term of the right-hand side of (2.4) has the same value in both limits, since $\varphi(1\pm0)-\varphi(c^*)=\int_{c^*}^{1}\varphi_x dx.$)

The equality holds only when $M_\infty=1$ and at the extremity, $M_\infty\to\infty$. These results may be considered to elucidate qualitatively the above-mentioned fact, the resonable behaviour of the supersonic flow at the trailing edge.

Moreover, it can be shown that when ξ_∞ is equal to 0.833 (which is smaller than the upper critical value), the oblique shock changes suddenly to that belonging to the weak family The proof is as follows.

According to the rule (2.5), the sign to be attached to $\sqrt{Y(1+0)}$ should change from minus to plus when

$$\varphi_x(1+0)=(1-M_\infty^2)/[(\gamma+1)M_\infty^2]\,. \tag{6.7}$$

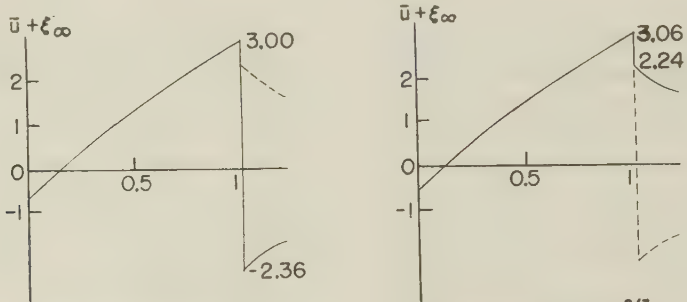
This condition is expressed by use of (6.4) as

$$2[e^{-|\alpha|}\{I_0(|\alpha|)+2I_1(|\alpha|)\}-1]=-\xi_\infty^{3/2}\,. \tag{6.8}$$

Since $|\alpha|$ is already uniquely related to ξ_∞ as described in § 4., we can solve (6.8) and obtain $|\alpha|\doteqdot3.85$ and $\xi_\infty^{3/2}\doteqdot0.76$ ($\xi_\infty\doteqdot0.833$). Then we have

$$Y(1+0)=2K/[(\gamma+1)M_\infty^2]\cdot\{\varphi(1+0)-\varphi(c^*)\}>0\,. \tag{6.9}$$

For example, velocity distributions for two cases are shown in Fig. 8; each corresponds to ξ_∞, a little smaller (a), and larger (b) than this value, respectively.



(a) $\xi_\infty=(0.746)^{2/3}=0.823$

(b) $\xi_\infty=(0.963)^{2/3}=0.975$

Fig. 8. Illustration of conversion of the shock-wave family at the trailing edge of a circular-arc aerofoil. ($\xi_\infty=0.833$ is the point of conversion.)

This result is qualitatively correct. Because, first, when the supersonic flow is deflected by a very small angle at the trailing edge, it can either drop to subsonic through a strong shock wave, or remain supersonic through a weak shock wave, as is known from the consideration by the shock polar; next there is a normal shock at the trailing edge in the case of $M_\infty=1$ in the present theory and, on the other hand, naturally we have a weak shock for higher Mach numbers where the flow about there is purely supersonic; and therefore it is quite unavoidable that a sudden, discontinuous change of the family of shock occurs at some value of M_∞ larger than one with increasing Mach number. As is proved already ((6.6)), the weak shock tends to the Mach wave in the supersonic linear theory.

§ 7. Pressure Drag

The reduced drag coefficient $\bar{C}_d$ is evaluated as follows:

$$\bar{C}_d = \frac{\{(\gamma+1)M_\infty^2\}^{1/3}}{t^{5/3}} C_d$$

$$= \frac{\{(\gamma+1)M_\infty^2\}^{1/3}}{t^{5/3}} \int_0^1 F'(x) C_p(x) dx \qquad (7.1)$$

$$= \int_0^1 (1/t) F'(x) \bar{C}_p(x;\ \xi_\infty) dx\ . \qquad (7.2)$$

In case of a circular-arc aerofoil,

$$\bar{C}_d = \int_0^1 4(1-2x) \bar{C}_p(x;\ \xi_\infty) dx\ . \qquad (7.3)$$

For the case of $M_\infty < 1$, the range of integration is conveniently reduced to (0.05—0.95), because the flow has singularities of the same type at the leading and trailing edges, and the maximum error of $\bar{C}_d$ due to this approximation will be within about 0.1.

The calculated results are shown in Fig. 9 with other data. It is noted, however, that in our result a slightly negative drag which amounts to -0.2 at most is obtained within a very small range of ξ_∞ just above the lower critical value. It is probably due to the concentrated effect of the theoretical error in the neighbourhood of the leading and trailing edges;[1] but it may be considered practically insignificant.

Comparing with the experimental data in the figure, Maeder's theory seems to give a

Maeder[11]

···◇··· $t=0.1$ (slotted wall)

good result at least for ξ_∞ near zero, in the subsonic side but it fails for other ranges of ξ_∞.[11] One of his results that there exists a supercritical, symmetric, shock-free solution for ξ_∞ smaller than $-(2/\pi)^{2/3}$ contradicts the experimental fact. On the other hand, Spreiter's integral equation method[6),12)] results in the unnatural, too rapid increase of drag for ξ_∞ just above the lower critical value, though it predicts that critical value itself rather well. This is considered a reflection of the rapid receding of the shock wave and the overestimation of the velocity distribution in his result as were stated before. The local linearization method gives good results locally for the proper ranges of ξ_∞.[6),13)] But it seems that the phenomenon of sonic freezing is not so remarkable in the subsonic side as expected, in this theory from the experimental point of view. Thus among all these results, the present theory seems to be the most satisfactory as a whole, considering the general trend of experiments.

For reference, the famous drag-curve for a diamond aerofoil is added, which was given theoretically by Trilling, Guderley and Yoshihara, and Vincenty and Wagoner. The both bear a much qualitative resemblance but that the lower critical value of ξ_∞ for a diamond aerofoil vanishes whereas that for the present aerofoil is equal to $-(4/\pi)^{2/3}$.

§ 8. Concluding Remarks

As an example of application of the author's method developed in the previous paper, various transonic flows around a circular-arc aerofoil were calculated with success. This method can be directly applied to any thin aerofoil as far as its profile is expressed by a polynomial. If a high speed computer is available, applicability will further be enlarged.

These results are significant in verifying the following facts: First, transonic flows around a thin aerofoil can be treated by systematical analysis throughout the whole range of Mach number so that a plausible transition of the flows with M_∞ be given in the first-order approximation, and secondly the quadratic nature of the nonlinear equation gives rise to the shock wave in the flow field inevitably in some case. This is also consistent with the general view that it is probably impossible to have a smooth supersonic zone enclosed within a subsonic field.

Finally the author wishes to express his hearty thanks to members of the National Aeronautical Laboratory for their valuable discussions.

Effect of a Magnetic Field upon the Stability of Free Boundary Layers between Two Uniform Streams

By Kanefusa GOTOH

Department of Physics, Faculty of Science,
Kyoto University

(Received December 2, 1960)

The stability of free boundary-layer flows of a viscous, incompressible, electrically conducting fluid is investigated. It is found generally that a uniform magnetic field parallel to the steady flows has an effect of stabilizing the flows. When the magnetic field is weak, i.e. when the Alfvén number A is less than unity, the flows are unstable with zero critical Reynolds number ($R_c=0$). But when the magnetic field is so strong that $A>1$, the flows are absolutely stable ($R_c=\infty$) provided $R_m/R>1$ where R_m is the magnetic Reynolds number. For small values of R_m/R, the flows are unstable even for $A>1$, so long as $(R_m/R)A^2 \ll 1$.

It is also shown that an oblique magnetic field cannot stabilize the flow, however strong it may be.

§1. Introduction

It is generally believed that the magnetic field imposed upon laminar flows of electrically conducting fluid makes the flows less unstable and there are many evidences supporting this conclusion. In the case of two-dimensional parallel flow between parallel planes, Stuart[1] found that if the magnetic Reynolds number R_m is sufficiently small, a uniform magnetic field parallel to the flow causes a steady rise of the critical Reynolds number with increasing magnetic field. For the plane flows of perfect conductor ($R_m=\infty$) between parallel planes, Velikhov[2] showed that the effect of magnetic field is also stabilizing, and if the Alfvén number A exceeds the critical value 0.2 the flow is entirely stabilized by the magnetic field.

In this paper we attempt to discuss the effect of a uniform magnetic field upon the stability of free boundary-layer flows between two parallel streams. The fluid is assumed to be incompressible with the constant density ρ, the kinematic viscosity ν, the electrical conductivity σ, and the magnetic permeability μ.

It was already established in ordinary hydrodynamical case that the free boundary-layer flows are unstable at all Reynolds numbers irrespective of the detailed structure of their velocity profiles (Tatsumi and Gotoh[3]). It may therefore be interesting to investigate whether the magnetic field stabilizes the free flows or not, and, in particular, to study how the critical Reynolds number changes, or does not change, with the intensity of the magnetic field.

It will be found that as in the case of the channel flows the magnetic field has a stabilizing effect in this case too, but the critical Reynolds number R_c rises in somewhat different manner with increasing magnetic field. In contrast with the continuous rise of R_c with increasing A for the bounded flows, R_c in the present case remains to be zero for $A<1$. For values of A greater than unity, R_c changes abruptly to infinity provided $R_m/R>1$. If, on the other hand, $R_m/R \ll 1$, the flow is unstable even for $A>1$ so long as $(R_m/R)A^2$ is small.

§2. Mathematical Formulation

Taking the x-axis of two-dimensional Cartesian coordinates along the direction of a steady plane parallel flow, let $U(y)$ and H be the velocity profile of this flow and the intensity of a uniform magnetic field respectively.

When the undisturbed magnetic field is parallel to the undisturbed velocity, Squire's theorem[4] in the non-magnetic stability theory of plane parallel flows is also valid in magnetic case, and it is sufficient to consider two-dimensional disturbances only (Michael[5]. By making use of the equations of continuity:

$$\operatorname{div} \boldsymbol{u}=0\ , \qquad \operatorname{div} \boldsymbol{H}=0\ , \tag{1}$$

two-dimensional disturbances may be expressed in terms of the stream function ψ and the magnetic stream function χ as follows:

$$\left.\begin{aligned} u_x&=\frac{\partial\psi}{\partial y}\,, & u_y&=-\frac{\partial\psi}{\partial x}\,,\\ h_x&=\frac{\partial\chi}{\partial y}\,, & u_y&=-\frac{\partial\chi}{\partial x}\,,\end{aligned}\right\} \tag{2}$$

If we consider infinitesimal disturbances only, the equations of motion and magnetic induction may be linearized with respect to the intensity of the disturbances, so that by virtue of the principle of superposition it suffices to deal with only one of their harmonic components:

$$\left.\begin{aligned} \psi&=\phi(y)\exp\{i\alpha(x-ct)\}\,,\\ \chi&=\theta(y)\exp\}i\alpha(x-ct)\}\,,\end{aligned}\right\} \tag{3}$$

where $\alpha\,(>0)$ represents the wave number in the x-direction, $\mathscr{R}_e(c)\equiv c_r$ the phase velocity, and $\mathscr{I}_m(\alpha c)\equiv\alpha c_i$ the amplification factor of the disturbance. According as c_i takes positive, zero or negative values, we have amplified, neutral or damped disturbances respectively.

Substituting (2) and (3), together with steady fields, into the equations of motion and magnetic induction, and neglecting quadratic terms of ϕ and θ, we obtain the following equations for the amplitude of disturbances ϕ and θ:

$$(U-c)(\phi''-\alpha^2\phi)-U''\phi-S(\theta''-\alpha^2\theta)=-\frac{i}{\alpha R}(\phi^{\mathrm{iv}}-2\alpha^2\phi''+\alpha^4\phi)\,, \tag{4}$$

$$(U-c)\theta-\phi=-\frac{i}{\alpha R_m}(\theta''-\alpha^2\theta)\,, \tag{5}$$

where primes denote differentiation with respect to y, and all quantities have been made non-dimensional with respect to the representative velocity U_0, magnetic field H_0 and length scale l of the field. Non-dimensional parameters R, R_m and S are defined as

the Reynolds number: $R=lU_0/\nu$,
the magnetic Reynolds number: $R_m=4\pi\sigma\mu lU_0$,
the pressure number: $S=\mu H_0^2/(4\pi\rho U_0^2)$.

In the following, both U_0 and H_0 are chosen such that

$$U(\infty)=-U(-\infty)=1\,,\qquad H=1\,.$$

Eliminating ϕ from Eqs. (4) and (5), we have a sixth-order equation for θ:

$$\begin{aligned}(U-c+A)(U-c-A)(D^2-\alpha^2)\theta+2U'(U-c)\theta'&=-\frac{i}{\alpha R_m}\{(U-c)(D^2-\alpha^2)-U''\}(D^2-\alpha^2)\theta\\ &\quad-\frac{i}{\alpha R}(D^2-\alpha^2)^2(U-c)\theta+\frac{1}{\alpha^2RR_m}(D^2-\alpha^2)^3\theta\,,\end{aligned} \tag{6}$$

where $D=d/dy$ and $A\ (=S^{1/2})$ denotes the Alfvén number. Since all disturbances must vanish at infinity, Eqs. (5) and (6) must be solved subject to the boundary conditions:

$$\left.\begin{aligned}\phi(\infty)&=\phi(-\infty)=0\,,\\ \theta(\infty)&=\theta(-\infty)=0\,.\end{aligned}\right\} \tag{7}$$

§ 3. Solutions for Large R and R_m

When both R and R_m are extremely large, Eq. (6) reduces to

$$\theta''+\frac{2U'(U-c)}{(U-c)^2-A^2}\theta'-\alpha^2\theta=0\,. \tag{8}$$

In order to solve this equation it is convenient to divide the y-space into three separate regions (I), (II) and (III) by two appropriate points y_1 $(>y_c)$, and y_2 $(<y_s)$ as:

$$\text{(I)}\quad y>y_1\,,\qquad \text{(II)}\quad y_1>y>y_2\,,\qquad \text{(III)}\quad y<y_2\,,$$

and to deal with these three regions separately, where y_c and y_s are defined by

$$U(y_c)=c+A\ , \qquad U(y_s)=c-A\ .$$

(i) *Solutions in the outer regions* (I) *and* (III)

Since, in the regions (I) and (III), U' tends to zero as $|y|\to\infty$, the first approximate solution of Eq. (8) may be obtained by neglecting the second term in (8), and the better approximation will be given by iteration process. If we denote the solutions in the regions (I) and (III) by θ_{I} and θ_{III} respectively, the above procedure is equivalent to expanding θ_j ($j=\text{I, III}$) into the following series of functions:

$$\theta_j=C_jF_j=C_j\sum_{n=0}^{\infty}F_j^{(n)}(y;\alpha,c,A)\ , \tag{9}$$

where C_j's are arbitrary constants and $F_j^{(n)}$'s are solutions of the following equations:

$$\left.\begin{aligned}
&F_j^{(0)\prime\prime}-\alpha^2F_j^{(0)}=0\ ,\\
&F_j^{(n)\prime\prime}-\alpha^2F_j^{(n)}=-\frac{2U'(U-c)}{(U-c)^2-A^2}F_j^{(n-1)\prime}\ , \qquad (n\geq 1)\ .
\end{aligned}\right\} \tag{10}$$

Equations (10) are easily solved and, taking the boundary conditions (7) into consideration, we have

$$\left.\begin{aligned}
&F_{\text{I}}^{(0)}=e^{-\alpha y}\ , \qquad F_{\text{III}}^{(0)}=e^{\alpha y}\ ,\\
&F_j^{(n)}(y)=\frac{2}{\alpha}\int_{\pm\infty}^{y}\frac{U'(\xi)\{U(\xi)-c\}}{\{U(\xi)-c\}^2-A^2}\sinh\alpha(\xi-y)F_j^{(n-1)\prime}(\xi)\,d\xi\ ,
\end{aligned}\right\} \tag{11}$$

where $\pm\infty$ in the integrals must be taken as $+\infty$ and $-\infty$ for $j=\text{I}$ and III respectively.

If, in particular, we take

$$U(y)=\tanh y$$

as the basic velocity profile, the integrals in (11) can be evaluated immediately, obtaining

$$\left.\begin{aligned}
F_{\text{I}}(y)=e^{-\alpha y}\Big[\,1&+\frac{2\alpha(1-c)}{(1-c+A)(1-c-A)(1+\alpha)}e^{-2y}\\
&+2\alpha\cdot\frac{(1-c)^2(2+\alpha+c+c\alpha)+(2-c)(1+\alpha)A^2}{(1-c+A)^2(1-c-A)^2(1+\alpha)(2+\alpha)}e^{-4y}+\text{O}(e^{-6y})\Big]\ ,\\
F_{\text{III}}(y)=e^{\alpha y}\Big[\,1&+\frac{2\alpha(1+c)}{(1+c+A)(1+c-A)(1+\alpha)}e^{2y}\\
&+2\alpha\cdot\frac{(1+c)^2(2+\alpha-c-c\alpha)+(2+c)(1+\alpha)A^2}{(1+c+A)^2(1+c-A)^2(1+\alpha)(2+\alpha)}c^{4y}+\text{O}(e^{6y})\Big]\ .
\end{aligned}\right\} \tag{12}$$

(ii) *Solutions in the inner region* (II)

Let f_1 and f_2 denote two particular solutions of Eq. (8) in the region (II).

If we assume f_k ($k=1, 2$) in the form of power series of α^2 as:

$$f_k=\sum_{n=0}^{\infty}\alpha^{2n}f_k^{(n)}(y;c,A)\ , \tag{13}$$

$f_k^{(n)}$'s must satisfy the following equations:

$$\left.\begin{aligned}
&f_k^{(0)\prime\prime}+\frac{2U'(U-c)}{(U-c)^2-A^2}f_k^{(0)\prime}=0\ ,\\
&f_k^{(n)\prime\prime}+\frac{2U'(U-c)}{(U-c)^2-A^2}f_k^{(n)\prime}=f_k^{(n-1)}\ , \qquad (n\geq 1)\ .
\end{aligned}\right\} \tag{14}$$

Formal solutions of (14) are readily obtained as

$$\left.\begin{aligned} &f_1^{(0)}=1\,, \qquad f_2^{(0)}=\int_{y_2}^{y}\frac{d\xi}{\{U(\xi)-c\}^2-A^2}\,,\\ &f_k^{(n)}(y)=\int_{y_2}^{y}\frac{d\xi}{\{U(\xi)-c\}^2-A^2}\int_{y_2}^{\xi}[\{U(\zeta)-c\}^2-A^2]\,f_k^{(n-1)}(\zeta)\,d\zeta\,, \qquad (k=1,2;\ n\geq 1)\,. \end{aligned}\right\} \tag{15}$$

Thus we get the general solution in the region (II) as:

$$\theta_{\mathrm{II}}=C_1 f_1+C_2 f_2\,. \tag{16}$$

The singularities in the integrands of (15) show that f_1 and f_2 are in general many-valued functions, so that we have to choose their correct branches by comparing them with the asymptotic behaviour of the solutions of the full equation (6). In the neighbourhood of $y=y_c$ f_1 and f_2 are expressed as a linear combination of two power series solutions:

$$\left.\begin{aligned} &\mathscr{F}_1(y)=1+\sum_{n=1}^{\infty}B_n^{(1)}(y-y_c)^n\,,\\ &\mathscr{F}_2(y)=\mathscr{F}_1(y)\log(y-y_c)+\sum_{n=1}^{\infty}B_n^{(2)}(y-y_c)^n\,, \end{aligned}\right\} \tag{17}$$

where $B_n^{(1)}$, $B_n^{(2)}$ $(n=1,2,\cdots)$ are numerical constants.

If we put $R_m=\infty$, but retaining R to be finite, Eq. (6) reduces to

$$(U-c+A)(U-c-A)(D^2-\alpha^2)\theta+2U'(U-c)\theta'=-\frac{i}{\alpha R}(D^2-\alpha^2)^2(U-c)\theta\,. \tag{18}$$

Changing the independent variable from y to η, where

$$\varepsilon\eta=y-y_c\,, \qquad \varepsilon=\{2\alpha R U'(y_c)\}^{-1/3}\,,$$

the above equation (18) becomes

$$\frac{d^4\theta}{d\eta^4}-i\left(\eta\frac{d^2\theta}{d\eta^2}+\frac{d\theta}{d\eta}\right)=\mathrm{O}(\varepsilon)\,. \tag{19}$$

Four independent solutions of this equation are expressed as:

$$\left.\begin{aligned} &\theta_1=1+\mathrm{O}(\varepsilon)\,,\\ &\theta_2=\int\left(h_1\int h_2\,d\eta-h_2\int h_1\,d\eta\right)d\eta+\mathrm{O}(\varepsilon)\,,\\ &\theta_3=\int h_2\,d\eta+\mathrm{O}(\varepsilon)\,,\\ &\theta_4=\int h_1\,d\eta+\mathrm{O}(\varepsilon)\,, \end{aligned}\right\} \tag{20}$$

where

$$h_1=\eta^{1/2}H_{1/3}^{(1)}\left[\frac{2}{3}(i\eta)^{3/2}\right], \qquad h_2=\eta^{1/2}H_{1/3}^{(2)}\left[\frac{2}{3}(i\eta)^{3/2}\right],$$

and $H_{1/3}^{(1)}$, $H_{1/3}^{(2)}$ denote the Hankel functions of order 1/3. The asymptotic form of (20) for $R\to\infty$ and for fixed $y-y_c$ is obtained by making $\eta\to\infty$, and for large values of η the solutions (20) become

$$\left.\begin{aligned}&\theta_1\sim 1\,,\\&\theta_2\sim\text{const.}\log\eta\,,\\&\theta_3\sim\text{const.}\,\eta^{-3/4}\exp\left[\frac{2}{3}\eta^{3/2}e^{i\pi/4}\right],\\&\theta_4\sim\text{const.}\,\eta^{-3/4}\exp\left[\frac{2}{3}\eta^{3/2}e^{5\pi i/4}\right],\end{aligned}\right\}\tag{21}$$

under the condition:

$$-\frac{7}{6}\pi\leq\arg\eta\leq\frac{1}{6}\pi\,.\tag{22}$$

It is easily seen that the first two solutions in (21) are identical with the solutions (17) if terms of $O(\varepsilon\log\varepsilon)$ are ignored. The condition (22) shows that the solutions (17) represent the correct solutions of the full equation (6) provided that y lies, if $U'(y_c)>0$, in the region *below* $y=y_c$. Thus, the path of integration in (15) must be taken through this region (see Fig. 1). The same rule is also valid at $y=y_s$.

Although the solutions (13) in power series of α^2 converge for all values of α, they are not conveniently calculated for non-small values of α. For $\alpha\approx 1$ another method of perturbation may be useful.

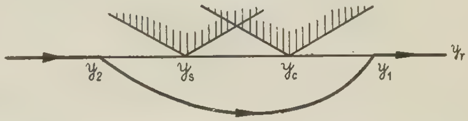

Fig. 1. Path of integration in complex y-plane.

If we take the velocity profile $U(y)=\tanh y$ and take the case in which

$$\alpha=1\,,\qquad A=c=0\,,\tag{23}$$

then Eq. (8) permits two independent solutions:

$$f_1=\operatorname{cosech}\,y,\qquad f_2=y\operatorname{cosech}\,y+\cosh\,y\,.\tag{24}$$

For small but non-zero values of A and c, we can take

$$A,\qquad c\ll U(y)\,,\tag{25}$$

and expand the coefficient of θ' in (8) as follows:

$$\frac{2U'(U-c)}{(U-c)^2-A^2}=\frac{2U'}{U}\left(1+\frac{c}{U}+\frac{c^2+A^2}{U^2}+\cdots\right).\tag{26}$$

Then the solutions of (8) may be expressed in the following series:

$$f_k(y)=\sum_{n=0}^{\infty}f_k^{(n)}(y)\,,\qquad(k=1,2)\,,\tag{27}$$

where $f_k^{(n)}$'s are solutions of equations:

$$\left.\begin{aligned}&f_k^{(0)\prime\prime}+2\frac{U'}{U}f_k^{(0)\prime}-f_k^{(0)}=0\,,\\&f_k^{(1)\prime\prime}+2\frac{U'}{U}f_k^{(1)\prime}-f_k^{(1)}=-2\frac{U'}{U}\left(\frac{c}{U}+\frac{A^2}{U^2}\right)f_k^{(0)\prime}-(1-\alpha^2)f_k^{(0)}\,,\\&\cdots\cdots\cdots\cdots\end{aligned}\right\}\tag{28}$$

§ 4. Eigenvalue Problem for Large Values of R and R_m

The complete solution of Eqs. (8) which satisfies the boundary conditions (7) is obtained by connecting analytically θ_{I} and θ_{II} at y_1, and θ_{II} and θ_{III} at y_2 respectively, that is,

$$\left.\begin{aligned} &\theta_{\mathrm{I}}(y_1)=\theta_{\mathrm{II}}(y_1)\,, && \theta_{\mathrm{I}}'(y_1)=\theta_{\mathrm{II}}'(y_1)\,,\\ &\theta_{\mathrm{II}}(y_2)=\theta_{\mathrm{III}}(y_2)\,, && \theta_{\mathrm{II}}'(y_2)=\theta_{\mathrm{III}}'(y_2)\,. \end{aligned}\right\} \tag{29}$$

In order that Eqs. (29) are satisfied by non-zero C_{I}, C_{III}, C_1 and C_2, the following determinant must vanish:

$$E=\begin{vmatrix} F_{\mathrm{I}}(y_1) & f_1(y_1) & f_2(y_1) & 0 \\ F_{\mathrm{I}}'(y_1) & f_1'(y_1) & f_2'(y_1) & 0 \\ 0 & f_1(y_2) & f_2(y_2) & F_{\mathrm{III}}(y_2) \\ 0 & f_1'(y_2) & f_2'(y_2) & F_{\mathrm{III}}'(y_2) \end{vmatrix}=0\,. \tag{30}$$

equation (30) gives a relationship between eigenvalues of α and c for $R=R_m=\infty$ and for given A.

For small values of α, substitution of (12) and (15) together with $U(y)=\tanh y$ into Eq. (30) gives the eigenvalue equation:

$$\begin{aligned} (1+c^2-A^2)-\alpha[1+(4A)^{-1}(1+c+A)(1-c-A)\{\log(1-c+A)-\log(-1-c+A)\} \\ -(4A)^{-1}(1+c-A)(1-c+A)\{\log(1-c-A)-\log(-1-c-A)\}] \\ +\mathrm{O}(\alpha^2)=0\,. \end{aligned} \tag{31}$$

It may readily be seen that this expression is free from the choice of the matching point. For $\alpha=0$ we have

$$1+c^2-A^2=0\,, \tag{32}$$

so that

$$\left.\begin{aligned} &c_r=0\,,\\ &c_i=\sqrt{1-A^2}\,, \end{aligned}\right\} \tag{33}$$

where the positive root has been taken for c_i, since it must conform with $c_i=1$ for $A=0$. For small values of α an approximate solution of (31) is obtained, by taking the second term into consideration, as:

$$\left.\begin{aligned} &c_r=0\,,\\ &\alpha=\frac{1-c_i^2-A^2}{1+c_i(\pi-\delta)+(4A)^{-1}(1+c_i^2-A^2)\log\dfrac{(1+A)^2+c_i^2}{(1-A)^2+c_i^2}}\,, \end{aligned}\right\} \tag{34}$$

where

$$\tan\delta=2c_i/(1-c_i^2-A^2)\,,\qquad (0<\delta<\pi/2)\,.$$

For $\alpha\approx1$, we substitute (27) and (12) together with $U(y)=\tanh y$ into (30), and obtain the equation:

$$\frac{4}{3}A^2-c\pi i-2(1-\alpha)+\mathrm{O}\{c^2, A^4, (1-\alpha)^2\}=0\,. \tag{35}$$

Thus, we have, for small values of c, A, $1-\alpha$,

$$\left.\begin{aligned} &c_r=0\,,\\ &\alpha=1-\frac{2}{3}A^2-\frac{1}{2}\pi c_i\,. \end{aligned}\right\} \tag{36}$$

The $\alpha-c_i$ curves for constant A are calculated from this result and (34), and are illustrated in Fig. 2.

It is seen in Fig. 2 that for fixed A the neutral disturbance ($c_i=0$) gives the maximum wave-number, α_m, say, and α_m decreases as A increases. For $A \geqq 1$, both α and c_i vanish, and the flow becomes entirely stable under this condition.

§ 5. Eigenvalue Problem for Small R and R_m

Next we proceed to solve the stability problem for small values of R and R_m. The method of approximation which will be employed here is similar to that already used by the author for ordinary hydrodynamical case (Tatsumi and Gotoh[3]).

If we divide the whole y-space into two regions (I) $y \geq y_0$ and (II) $y \leq y_0$, where y_0 is an arbitrary finite point, Eq. (6) may be modified, for these two regions (I) and (II), as:

$$(D^2-\alpha^2)(D^2-\beta_j^2)(D^2-\gamma_j^2)\theta = L_j[\theta]\ , \quad (j=\mathrm{I}, \mathrm{II}) \tag{37}$$

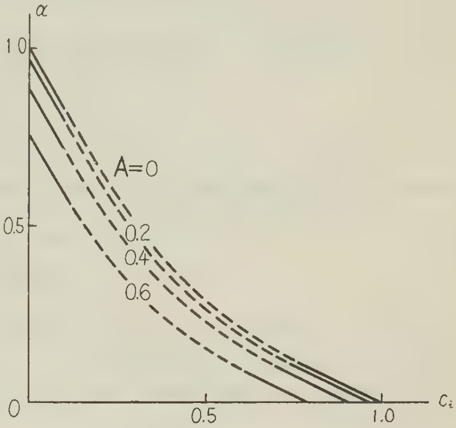

Fig. 2. $\alpha-c_i$ curves for $R=R_m=\infty$.

where

$$\left.\begin{aligned} U_{\mathrm{I}}(y) &= U(y)-U(\infty)=U(y)-1\ , \\ U_{\mathrm{II}}(y) &= U(y)-U(-\infty)=U(y)+1\ , \end{aligned}\right\} \tag{38}$$

$$\left.\begin{aligned} 2\beta_{\mathrm{I}}^2 &= 2\alpha^2+i\alpha(R+R_m)(1-c)+i\{\alpha^2(R-R_m)^2(1-c)^2+4\alpha^2RR_mS\}^{1/2}\ , \\ 2\gamma_{\mathrm{I}}^2 &= 2\alpha^2+i\alpha(R+R_m)(1-c)-i\{\alpha^2(R-R_m)^2(1-c)^2+4\alpha^2RR_mS\}^{1/2}\ , \\ 2\beta_{\mathrm{II}}^2 &= 2\alpha^2-i\alpha(R+R_m)(1+c)+i\{\alpha^2(R-R_m)^2(1+c)^2+4\alpha^2RR_mS\}^{1/2}\ , \\ 2\gamma_{\mathrm{II}}^2 &= 2\alpha^2-i\alpha(R+R_m)(1+c)-i\{\alpha^2(R-R_m)^2(1+c)^2+4\alpha^2RR_mS\}^{1/2}\ , \\ &\mathscr{R}_e(\beta_j, \gamma_j)>0\ , \end{aligned}\right\} \tag{39}$$

and

$$\begin{aligned} L_{\mathrm{I}} = {} & i\alpha R\{U_{\mathrm{I}}(D^2-\alpha^2)-U_{\mathrm{I}}''\}(D^2-\alpha^2)+i\alpha R_m(D^2-\alpha^2)^2U_{\mathrm{I}} \\ & +\alpha^2RR_m[\{U_{\mathrm{I}}(D^2-\alpha^2)-U_{\mathrm{I}}''\}U_{\mathrm{I}}+(1-c)\{U_{\mathrm{I}}(D^2-\alpha^2)+(D^2-\alpha^2)U_{\mathrm{I}}-U_{\mathrm{I}}''\}]\ , \end{aligned} \tag{40}$$

$$\begin{aligned} L_{\mathrm{II}} = {} & i\alpha R\{U_{\mathrm{II}}(D^2-\alpha^2)-U_{\mathrm{II}}''\}(D^2-\alpha^2)+i\alpha R_m(D^2-\alpha^2)^2U_{\mathrm{II}} \\ & +\alpha^2RR_m[\{U_{\mathrm{II}}(D^2-\alpha^2)-U_{\mathrm{II}}''\}U_{\mathrm{II}}-(1+c)\{U_{\mathrm{II}}(D^2-\alpha^2)+(D^2-\alpha^2)U_{\mathrm{II}}-U_{\mathrm{II}}''\}]\ . \end{aligned} \tag{41}$$

It may easily be seen that the right-hand sides of Eq. (37) for $j=\mathrm{I}$ and II tend to zero as $y\to\infty$ and $y\to-\infty$ respectively, so that the first approximate solution is obtained by neglecting the right-hand sides. The second approximate solution will be obtained by substituting the first approximate solution into the right-hand sides of (37), and the approximation may be made arbitrarily better by repeating the iteration. This procedure is equivalent to expanding θ_j into the following series:

$$\theta_j(y)=\sum_{n=0}^{\infty} g_j^{(n)}(y;\, \alpha^2, \alpha R, \alpha R_m, A, c)\ , \tag{42}$$

where $g_j^{(n)}$'s are the solutions of the following equations:

$$\left.\begin{aligned} (D^2-\alpha^2)(D^2-\beta_j^2)(D^2-\gamma_j^2)g_j^{(0)} &= 0\ , \\ (D^2-\alpha^2)(D^2-\beta_j^2)(D^2-\gamma_j^2)g_j^{(n)} &= L_j[g_j^{(n-1)}]\ . \end{aligned}\right\} \tag{43}$$

The series of Eqs. (43) are solved successively, giving the results:

$$\left.\begin{aligned}
&g_{\mathrm{I}1}^{(0)}=e^{-\alpha y}\,, \qquad g_{\mathrm{I}2}^{(0)}=e^{-\beta_{\mathrm{I}}y}\,, \qquad g_{\mathrm{I}3}^{(0)}=e^{-\gamma_{\mathrm{I}}y}\,,\\
&g_{\mathrm{II}1}^{(0)}=e^{\alpha y}\,, \qquad g_{\mathrm{II}2}^{(0)}=e^{\beta_{\mathrm{II}}y}\,, \qquad g_{\mathrm{II}3}^{(0)}=e^{\gamma_{\mathrm{II}}y}\,,\\
&g_{jk}{}^{(n)}(y)=\frac{1}{\alpha(\alpha^2-\beta_j{}^2)(\alpha^2-\gamma_j{}^2)}\int_{\pm\infty}^{y}\sinh\{\alpha(y-\xi)\}L_j[g_{jk}{}^{(n-1)}(\xi)]\,d\xi\\
&\qquad+\frac{1}{\beta_j(\beta_j{}^2-\alpha^2)(\beta_j{}^2-\gamma_j{}^2)}\int_{\pm\infty}^{y}\sinh\{\beta_j(y-\xi)\}L_j[g_{jk}{}^{(n-1)}(\xi)]\,d\xi\\
&\qquad+\frac{1}{\gamma_j(\gamma_j{}^2-\alpha^2)(\gamma_j{}^2-\beta_j{}^2)}\int_{\pm\infty}^{y}\sinh\{\gamma_j(y-\xi)\}L_j[g_{jk}{}^{(n-1)}(\xi)]\,d\xi\,.
\end{aligned}\right\}\tag{44}$$

The general solutions satisfying the boundary conditions (7) are given by

$$\left.\begin{aligned}
&\theta_{\mathrm{I}}=C_{\mathrm{I}1}g_{\mathrm{I}1}+C_{\mathrm{I}2}g_{\mathrm{I}2}+C_{\mathrm{I}3}g_{\mathrm{I}3} \qquad (y\geq y_0)\,,\\
&\theta_{\mathrm{II}}=C_{\mathrm{II}1}g_{\mathrm{II}1}+C_{\mathrm{II}2}g_{\mathrm{II}2}+C_{\mathrm{II}3}g_{\mathrm{II}3} \qquad (y\leq y_0)\,.
\end{aligned}\right\}\tag{45}$$

In order to obtain the complete solution over the whole y-space, we have to connect the two solutions θ_{I} and θ_{II} analytically at $y=y_0$. This is attained by equating the values at $y=y_0$ of θ_{I} and θ_{II} themselves and their first five derivatives respectively. Thus,

$$\left.\begin{aligned}
&(\theta_{\mathrm{I}})_{y_0}=(\theta_{\mathrm{II}})_{y_0}\,,\\
&\left(\frac{d^p\theta_{\mathrm{I}}}{dy^p}\right)_{y_0}=\left(\frac{d^p\theta_{\mathrm{II}}}{dy^p}\right)_{y_0} \qquad (p=1,\cdots,5)\,.
\end{aligned}\right\}\tag{46}$$

In order that these conditions are satisfied by non-zero C's, the following determinant must vanish:

$$E=\begin{vmatrix}
g_{\mathrm{I}1}(y_0) & g_{\mathrm{I}2}(y_0) & g_{\mathrm{I}3}(y_0) & g_{\mathrm{II}1}(y_0) & g_{\mathrm{II}2}(y_0) & g_{\mathrm{II}3}(y_0)\\

\end{vmatrix}=0\,.\tag{47}$$

The enormous complexity of Eq. (47) compels us to restrict our consideration to the case of small values of R and R_m.

First we look for the solution of (47) for those values of R and R_m which satisfy $R_m\ll R$, and expand (47) into powers of α^2, αR, αR_m and R_m/R:

$$\begin{aligned}
E=-16(\beta_{\mathrm{I}}-\alpha)(\beta_{\mathrm{II}}-\alpha)(\gamma_{\mathrm{I}}-\alpha)(\gamma_{\mathrm{II}}-\alpha)(\beta_{\mathrm{I}}-\gamma_{\mathrm{I}})(\beta_{\mathrm{II}}-\gamma_{\mathrm{II}})&\\
\times[E_0(\alpha,\beta_j,\gamma_j)+\mathrm{O}(\alpha^{10},\beta_j{}^{10},\gamma_j{}^{10})]=0\,,&
\end{aligned}\tag{48}$$

where

$$\begin{aligned}
&E_0=E_{00}+(R_m/R)E_{01}\,,\\
&E_{00}=\alpha^4(\beta_{\mathrm{I}0}+\alpha)(\beta_{\mathrm{II}0}+\alpha)(\beta_{\mathrm{I}0}+\beta_{\mathrm{II}0})(\beta_{\mathrm{I}0}^2+\beta_{\mathrm{II}0}^2-\beta_{\mathrm{I}0}\beta_{\mathrm{II}0}+\alpha\beta_{\mathrm{I}0}+\alpha\beta_{\mathrm{II}0}+\alpha^2)\,,
\end{aligned}\tag{49}$$

$$\begin{aligned}
E_{01}=\frac{\alpha^4R^2A^2}{4\beta_{\mathrm{I}0}\beta_{\mathrm{II}0}(\beta_{\mathrm{I}0}+\alpha)(\beta_{\mathrm{II}0}+\alpha)}&[\alpha\beta_{\mathrm{I}0}(\beta_{\mathrm{I}0}+\alpha)^4(\beta_{\mathrm{I}0}-\alpha)+\alpha\beta_{\mathrm{II}0}(\beta_{\mathrm{II}0}+\alpha)^4(\beta_{\mathrm{II}0}-\alpha)\\
&+3\alpha(\beta_{\mathrm{I}0}+\alpha)^2(\beta_{\mathrm{II}0}+\alpha)^2(\beta_{\mathrm{I}0}+\beta_{\mathrm{II}0})(2\beta_{\mathrm{I}0}+2\beta_{\mathrm{II}0}+\alpha)\\
&+\beta_{\mathrm{I}0}\beta_{\mathrm{II}0}(\beta_{\mathrm{I}0}+\alpha)^2(\beta_{\mathrm{II}0}+\alpha)^2(3\beta_{\mathrm{I}0}+3\beta_{\mathrm{II}0}-4\alpha)\\
&-\beta_{\mathrm{I}0}\beta_{\mathrm{II}0}(\beta_{\mathrm{I}0}+\alpha)(\beta_{\mathrm{II}0}+\alpha)\{(\beta_{\mathrm{I}0}+\alpha)^3+(\beta_{\mathrm{II}0}+\alpha)^3\}]\,,
\end{aligned}\tag{50}$$

and

$$\beta_{\mathrm{I}0}^2=\alpha^2-i\alpha R(c-1)\,, \qquad \beta_{\mathrm{II}0}^2=\alpha^2-i\alpha R(c+1)\,.\tag{51}$$

The first approximate equation $E_{00}=0$ gives the set of eigenvalues which have already been obtained in ordinary hydrodynamics (Tatsumi and Gotoh[3]), namely,

$$c_r=0\ , \qquad R=\frac{4(\sqrt{3}-c_i)}{(1-\sqrt{3}\,c_i)^2}\alpha\ . \tag{52}$$

Using this result as the first approximation, the second approximate solution is obtained as

$$\left.\begin{aligned} &c_r=0\ ,\\ &R=\frac{4(\sqrt{3}-c_i)}{(1-\sqrt{3}\,c_i)^2}\left[1+\frac{9c_i^2-26\sqrt{3}\,c_i+39}{(1-\sqrt{3}\,c_i)^3(3-\sqrt{3}\,c_i)}\frac{R_m}{R}A^2\right]\alpha+\mathrm{O}(\alpha^2,\,R_m^2/R^2)\ . \end{aligned}\right\} \tag{53}$$

Putting $c_i=0$, we find the following relationship between α, R and R_m for neutral disturbances:

$$R=4\sqrt{3}\left(1+13\frac{R_m}{R}A^2\right)\alpha+\mathrm{O}(\alpha^2,\,R_m^2/R^2)\ . \tag{54}$$

In Fig. 3 the neutral curves as calculated from (54) are plotted in the α-R plane for various values of $(R_m/R)A^2$. All neutral curves pass through the origin, giving the zero critical Reynolds number, and their slope decreases with increasing A, that is, the unstable region becomes narrower for stronger magnetic field.

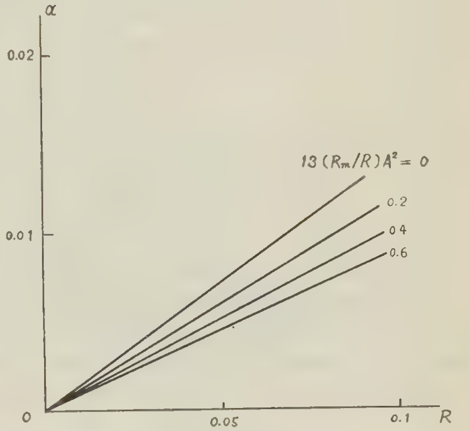

Fig. 3. Effects of magnetic field on neutral curves for $A^2R_m/R\ll 1$.

Next we consider another special case in which $\alpha\ll R\ll R_m$. Then E_0 in (48) is expressed as:

$$-\frac{1}{8}\alpha^5R_m^4[(R/R_m)^{3/2}(\kappa_{\mathrm{I}}+\kappa_{\mathrm{II}})(\kappa_{\mathrm{I}}\kappa_{\mathrm{II}})^{-1}(1+A^2-c^2) \\ \times\{\kappa_{\mathrm{I}}^2(\kappa_{\mathrm{I}}^2+A^2\kappa_{\mathrm{I}}^{-2})^{1/2}+\kappa_{\mathrm{II}}^2(\kappa_{\mathrm{II}}^2+A^2\kappa_{\mathrm{II}}^{-2})^{1/2}\}+\mathrm{O}(\alpha^{1/2},\,R^2/R_m^2)]\ , \tag{55}$$

where

$$\left.\begin{aligned} &\kappa_{\mathrm{I}}^2=-i(c-1)\ , \qquad \kappa_{\mathrm{II}}^2=-i(c+1)\ ,\\ &\mathscr{Re}\{\kappa_{\mathrm{I}},\ \kappa_{\mathrm{II}},\ (\kappa_{\mathrm{I}}^2+A^2\kappa_{\mathrm{I}}^{-2})^{1/2},\ (\kappa_{\mathrm{II}}^2+A^2\kappa_{\mathrm{II}}^{-2})^{1/2}\}>0\ . \end{aligned}\right\} \tag{56}$$

The first approximate equation for $E=0$ is given by

$$\kappa_{\mathrm{I}}^2(\kappa_{\mathrm{I}}^2+A^2\kappa_{\mathrm{I}}^{-2})^{1/2}+\kappa_{\mathrm{II}}^2(\kappa_{\mathrm{II}}^2+A^2\kappa_{\mathrm{II}}^{-2})^{1/2}=0\ , \tag{57}$$

from which it follows that

$$c_r=0\ , \qquad c_i=\sqrt{(1-A^2)/3} \qquad \text{for} \quad A\leq 1\ , \tag{58}$$

where the positive root has been taken for c_i, because it must conform with $c_i=1/\sqrt{3}$ for $A=0$.

Lastly, in case when $\alpha\ll R=R_m$, E_0 takes the form;

$$i\alpha^5R_m^4\Big[(A^2-1-c^2)\Big\{\frac{i}{2}(\beta_{\mathrm{I}}\gamma_{\mathrm{I}}+\beta_{\mathrm{II}}\gamma_{\mathrm{II}})(\beta_{\mathrm{I}}+\gamma_{\mathrm{I}}+\beta_{\mathrm{II}}+\gamma_{\mathrm{II}})^2+4i+2(\beta_{\mathrm{I}}\gamma_{\mathrm{I}}-\beta_{\mathrm{II}}\gamma_{\mathrm{II}})\Big\} \\ +4c(\beta_{\mathrm{I}}+\gamma_{\mathrm{I}})(\beta_{\mathrm{II}}+\gamma_{\mathrm{II}})+4A(\beta_{\mathrm{I}}\beta_{\mathrm{II}}-\gamma_{\mathrm{I}}\gamma_{\mathrm{II}})+\mathrm{O}(\alpha^{1/2})\Big]\ . \tag{59}$$

For small values of A^2 a perturbation of the result $c_r=0$, $c_i=1/\sqrt{3}$ for $A=0$ gives

$$c_r=0\,, \qquad c_i=\frac{1}{\sqrt{3}}\left(1-\frac{9}{8}A^2\right)+\mathrm{O}(A^4)\,, \tag{60}$$

and it may therefore be expected that c_r remains zero for also finite A. Assuming this, β_j and γ_j are expressed as:

$$\left.\begin{array}{ll} \beta_{\mathrm{I}}=(\xi_1+i\eta_1)/\sqrt{2}\,, & \gamma_{\mathrm{I}}=(\xi_2+i\eta_2)/\sqrt{2}\,, \\ \beta_{\mathrm{II}}=\gamma_{\mathrm{I}}^*\,, & \gamma_{\mathrm{II}}=\beta_{\mathrm{I}}^*\,, \end{array}\right\} \tag{61}$$

where the asterisk denotes the complex conjugate, and

$$\left.\begin{array}{l} \xi_1=[\{c_i^2+(1+A)^2\}^{1/2}+c_i]^{1/2}\,, \\ \eta_1=[\{c_i^2+(1+A)^2\}^{1/2}-c_i]^{1/2}\,, \\ \xi_2=[\{c_i^2+(1-A)^2\}^{1/2}+c_i]^{1/2}\,, \\ \eta_2=[\{c_i^2+(1-A)^2\}^{1/2}-c_i]^{1/2}\,. \end{array}\right\} \tag{62}$$

In terms of these (real) variables, approximate equation for $E=0$ is written as:

$$\begin{aligned} &(A^2-1+c_i^2)[(\xi_1\xi_2-\eta_1\eta_2)(\xi_1+\xi_2)^2+4+2(\xi_1\eta_2+\eta_1\xi_2)] \\ &\qquad +2c_i[(\xi_1+\xi_2)^2+(\eta_1+\eta_2)^2]+4A(\eta_1\xi_2-\xi_1\eta_2)=0\,. \end{aligned} \tag{63}$$

The relationship between c_i and A is derived by solving this equation numerically and the result is tabulated in Table I and shown graphically in Fig. 4, together with the result (58). It may be seen that $c_i>0$ for $0\leq A\leq 1$, c_i decreasing monotonously with increasing A, and $c_i=0$ for $A=1$. Consequently it is concluded that the effect of the magnetic field is always stabilizing, however weak it may be, and the flow is completely stabilized at $A\geq 1$ provided $R_m/R>1$. This tendency of the magnetic effect is the same with that obtained in § 4 for $R=R_m=\infty$. There is, however, an exceptional case in which the flow is unstable even for $A>1$, so long as $(R_m/R)A^2\ll 1$ is satisfied.

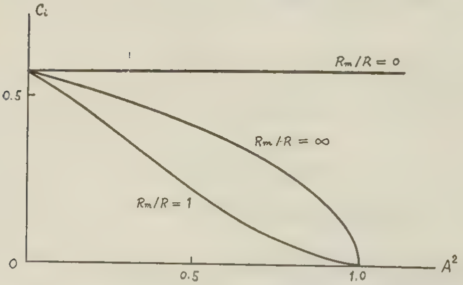

Fig. 4. c_i-A curves for small values of α.

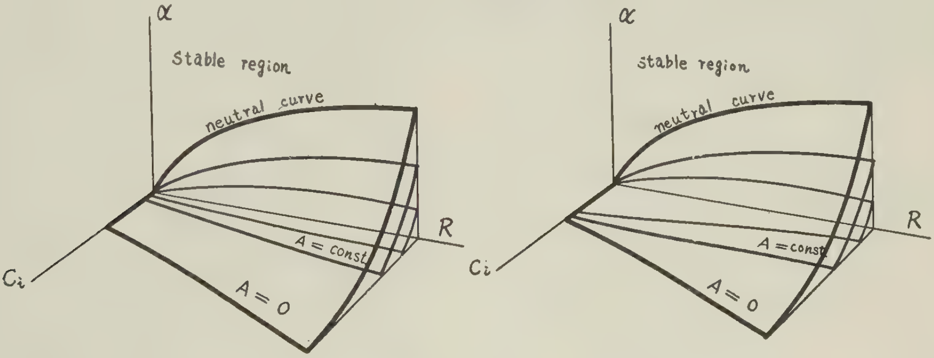
§ 6. Concluding Remarks

The results obtained in the preceding sections all indicate the stabilizing effect of the magnetic field. Although the results of calculation are partial and not sufficient for giving the whole picture of the stability characteristics of the free boundary-layer flow, yet we can draw its outline by interpolating these partial informations. The relationship between eigenvalues α, R, R_m and c_i seems to be as sketched in Figs. 5(a) and 5(b). Different constant values of A determine surfaces in the octant (α, R, c_i)-space. The behaviour of the surfaces is somewhat different for $R_m/R>1$ and $R_m/R\ll 1$. For $R_m/R>1$, the area of the surfaces decreases with increasing A, and for the limit of $A\to 1$ the surface shrinks into the R-axis. For $R_m/R\ll 1$, however, it is seen from Fig. 4 that the circumstance around the c_i-axis does not change appreciably with increasing A, and it is difficult to tell what limiting form will the surface take in this region for $A\to 1$.

It was already verified by Velikhov[2] for the limiting case of $R=R_m=\infty$ that $A>2$ is the sufficient condition for the stability of parallel flows. But the critical value of the Alfvén number A_c, say, which gives the conditions for the marginal stability, is expected to vary with different velocity distributions of steady flows. According to the present result (Figs. 2 and 5a), we have $A_c=1$ for the free boundary-layers between two parallel streams provided $R_m/R>1$, in contrast with the value $A_c=0.2$ for the plane Poiseuille flow (Velikhov[2]). The larger value of A_c in this case agrees with our expectation, because in ordinary hydrodynamical case the free boundary-layer flows were found to be more unstable than bounded flows.

It is seen in Figs. 2 and 3 that the stabilizing effect of the magnetic field appears first in disturbances of short wavelength and then extends gradually to those of longer wavelength as A increases up to unity. This tendency is just opposite to that in the broken-line jet in which the disturbance of the longest wavelength ($\alpha=0$) first become stable (Drazin[6]).

When the ratio R_m/R $(=4\pi\sigma\nu\mu)$ is kept constant, c_i decreases monotonously with increasing A, that is, the stronger magnetic field more stabilizes the disturbances. However, the magnetic field does not change the critical Reynolds number, and R_c remains zero provided $A<1$.



(a) $R_m/R>1$. (b) $R_m/R\ll 1$.

Fig. 5. Relation between α, R and c_i for different constant A and R_m/R.

It is found in Fig. 4 that for fixed values of R and A (<1) the flow of the perfect conductor $(R_m=\infty)$ is more unstable than that with finite conductivity $(R_m<\infty)$ just as was the case for the plane Poiseuille flow (Velikhov[2]).

The conclusions obtained for small values of α apply universally to all velocity profiles of the free boundary-layer type. On the other hand, the results for finite values of α vary with the type of the velocity profile under consideration, and the detailed information obtained here for the profile $U(y)=\tanh y$ may hold only qualitatively for other profiles.

Finally, it should be noted that if the magnetic field is not parallel to the undisturbed velocity, the flow cannot be stabilized by the magnetic field, however strong it may be. This is due to the fact that in this case Squire's theorem referred in §2 is no longer valid and therefore the general three-dimensional disturbances must be considered. Let the magnetic field be $(H_x, 0, H_z)$. One harmonic component of the disturbance may be expressed in vector form as:

$$\boldsymbol{u}=\boldsymbol{v}(y)\exp\{i\alpha(x-ct)+i\gamma z\}\,,$$

$$\boldsymbol{h}=\boldsymbol{f}(y)\exp\{i\alpha(x-ct)+i\gamma z\}\,,$$

where γ denotes the wave-number in the z-direction. The amplitude functions of the y-component of disturbances v_y and f_y are governed by equations:

$$\left.\begin{aligned}&(U-c)(D^2-\beta^2)v_y-U''v_y-S(H_x+\gamma H_z/\alpha)(D^2-\beta^2)f_y=-\frac{i}{\alpha R}(D^2-\beta^2)^2v_y\,,\\&(U-c)f_y-(H_x+\gamma H_z/\alpha)v_y=-\frac{i}{\alpha R_m}(D^2-\beta^2)f_y\,,\\&\qquad\qquad\beta^2=\alpha^2+\gamma^2\,,\end{aligned}\right\}\tag{64}$$

which correspond to Eqs. (4) and (5) in § 2 for the two-dimensional disturbances. If the wave-numbers α and γ satisfy the relation:

$$\alpha H_x + \gamma H_z = 0 , \tag{65}$$

the simultaneous equations (64) become two separate equations for v_y and f_y, and the disturbance velocity has no means of interaction with the magnetic field. The general three-dimensional disturbances always involve the one with those wave-numbers which satisfy the relation (65) and to such disturbances the conclusion of entire instability in ordinary hydrodynamical case applies unchanged. Thus, it is concluded that the oblique magnetic field cannot stabilize the flow, however strong it may be.

On the New Magnetic Phase in Manganese-Aluminium-Copper System

By Ichiro TSUBOYA and Makoto SUGIHARA

Electrical Communication Laboratory Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan

(Received November 1, 1960)

In Mn-Al-Cu alloys, there is the ferromagnetic phase corresponding to the composition of Cu_2MnAl which is well known as the Heusler alloy[1]. The other ferromagnetic phase, however, in this system has not been discovered. In this note, the present authors would like to report the existence of a new ferromagnetic phase in this alloy system.

The electrolytic Cu (99.9%), electrolytic Mn (99.9%) and pure Al (99.99%) were mixed in the desired proportion and melted in air and cast into rods of 10 mm in diameter. These specimens were annealed for one hour at 900°C in vacuum to remove the segregation, then cooled to room temperature at the rate of 150°C/hr.

The composition range, in which the specimens seem to show ferromagnetism, was determined by the magnetic testing.

According to X-ray powder analysis, the composition range showing ferromagnetism is found to be a single cubic phase. The crystal structures of non-ferromagnetic specimens are the mixture of β-Mn phase and Cu_9Al_4 phase in Cu rich region, the β-Mn in Cu poor and Mn rich region, and orthorhombic Y-phase[2] in Al rich side. These results are shown in Fig. 1.

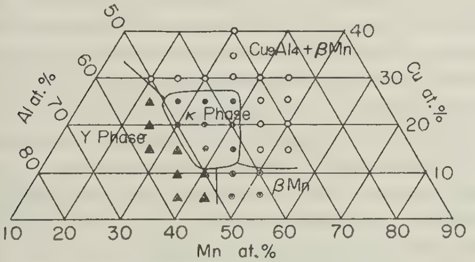

Fig 1. Results of X-ray diffraction
● κ phase (magnetic).
○ $Cu_9Al_4+\beta$-Mn.
▲ Orthorhombic *Y* phase.
⊙ $\beta-$Mn.

The ferromagnetic cubic phase is the same structure as the κ phase of Mn-Al-Fe alloy system[3], but it covers the larger composition range. The structure of this κ phase show the b.c.c. CsCl (B 2) type with the lattice constant 2.984±0.005Å which is not appreciably dependent on the composition. In this structure, it seems that Al atoms occupy body centered sites and Cu and Mn atoms occupy the cube corner sites but the excess of Mn atoms occupy the body centered Al sites.

The magnetic properties of this κ phase such as Curie temperature, $\sigma-T$ curve, and $1/\chi-T$ curve were measured by magnetic balance. The Curie temperatures at 20 at.% Cu specimens increase with an increase of Mn content. Namely it was 370°K at 30 at.% Mn, and 550°K at 40 at.% Mn. The saturation magnetizations at 0°K, however, decrease with an increase of Mn content. Namely it was 270 gauss (per c.c.) at 40 at.% Mn and 160 gauss (per c.c.) at 30 at.% Mn.

Tne temperature dependence of saturation magnetization (I_s-T curve) and inverse susceptibility above Curie temperature ($1/\chi-T$ cnrve) are shown in Fig. 2. $1/\chi-T$ curves of the alloy in this κ phase region show generally non-linear relations. This relations suggest that the magnetic interactions in the κ phase are not ferromagnetic but ferrimagnetic.

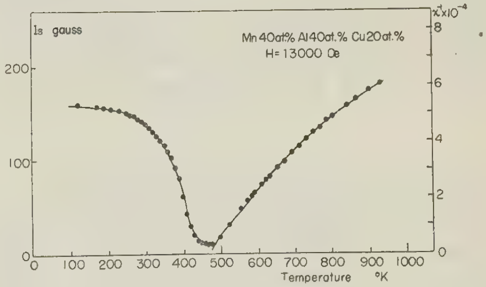

Fig. 2. I_s-T and $1/\chi-T$ curve of 20 at.% Cu, 35 at.% Mn 45 at.% Al specimen at the field strength of 13000 Oe.

As seen in the above results of crystallographic and magnetic observations, the magnetism of this κ-phase seems to be understood by assuming the antiferromagnetic interaction between body centered (Al site) Mn atoms and cube-corner (Cu site) Mn atoms, and ferromagnetic interaction between cube corner Mn atoms.

Further discussion with detailed measurements will be reported later on.

Optical Absorption and Electrical Conductivity of Reduced $BaTiO_3$ Single Crystal

Seiji Ikegami, Ichiro Ueda and Yukihiko Ise

Technical Research Department, Wireless Division, Matsushita Electric Industrial Company, Kadoma, Osaka

(Received December 9, 1960)

It has been well known that some properties of $BaTiO_3$ single crystals are changed by reduction treatment. In order to investigate the effects of reduction, preliminary measurements of optical absorption and electrical conductivity were made on untreated and reduced single crystals.

$BaTiO_3$ single crystals were grown from highly purified $BaTiO_3$ powder and KF by H. Sasaki of this department. Crystals were reduced by heating in hydrogen atmosphere, and reduction degree was varied by the temperature and time of heating.

The optical transmissions were measured on a single crystal at room temperature in a range of wavelengths from 0.2 to 33μ. The transmission spectra of weakly reduced specimens are shown together with that for the untreated crystal in Fig. 1. In the case of treatment at 1000°C for 1 hour, no transmission was measurable by our instrument. As shown in Fig. 1, a broad absorption band centered near 2.8μ in the infrared region was observed. The absorption coefficient at 2.8μ for curve 2 is about 70 cm^{-1}. This absorption is similar to that of the slightly reduced rutile[1]. Fig. 1 also shows that the transmission near the absorption edge is decreased by reduction. This change of spectra in the visible region is the cause for the coloration of a reduced crystal.

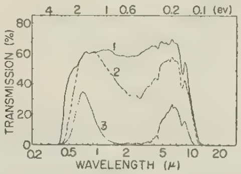

Fig. 1. Transmission spectra of reduced $BaTiO_3$ single crystals at room temperature. (1) untreated; (2) and (3) reduced at 600°C and 700°C, respectively, for 1 hour in hydrogen atmosphere. Thickness of crystal is 0.012 cm.

The measurements of conductivity were made on one untreated crystal and four reduced crystals in a temperature range of −120°C to 400°C. Fig. 2 shows the results of conductivity measurements. The conductivities are plotted against the reciprocal absolute temperatures. The values of thermal activation energy E for each crystal and temperature range are shown in Fig. 2, assuming the conductivity is represented in the form $\sigma=\sigma_0 \exp(-E/2kT)$. Generally E changes at the transition temperatures. As seen in Fig. 2, curve 2 for the slightly reduced crystal is still similar to that for the untreated one, therefore the effect of reduction does not appear on the conductivity. But in the cases of more heavily reduced crystals (curves 3, 4 and 5), the effects clearly appear on their conductivities, and the resistivity and E decrease with increasing reduction. The crystal for curve 3 has the lowest conductivity among these three crystals, therefore the thermal activation energy at room temperature for curve 3 may be compared with the optical one. These two values are 0.44 and 0.39 ev for infrared absorption and conductivity, respectively, and they are in reasonable agreement.

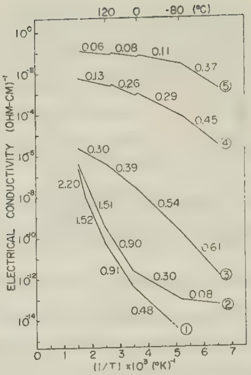

Fig 2. Electrical conductivity *vs.* reciprocal absolute temperature. (1) untreated; (2), (3), (4) and (5) reduced at 600°C, 800°C, 900°C and 1000°C, respectively, for 1 hour in hydrogen atmosphere.

From the results mentioned above, it is probable that: (1) In the reduced $BaTiO_3$ single crystals, the conduction mechanism is similar to that in the reduced rutile involving electrons trapped at the oxygen vacancies. (2) The energy gap between the conduction band and the induced donor level decreases with increasing reduction because of the interaction of individual donor centers. (3) The conduction mechanism of the untreated crystal at room temperature cannot be explained by oxygen vacancy model. (4) The conduction of the untreated crystal at high temperature is intrinsic as suggested by Branwood and Tredgold[2].

In addition, it is expected that the wavelength of maximum absorption increases with increasing reduction, although our instrument could not detect clearly. Further experiments are now in progress.

The authors wish to express their sincere thanks to Mr. S. Kisakà, manager of this department, for his support, and also to Drs. H. Sato and C. Oka-

zaki for their helpful advice.

Impedance Changes Induced by Light in ZnS Phosphors

By Ichizo UCHIDA and Kimihiko SATAKE

Research Laboratory, Nippon Electric Co. Ltd. Tokyo

(Received April 18, 1960)

The impedance changes are induced by light in ZnS phosphor powders which are arranged so as to form the dielectrics of capacitor. This phenomenon is interpreted in terms of the increase in free electron density and the polarization of the phosphor grains caused by electron trapping process1),2),3). The electrical equivalent circuit of the capacitor containning the phosphors as dielectrics is considered to be such as shown in Fig. 12),3). Under illumination, the increase in free electron density causes the decrease of R_P (photoconductive effect) and the polarization of the phosphor grains causes the increase of C_P (photodielectric effect). From the frequency properties of the capacitance, the photodielectric effect is not apreciable in ZnS:Cu:Pb:Cl phosphors used in this experiment3). Therefore, the photoconductivity of the phosphors can be readily estimated from a.c measurement4).

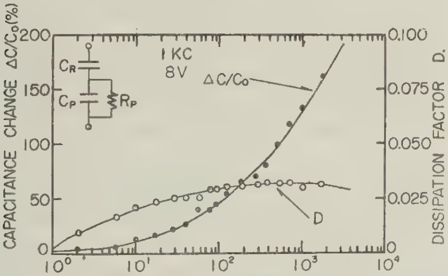

Fig. 1. Equivalent circuit and impedance changes vs incident light intensity (2500°K tungsten lamp). C_R: Capacitance of non sensitive part as resin. C_P, R_P: Capacitance and resistance of sensitive part as phosphors.

ZnS:Cu:Pb Cl phosphors have green emission when excited by 3650Å ultraviolet and show good electroluminescence. The electroluminescent emission is green at lower frequency but becomes blue at higher frequency. The samples were prepared by spraying the phosphor powders mixed with epoxiresin on a quartz plate coated with conductive tin oxide and by evaporating the aluminum film on the phosphor layer as the another electrode.

The capacitance change increases monotonically with the intensity of incident light and dissipation factor has a peak at about 6×10^2 lux as shown in Fig. 1. These properties coinside with the results calculated from the equivalent circuit2),3). Consequently it is adequate to measure the capacitance change in order to estimate the photoconductivity.

In this paper, the spectral sensitivity of the capacitance change induced in ZnS:Cu:Pb:Cl was measured at room temperature. (Fig. 2.) The curve of the spectral sensitivity has high sensitivity in the region of the absorption edge and two peaks at 3580Å and 3860Å. It is supposed that the peak at 3580Å is due to the increase of the free electron density excited from the blue emission centers and the peak at 3860Å is caused by the green emission centers.

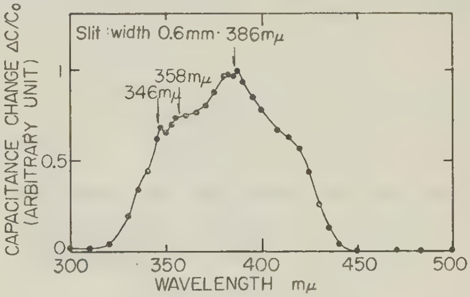

Fig. 2. Spectral sensitivity of the capacitance change.

The authers would like to express their thanks to Dr. Osamu Harashima for his guidance and encouragement.

NMR of Co^{59} in Forromagnetic Cobalt Alloys

By Yoshitaka KÔI, Akira TSUJIMURA
Facutly of Engineering, Tokushima University
Tokushima, Japan
Tadamiki HIHARA, and Toshimoto KUSHIDA
Faculty of Science, Hiroshima University
Hiroshima, Japan

(Received January 7, 1961)

Internal magnetic field H_i seen at nuclei in ferromagnets can be measured by observing nuclear magnetic resonance (NMR) of these nuclei.1) Since the intensity of NMR line in ferromagnets is anomalously strong,1) the detailed structures of the resonance line, which are caused by alloying and reflect a distribution of H_i in the alloys most directly, can be observed clearly.

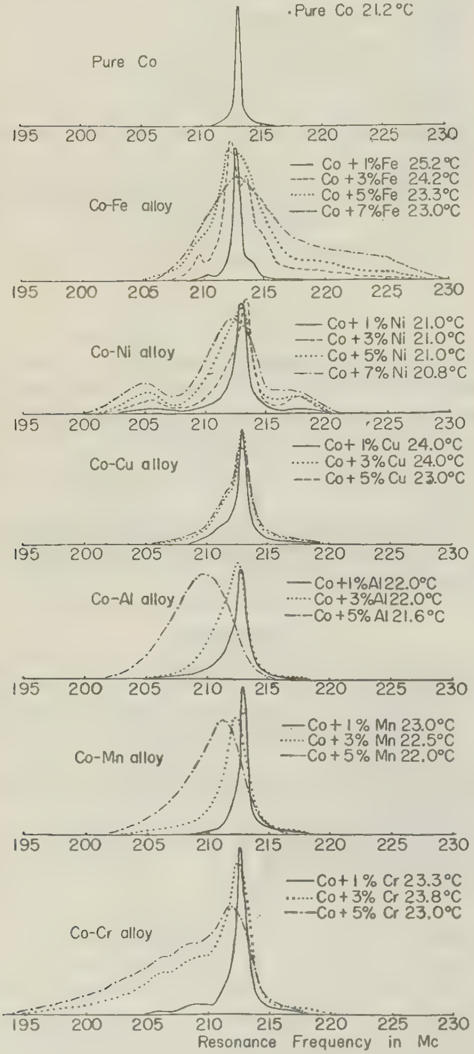

Fig. 1. NMR lines of Co^{59} in cobalt alloys.

Co^{59} resonances in several ferromagnetic cobalt alloys in fcc phase were observed by using a frequency-modulated autodyne spectrometer. The samples were well-annealed powder of the alloys which were prepared from high-purity metals in an induction furnace. The derivatives of the resonance lines of the alloys as well as that for pure cobalt metal thus observed are shown in Fig. 1.

Total integrated intensity of the line is essentially unchanged by alloying, although the vertical scale in the figure is not exactly the same for each specimen.

The alloy lines generally have structures, which are less pronounced in highly-doped specimens. In the case of Co-Fe and Co-Ni, we see resolved satellites at both wings of the main lines, whereas in the other cases investigated here the lower frequency tail (some of them have fine structures) spreads more strongly than the higher-frequency tail by alloying.

One can estimate the quadrupole broadening of the Co lines in the alloys to be of the order of 1Mc, using the value of nuclear quadrupole coupling in copper alloys2−3). Therefore the observed structure is not quadrupole origin, but it describes the distribution of hyperfine field in the alloy.

The present results may well be accounted for in terms of the spacial distribution of hyperfine field around the impurity caused by the spin-dependent scattering of *s*-electrons by the impurity4). Our results, however, do not exclude the possibility of the scattering of *d*-electron waves. The shift in the center-of-gravity of the line is compatible with the observation of average H_i in Co-Fe and Co-Ni alloys by means of low-temperature-specific-heat measurement5).

The details will be published in near future, but it is noted that the similar structure is observed in Fe^{57} resonance in Fe-Ni and Fe-Cr alloys as well.

It is a pleasure to acknowledge the valuable comments made by Professor T. Nagamiya and by Professor N. Bloembergen.

Hot Electron Nonequilibrium Carrier Distribution in a Many-Valley Semiconductor

By Louis Gold

Radiation Laboratory and Department of Nuclear Engineering, University of Michigan, Ann Arbor, Michigan

(Received December 12, 1960)

Recent experiments[1),2)] on hot electron departure from Ohm's law fail to show reasonable agreement with Shibuya's theory[3)] for N-germanium. In particular, the deviation of collinear current and voltage directions was so large as to imply[1)] that a thermal equilibrium distribution of electrons over the several energy minima likely did not prevail as originally supposed[3)]. During the course of preparation of this note the publication by Reik, Risken and Finger[4)] appeared in which an attempt was made to improve Shibuya's theory; but without allowance for intervalley scattering, agreement with experiment was still lacking.

Based on a hot electron formalism already described[5)], a study of the contribution of non-uniform charge density for the ellipsoidal energy surfaces in germanium was carried out. Presumably the imbalance or nonequilibrium distribution of the carriers arises from the anisotropy of the masses which produces differing scattering rates among the valleys. No effort is made to embody details of the various modes of scattering but rather the ad hoc assumption of of different electron densities for the several energy minima is introduced. This approach by-passes the difficult matter of dealing with optical and acoustical modes of scattering and evaluating the role of intra and intervalley effects.

It thus develops that a reasonable departure for collinear current and voltage, (i.e. sensible $\tan \varepsilon$ values) comes about and, moreover, the first clue of temperature dependency is evidenced.

In view of the findings, it appears that such measurements of the angular deviation of the current and voltage coincidence may prove complementary to other techniques for delineating effective masses and carrier density; combined with galvanomagnetic and cyclotron resonance observations, the nonequilibrium redistribution of carriers associated with the hot electron phenomenon may be measured. It may be anticipated that such data ought to shed light on the character of scattering processes responsible for the non-thermal carrier distribution.

The following underlying relation has been deduced for N-germanium:

$$\tan \varepsilon = \frac{1}{N_1}\left(\frac{K-1}{2K+1}\right) \cdot \frac{\sqrt{(\quad)_1^2+(\quad)_2^2+(\quad)_3^2-4[\quad]}}{1-\frac{2}{N_1}\left(\frac{K-1}{2K+1}\right)[\quad]} \qquad (1)$$

where, in terms of the electron densities n_i for the 4 sets of energy surfaces and the directions cosines l_j of the electric vector $\vec{E}$ referred to the cubic axis,

$$\begin{aligned} N_1 &= \sum_i n_i = n_1+n_2+n_3+n_4 \\ N_2 &= (n_1+n_3)-(n_2-n_4) \\ N_3 &= (n_1+n_4)-(n_2+n_3) \\ N_4 &= (n_1+n_2)-(n_3+n_4) \qquad (1a) \\ [\quad] &= N_2 l_1 l_2 + N_3 l_1 l_3 + N_4 l_2 l_3 \\ (\quad)_1 &= N_2 l_2 + N_3 l_3 \\ (\quad)_2 &= N_2 l_1 + N_4 l_3 \\ (\quad)_3 &= N_4 l_2 + N_3 l_1 \,. \end{aligned}$$

If the scattering tensor is of similar symmetry as the mass tensor and the possible variance in the ratio $K'=\nu_l/\nu_t$ for the separate ellipsoids be ignored, then replacement of K by KK' enters[5)]; here ν_l and ν_t are respectively the longitudinal and transverse scattering frequencies, corresponding to the mass ratio $m_l/m_t=K$.

It is instructive to consider formula (1) for the circumstance $l_1 \cong 1$, $l_2=l_3 \cong 0$ (corresponds to E nearly aligned along a cubic axis) which leads to

$$\tan \varepsilon \cong \left(\frac{K-1}{2K+1}\right) \cdot 2\frac{\Delta}{N_1} \qquad (2)$$

where

$$\Delta = n_1 - n_2 = n_3 - n_4 \,. \qquad (2a)$$

As Δ is inclined to be very small, ε itself is seen to be inherently small. Clearly, the existence of an angle between current and voltage is not only a property of the anisotropic mass, but its very manifestation relates to an overall low carrier density. In the extreme case where $\Delta \to 1/2N_1$, the ultimate maximum value of $\tan \varepsilon$ is simply $(K-1)/(2K+1)$ which for N-germanium means $\varepsilon_{\max} \sim 25°$.

The central influence of the total carrier density N_1 emerges and accounts for the experimentally observed fact that larger $\tan \varepsilon$ obtain at reduced temperatures; the exponential behavior $\tan \varepsilon \alpha e^{\varepsilon kT}$ seems indicated, ε being an appropriate activation energy. Furthermore, the maxima for $\tan \varepsilon$ vs electric field may be accounted for on the basis of carrier generation by impact ionization which will cause a fall-off of ε as N_1 rises.

Since K and N_1 can be separately determined, experimental means are now afforded for investigating the manner in which the carrier density redistributes itself in a many-valley semiconductor at increasingly higher electric fields.

Nature of the A-Centers in KCl

By Noriko NISHIMAKI, Kazuko KOJIMA
Osaka Women's University
and Tadanobu KOJIMA
Osaka City University

(Received January 6, 1961)

In the previous paper[1], it was reported that the *A*-band in additively colored KCl crystals arises from a sort of impurities involved in the specimens, and that the *A*-center can trap another electron to become an *A′*-center at about −50°C. Further experiments reported here revealed that the *A*-center is probably an *F*-center having a Na^+ ion on one of its six neighboring cation sites.

By quenching an additively colored KCl crystal containing 1 nominal mole % of NaCl, we get only *F*-centers as in the case of pure crystals. Illuminating this sample with *F*-light at −30°C, a much more pronounced *A*-band was found to develop than hitherto obtained (Fig. 1). This band duplicates the characteristic properties of the *A*-band in apparently pure specimens, such as thermal stability, $A \rightarrow A'$ conversion with *F*-light at −50°C, and dichroic properties as explained below.

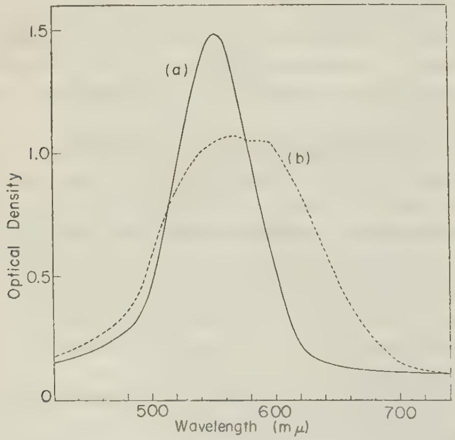

Fig- 1. Absorption curves of an additively colored KCL crystal containing 1 nominal mole % of NaCl, measured at −70°C. (a) initial; (b) after 50 min irradiation with *F*-light at −30°C.

Since the *A*-band is enhanced with the addition of NaCl, the *A′*-band shows similar behavior to the *F′*-band, and the *A*-band has its peak near the *F*-band, we may propose a model for the *A*-center that it consists of an *F*-center adjacent to a substitutional Na^+ ion. A theoretical consideration shows that, as a result of perturbation due to the Na^+ ion, the triply degenerate excited states of the *F*-center split into two levels, the lower (A_1) nondegenerate and the higher (E) doubly degenerate. It can also be shown that among the two the possible absorption bands, the one should lie to the longer wavelength side and the other to the slightly shorter wavelength side of the *F*-band. We call the former the A_1-band and the latter the A_2-band.

Now consider a sample which has been irradiated with A_2-light polarized along the [100] direction. Then our model predicts that the A_1-band will remain unchanged whereas the A_2-band decreases, when measured with light polarized along [100], provided the dichroism is caused only through preferential ionization. When measurement is made with light polarized along [010], we shall find both the bands decreased, and the decrease will be more conspicuous for the A_1-band. Moreover, no difference will be observed between two absorption curves measured with light polarized along [110] and that along [$1\bar{1}0$].

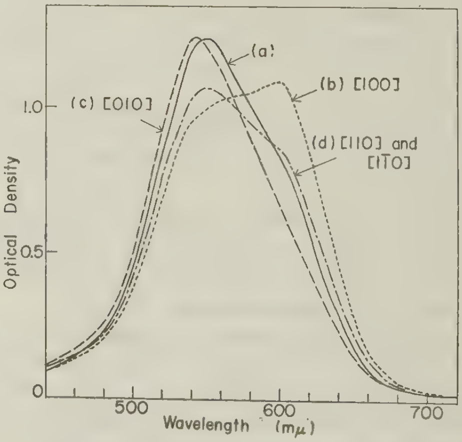

Fig. 2. Dichroic absorption of KCl containing *A*-centers, irradiated with 520 mμ light polarized along [100] at −30°C. (a) before irradiation; (b)-(d) after irradiation, measured with polarized light. All measurements were made at −70°C.

Most of these predictions were confirmed by experiments (Fig. 2). However, the A_1-band in the [100] direction and the A_2-band in the [010] direction were considerably higher than predicted. This indicates that the dichroism was caused primarily by reorientation of the centers rather than through ionization. It should be noted that Ohkura's experiment[2)] on the optical conversion between the *A*- and *B*-bands can also be well accounted for on the basis of our model. The conversion is presumably nothing but a result of reorientation of *A*-centers induced by optical excitation, and the assumptions seem unnecessary such as the existence of *B*-centers or the production of photoelectrons.

A more detailed account of this work will be published elsewhere.

Impurity Effect upon Mobility in Heavily Doped Silicon

By Yoshitaka FURUKAWA

The Electrical Communication Laboratory, Musashino-shi, Tokyo

(Received December 27, 1960)

Conductivity mobilities of electrons and holes in heavily doped silicon have already been reported by Backenstoss.[1)] In his experiment, measurements were taken with several Group III and Group V impurities up to concentration of 6×10^{19} cm^{-3} and and 6×10^{18} cm^{-3} for n- and p-type silicon, respectively. Resistivity was measured by using a four-point probe method and impurity concentration was obtained with radioactive tracers or from thermal neutron activiation. Resistivity *versus* impurity concentration relations thus obtained were represented with a single curve each for *n*- and *p*-type silicon respectively except for In-doped case.

Recently, however, impurity effect upon mgoility in heavily doped Germanium was observed[2)] and this effect was attributed to the difference in carrier—ionized impurity interaction. The same effect is expected in heavily doped silicon.

In the present experiment, impurity effect upon Hall mobility in heavily doped silicon was measured with the bridge shape samples by using a conventional D.C method and carrier concentrations were obtained from the relation n (or p)$=1/eR$ where R is the Hall coefficient.

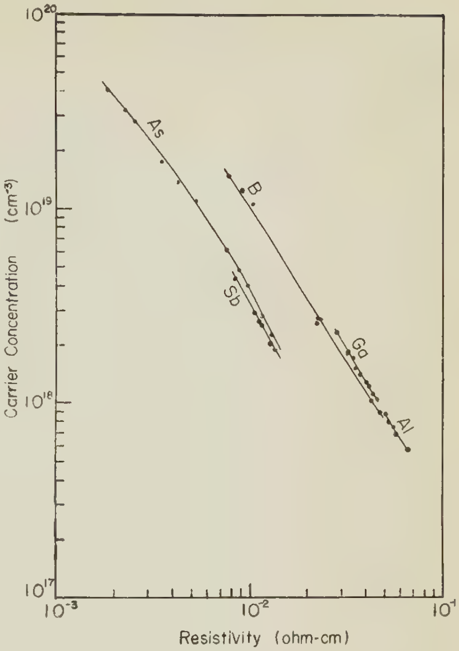

Fig. 1. Resistivity *versus* carrier concentration curves for *n*- and *p*- type silicon at room temperature.

Table I. Mobility at carrier concentration of 2×10^{18} cm^{-3}.

Impurity	donor		acceptor		
	Sb	As	B	Al	Ga
ionization energy (eV)	0.039	0.049	0.045	0.057	00.65
mobility (cm^2 volt^{-1} sec^{-1})	235	220	110		100

The results are shown in Fig. 1. The impurity effect has been observed in heavily doped silicon and there exists some correlation between impurity scattering mobility and ionization energy of impurities. As shown in Table I, the lower the ionization energy of the impurities is, the higher the mobility becomes. This tendency was also observed in heavily doped germanium.

The author thanks Dr. Z. Kiyasu and Dr. T. Niimi heartily for the guidance in this work.

X-ray Small Angle Scattering from Precipitated Platelets in Al-Ag Alloy

By Yasuharu YONEDA and Kouzou NISHIOKA

Department of Applied Physics, Kyushu University, Fukuoka

(Received September 8, 1960)

Geisler et al[1] studied the precipitated platelets of γ' phase iu Al-Ag alloy with diffuse streaks in the Laue pattern. Further, with small angle scattering of X-rays Guinier[2] studied it and measured the mean value of the thickness of the platelets from the length of the streaks.

We have also measured small angle scattering from these platelets and calculated the distribution of their thickness by extending the Fankuchen method to one dimentional case.

In the present experiment Cu $K\alpha$ radiation monochromatized with LiF crystal monochrometer was used. The widths of the 1st and 2nd slit were 0.5 mm and 0.1 mm respectively, the slit distance 320 mm, the distance between the 2nd slit and the sample 10 mm. The path 340 mm long between the sample and the detecter slit was evacuated. 0.07 mm thick sample was prepared from Al-Ag alloy containing 20 weight percent of Ag by etching the surface with Nitric-Acid alcohl.

Fig. 1 (a) shows a scattering photograph of the sample. The two streaks were considered to be the scattering from individual grain. The streaks showed unsymmetrical change with the rotation of the sample. This phenomenon was well explained later by the Eq. (1), which was deduced with the assumption of the platelet structure. In this experiment the double reflection was not observed[3),4)].

For the purpose of evaluating the distribution of thickness of the platelet, we measured the scattering intensity with G.M. counters, diminishing the height of beam so as to measure only one streak from a single grain. The curve is given in Fig. 1 (b).

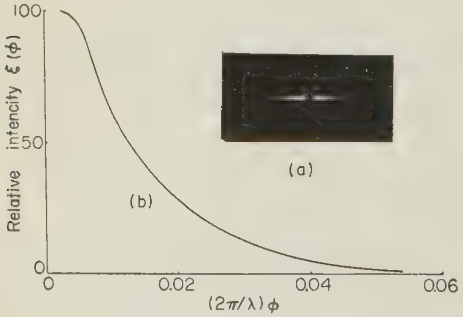

Fig. 1. Photograph (a) and intensity curve (b) of small angle scattering from Al-Ag, water-quenched from 520°C and annealed 240 hours at 140°C.

It is shown by a simple calculation that the coherent scattering intensity except the neighbourhood of zero angle, when the platelets distribute at random both in thickness and relative distance, is given by

$$I(\phi)=I_e\rho^2 4\bar{H}^2 \sum_i \left(\frac{2\sin t_i(2\pi/\lambda)\phi}{(2\pi/\lambda)\phi}\right)^2 \times\left[\frac{2\sin T_i(\pi/\lambda)\{\phi-\psi)^2-\psi^2\}}{(\pi/\lambda)\{(\phi-\psi)^2-\psi^2\}}\right]^2, \qquad (1)$$

where I_e is the scattering intensity of one electron, ρ the differential electron density of the platelets and the matrix, $4\bar{H}^2$ the mean square of platelet's height, $2t_i$ the thickness of platelet, $2T_i$ the length of platelet, ϕ the scattering augle, ψ the angle between incident beam and platelet, and λ the wave length.

When T_i is a constant T, Eq. (1) can be written as follows:

$$\xi(\phi)\equiv I(\phi)\left[\frac{(\pi/\lambda)\{\phi-\psi)^2-\psi^2\}}{2\sin T(\pi/\lambda)\{(\phi-\psi)^2-\psi^2\}}\right]^2 = I_e\rho^2 4\bar{H}^2 \sum_i \left(\frac{2\sin t_i(2\pi/\lambda)\phi}{(2\pi/\lambda)\phi}\right)^2. \qquad (2)$$

This corresponds to the transformation from the scattering intensity on the reflection sphere to that on the perpendicular reciprocal axis of platelets. In the case of practical measurement, $\xi(\phi)$ is obtained directly from measurement by choosing so as to satisfy $(\phi-\psi)^2-\psi^2=0$ as can be seen from Eq. (1). But when T_i is constant as in this case, $\xi(\phi)$ can be obtained from measurement on the reflection sphere by Eq. (2). Eq. (2) agreed well with the result of our experiment by putting $2T$=1000A.

By use of $\xi(\phi)$ we calculated the distribution curve of thickness of the platelet by Fankuchen method[5]: (Fig. 2). The mean value of thickness is about 30A. This is close to the results of Guinier et al.[6] of 30~50A.

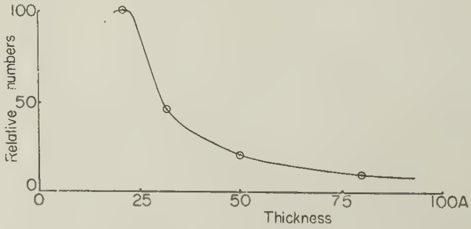

Fig. 2. Distribution curve of thickness of platelet.

We wish to express our sincere thanks to Professor T. Futagami for his continued encouragement during the course of this research.

Microdomain Structure in Paraelectric Phase of NaNO$_2$

By Sigetosi TANISAKI
Faculty of Literature and Science, Yamaguchi University

(Received December 26, 1960)

Sodium Nitrite (NaNO$_2$) was first reported to be a ferroelectric by Sawada et al.[1], Curie point of which is about 160°C. The crystal structure of this material has been studied by several researchers[2),3),4),5),6)]. From these structure analysis, the ferroelectricity in the low temperature phase has been considered to be due to the ordered arrangement of NO$_2$ groups, which becomes disordered above the Curie point. In this note the microdomain structure in the paraelectric phase found by X-ray study will be reported.

Oscillation photographs and Laue photographs were taken with a and b axes vertical just above the Curie point. From these photographs it was found that, besides the normal Bragg- and Laue-reflections and the ordinal thermal diffuse scatterings, two sharp satellites in each side of some of the normal reflections along a axis, and the weak plate like diffuse scatterings around those normal spots whose intensities are distributed vertically to b axis appear. Fig. 1 shows an example of oscillation photograph by 30° with a axis vertical. The satellites correspond to a certain periodical structure along a axis, and the period calculated from the separation between satellite and normal spot is about 8.4 a. These satellites can be interpreted by the following model. Let us consider two kinds of atomic layers parallel to (100) in which the arrangement of NO$_2$ groups is perfectly ordered as shown in Fig. 2(a). It is assumed that the interchanges of the two kinds of layers occur along a axis once in every eight or nine layers of the same kind as shown in Fig. 2(b). This model corresponds to the extreme case in which the width of the (100) domain in ferroelectric phase becomes as short as 4 a or 4.5 a, and so it may be called the "microdomain structure". Suppose that the structure factor F of the basic structure shown in Fig. 2(a) are given by $F=A+iB$, then $|A|^2$ and $|B|^2$ are to be proportional to the intensities of normal Bragg spots and satellites respectively. The result of calculation by the use of the atomic parameters obtained by small modifications of Strijk and MacGillavry's data[5] and on the assumption of the appropriate temperature factors, shows a satisfactory agreement with the observed values.

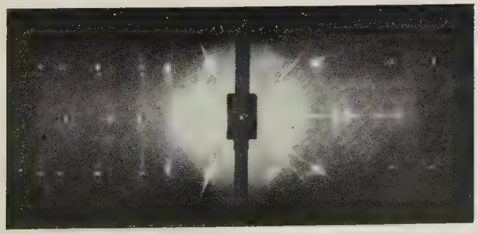

Fig. 1. X-ray oscillation photograph with a axis vertical.

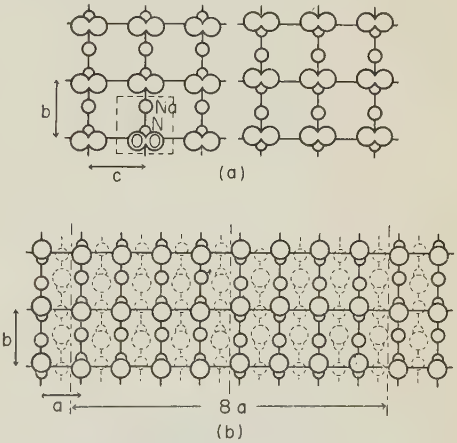

Fig. 2. (a) Two kinds of atomic layers with perfectly ordered arrangement of NO$_2$ groups. The basic structure is shown in the rectangle of broken line. (b) Projection of the microdomain structure along c axis. Circles of broken lines represent atoms whose positions are higher as much as 1/2 c than those of the corresponding atoms represented by circles of full lines.

The detailed investigations about the temperature dependencies of satellites and diffuse scatterings are now in progress.
